```

two more lines must be added:

```
#define SPAM_MODULE
#include "spammodule.h"
```

The `#define` is used to tell the header file that it is being included in the exporting module, not a client module. Finally, the module’s **`mod_exec`** function must take care of initializing the C API pointer array:

```
static int
spam_module_exec(PyObject *m)
{
    static void *PySpam_API[PySpam_API_pointers];
    PyObject *c_api_object;

    /* Initialize the C API pointer array */
    PySpam_API[PySpam_System_NUM] = (void *)PySpam_System;

    /* Create a Capsule containing the API pointer array's
address */
    c_api_object = PyCapsule_New((void *)PySpam_API,
"spam._C_API", NULL);
```

```
    if (PyModule_Add(m, "_C_API", c_api_object) < 0) {
        return -1;
    }

    return 0;
}
```

Note that `PySpam_API` is declared `static`; otherwise the pointer array would disappear when **`PyInit_spam()`** terminates!

The bulk of the work is in the header file `spammodule.h`, which looks like this:

```
#ifndef Py_SPAMMODULE_H
#define Py_SPAMMODULE_H
#ifdef __cplusplus
extern "C" {
#endif

/* Header file for spammodule */

/* C API functions */
#define PySpam_System_NUM 0
#define PySpam_System_RETURN int
#define PySpam_System_PROTO (const char *command)

/* Total number of C API pointers */
#define PySpam_API_pointers 1

#ifdef SPAM_MODULE
/* This section is used when compiling spammodule.c */

static PySpam_System_RETURN PySpam_System PySpam_System_PROTO;

#else
/* This section is used in modules that use spammodule's API */

static void **PySpam_API;

#define PySpam_System \
 (*(PySpam_System_RETURN (*)PySpam_System_PROTO)
PySpam_API[PySpam_System_NUM])

/* Return -1 on error, 0 on success.
 * PyCapsule_Import will set an exception if there's an error.
 */
static int
import_spam(void)
{
    PySpam_API = (void **)PyCapsule_Import("spam._C_API", 0);
    return (PySpam_API != NULL) ? 0 : -1;
}

#endif

#ifdef __cplusplus
}
#endif

#endif /* !defined(Py_SPAMMODULE_H) */
```

All that a client module must do in order to have access to the function **`PySpam_System()`** is to call the function (or rather macro) **`import_spam()`** in its **`mod_exec`** function:

```
static int
client_module_exec(PyObject *m)
{
    if (import_spam() < 0) {
        return -1;
    }
    /* additional initialization can happen here */
    return 0;
}
```

The main disadvantage of this approach is that the file `spammodule.h` is rather complicated. However, the basic structure is the same for each function that is exported, so it has to be learned only once.

Finally it should be mentioned that Capsules offer additional functionality, which is especially useful for memory allocation and deallocation of the pointer stored in a Capsule. The details are described in the Python/C API Reference Manual in the section Capsules and in the implementation of Capsules (files `Include/pycapsule.h` and `Objects/pycapsule.c` in the Python source code distribution).

Footnotes

[1]

An interface for this function already exists in the standard module **`os`** — it was chosen as a simple and straightforward example.

[2]

The metaphor of “borrowing” a reference is not completely correct: the owner still has a copy of the reference.

[3]

Checking that the reference count is at least 1 **does not work** — the reference count itself could be in freed memory and may thus be reused for another object!

[4]

These guarantees don’t hold when you use the “old” style calling convention — this is still found in much existing code.

2. Defining Extension Types: Tutorial

Python allows the writer of a C extension module to define new types that can be manipulated from Python code, much like the built-in `str` and `list` types. The code for all extension types follows a pattern, but there are some details that you need to understand before you can get started. This document is a gentle introduction to the topic.

2.1. The Basics

The CPython runtime sees all Python objects as variables of type PyObject*, which serves as a “base type” for all Python objects. The `PyObject` structure itself only contains the object’s reference count and a pointer to the object’s “type object”. This is where the action is; the type object determines which (C) functions get called by the interpreter when, for instance, an attribute gets looked up on an object, a method called, or it is multiplied by another object. These C functions are called “type methods”.

So, if you want to define a new extension type, you need to create a new type object.

This sort of thing can only be explained by example, so here’s a minimal, but complete, module that defines a new type named `Custom` inside a C extension module `custom`:

Note

What we’re showing here is the traditional way of defining *static* extension types. It should be adequate for most uses. The C API also allows defining heap-allocated extension types using the `PyType_FromSpec()` function, which isn’t covered in this tutorial.

```
#define PY_SSIZE_T_CLEAN
#include <Python.h>

typedef struct {
    PyObject_HEAD
    /* Type-specific fields go here. */
} CustomObject;

static PyTypeObject CustomType = {
    .ob_base = PyVarObject_HEAD_INIT(NULL, 0)
    .tp_name = "custom.Custom",
    .tp_doc = PyDoc_STR("Custom objects"),
    .tp_basicsize = sizeof(CustomObject),
    .tp_itemsize = 0,
    .tp_flags = Py_TPFLAGS_DEFAULT,
    .tp_new = PyType_GenericNew,
};

static int
custom_module_exec(PyObject *m)
{
    if (PyType_Ready(&CustomType) < 0) {
        return -1;
    }

    if (PyModule_AddObjectRef(m, "Custom", (PyObject *)
&CustomType) < 0) {
        return -1;
    }

    return 0;
}

static PyModuleDef_Slot custom_module_slots[] = {
    {Py_mod_exec, custom_module_exec},
    // Just use this while using static types
    {Py_mod_multiple_interpreters,
Py_MOD_MULTIPLE_INTERPRETERS_NOT_SUPPORTED},
    {0, NULL}
};

static PyModuleDef custom_module = {
    .m_base = PyModuleDef_HEAD_INIT,
    .m_name = "custom",
    .m_doc = "Example module that creates an extension type.",
    .m_size = 0,
    .m_slots = custom_module_slots,
};

PyMODINIT_FUNC
PyInit_custom(void)
{
    return PyModuleDef_Init(&custom_module);
}
```

Now that’s quite a bit to take in at once, but hopefully bits will seem familiar from the previous chapter. This file defines three things:

1. What a **`Custom`** **object** contains: this is the `CustomObject` struct, which is allocated once for each **`Custom`** instance.
2. How the **`Custom`** **type** behaves: this is the `CustomType` struct, which defines a set of flags and function pointers that the interpreter inspects when specific operations are requested.
3. How to define and execute the **`custom`** module: this is the `PyInit_custom` function and the associated `custom_module` struct for defining the module, and the `custom_module_exec` function to set up a fresh module object.

The first bit is:

```
typedef struct {
    PyObject_HEAD
} CustomObject;
```

This is what a Custom object will contain. `PyObject_HEAD` is mandatory at the start of each object struct and defines a field called `ob_base` of type **`PyObject`**, containing a pointer to a type object and a reference count (these can be accessed using the macros **`Py_TYPE`** and **`Py_REFCNT`** respectively). The reason for the macro is to abstract away the layout and to enable additional fields in debug builds.

Note

There is no semicolon above after the **`PyObject_HEAD`** macro. Be wary of adding one by accident: some compilers will complain.

Of course, objects generally store additional data besides the standard `PyObject_HEAD` boilerplate; for example, here is the definition for standard Python floats:

```
typedef struct {
    PyObject_HEAD
    double ob_fval;
} PyFloatObject;
```

The second bit is the definition of the type object.

```
static PyTypeObject CustomType = {
    .ob_base = PyVarObject_HEAD_INIT(NULL, 0)
    .tp_name = "custom.Custom",
    .tp_doc = PyDoc_STR("Custom objects"),
    .tp_basicsize = sizeof(CustomObject),
    .tp_itemsize = 0,
    .tp_flags = Py_TPFLAGS_DEFAULT,
    .tp_new = PyType_GenericNew,
};
```

Note

We recommend using C99-style designated initializers as above, to avoid listing all the **`PyTypeObject`** fields that you don’t care about and also to avoid caring about the fields’ declaration order.

The actual definition of **`PyTypeObject`** in `object.h` has many more fields than the definition above. The remaining fields will be filled with zeros by the C compiler, and it’s common practice to not specify them explicitly unless you need them.

We’re going to pick it apart, one field at a time:

```
.ob_base = PyVarObject_HEAD_INIT(NULL, 0)
```

This line is mandatory boilerplate to initialize the `ob_base` field mentioned above.

```
.tp_name = "custom.Custom",
```

The name of our type. This will appear in the default textual representation of our objects and in some error messages, for example:

```
>>> "" + custom.Custom()
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
TypeError: can only concatenate str (not "custom.Custom") to
str
```

Note that the name is a dotted name that includes both the module name and the name of the type within the module. The module in this case is **`custom`** and the type is **`Custom`**, so we set the type name to **`custom.Custom`**. Using the real dotted import path is important to make your type compatible with the **`pydoc`** and **`pickle`** modules.

```
.tp_basicsize = sizeof(CustomObject),
.tp_itemsize = 0,
```

This is so that Python knows how much memory to allocate when creating new `Custom` instances. `tp_itemsize` is only used for variable-sized objects and should otherwise be zero.

Note

If you want your type to be subclassable from Python, and your type has the same `tp_basicsize` as its base type, you may have problems with multiple inheritance. A Python subclass of your type will have to list your type first in its `__bases__`, or else it will not be able to call your type's `__new__()` method without getting an error. You can avoid this problem by ensuring that your type has a larger value for `tp_basicsize` than its base type does. Most of the time, this will be true anyway, because either your base type will be `object`, or else you will be adding data members to your base type, and therefore increasing its size.

We set the class flags to `Py_TPFLAGS_DEFAULT`.

```
.tp_flags = Py_TPFLAGS_DEFAULT,
```

All types should include this constant in their flags. It enables all of the members defined until at least Python 3.3. If you need further members, you will need to OR the corresponding flags.

We provide a doc string for the type in `tp_doc`.

```
.tp_doc = PyDoc_STR("Custom objects"),
```

To enable object creation, we have to provide a `tp_new` handler. This is the equivalent of the Python method `__new__()`, but has to be specified explicitly. In this case, we can just use the default implementation provided by the API function `PyType_GenericNew()`.

```
.tp_new = PyType_GenericNew,
```

Everything else in the file should be familiar, except for some code in **`custom_module_exec()`**:

```
if (PyType_Ready(&CustomType) < 0) {
    return -1;
}
```

This initializes the **`Custom`** type, filling in a number of members to the appropriate default values, including `ob_type` that we initially set to `NULL`.

```
if (PyModule_AddObjectRef(m, "Custom", (PyObject *)
&CustomType) < 0) {
    return -1;
}
```

This adds the type to the module dictionary. This allows us to create **`Custom`** instances by calling the **`Custom`** class:

```
>>> import custom
>>> mycustom = custom.Custom()
```

That’s it! All that remains is to build it; put the above code in a file called `custom.c`,

```
[build-system]
requires = ["setuptools"]
build-backend = "setuptools.build_meta"

[project]
name = "custom"
version = "1"
```

in a file called `pyproject.toml`, and

```
from setuptools import Extension, setup
setup(ext_modules=[Extension("custom", ["custom.c"])])
```

in a file called `setup.py`; then typing

```
$ python -m pip install .
```

in a shell should produce a file `custom.so` in a subdirectory and install it; now fire up Python — you should be able to `import custom` and play around with `Custom` objects.

That wasn’t so hard, was it?

Of course, the current Custom type is pretty uninteresting. It has no data and doesn’t do anything. It can’t even be subclassed.

2.2. Adding data and methods to the Basic example

Let’s extend the basic example to add some data and methods. Let’s also make the type usable as a base class. We’ll create a new module, **`custom2`** that adds these capabilities:

```
#define PY_SSIZE_T_CLEAN
#include <Python.h>
#include <stddef.h> /* for offsetof() */

typedef struct {
    PyObject_HEAD
    PyObject *first; /* first name */
    PyObject *last;  /* last name */
    int number;
} CustomObject;

static void
Custom_dealloc(PyObject *op)
{
    CustomObject *self = (CustomObject *) op;
    Py_XDECREF(self->first);
    Py_XDECREF(self->last);
    Py_TYPE(self)->tp_free(self);
}

static PyObject *
Custom_new(PyTypeObject *type, PyObject *args, PyObject *kwds)
{
    CustomObject *self;
    self = (CustomObject *) type->tp_alloc(type, 0);
    if (self != NULL) {
        self->first = Py_GetConstant(Py_CONSTANT_EMPTY_STR);
        if (self->first == NULL) {
            Py_DECREF(self);
            return NULL;
        }
        self->last = Py_GetConstant(Py_CONSTANT_EMPTY_STR);
        if (self->last == NULL) {
            Py_DECREF(self);
            return NULL;
        }
        self->number = 0;
    }
    return (PyObject *) self;
}

static int
Custom_init(PyObject *op, PyObject *args, PyObject *kwds)
{
    CustomObject *self = (CustomObject *) op;
    static char *kwlist[] = {"first", "last", "number", NULL};
    PyObject *first = NULL, *last = NULL;

    if (!PyArg_ParseTupleAndKeywords(args, kwds, "|OOi",
kwlist,
                                     &first, &last,
                                     &self->number))
        return -1;

    if (first) {
        Py_XSETREF(self->first, Py_NewRef(first));
    }
    if (last) {
        Py_XSETREF(self->last, Py_NewRef(last));
    }
    return 0;
}

static PyMemberDef Custom_members[] = {
    {"first", Py_T_OBJECT_EX, offsetof(CustomObject, first), 0,
     "first name"},
    {"last", Py_T_OBJECT_EX, offsetof(CustomObject, last), 0,
     "last name"},
    {"number", Py_T_INT, offsetof(CustomObject, number), 0,
     "custom number"},
    {NULL}  /* Sentinel */
};

static PyObject *
Custom_name(PyObject *op, PyObject *Py_UNUSED(dummy))
{
    CustomObject *self = (CustomObject *) op;
    if (self->first == NULL) {
        PyErr_SetString(PyExc_AttributeError, "first");
        return NULL;
    }
    if (self->last == NULL) {
        PyErr_SetString(PyExc_AttributeError, "last");
        return NULL;
    }
    return PyUnicode_FromFormat("%S %S", self->first, self-
>last);
}

static PyMethodDef Custom_methods[] = {
    {"name", Custom_name, METH_NOARGS,
     "Return the name, combining the first and last name"
    },
    {NULL}  /* Sentinel */
};

static PyTypeObject CustomType = {
    .ob_base = PyVarObject_HEAD_INIT(NULL, 0)
    .tp_name = "custom2.Custom",
    .tp_doc = PyDoc_STR("Custom objects"),
    .tp_basicsize = sizeof(CustomObject),
    .tp_itemsize = 0,
    .tp_flags = Py_TPFLAGS_DEFAULT | Py_TPFLAGS_BASETYPE,
    .tp_new = Custom_new,
    .tp_init = Custom_init,
    .tp_dealloc = Custom_dealloc,
    .tp_members = Custom_members,
    .tp_methods = Custom_methods,
};

static int
custom_module_exec(PyObject *m)
{
    if (PyType_Ready(&CustomType) < 0) {
        return -1;
    }

    if (PyModule_AddObjectRef(m, "Custom", (PyObject *)
&CustomType) < 0) {
        return -1;
    }

    return 0;
}

static PyModuleDef_Slot custom_module_slots[] = {
    {Py_mod_exec, custom_module_exec},
    {Py_mod_multiple_interpreters,
Py_MOD_MULTIPLE_INTERPRETERS_NOT_SUPPORTED},
    {0, NULL}
};

static PyModuleDef custom_module = {
    .m_base = PyModuleDef_HEAD_INIT,
    .m_name = "custom2",
    .m_doc = "Example module that creates an extension type.",
    .m_size = 0,
    .m_slots = custom_module_slots,
};

PyMODINIT_FUNC
PyInit_custom2(void)
{
    return PyModuleDef_Init(&custom_module);
}
```

This version of the module has a number of changes.

The **`Custom`** type now has three data attributes in its C struct, *first*, *last*, and *number*. The *first* and *last* variables are Python strings containing first and last names. The *number* attribute is a C integer.

The object structure is updated accordingly:

```
typedef struct {
    PyObject_HEAD
    PyObject *first; /* first name */
    PyObject *last;  /* last name */
    int number;
} CustomObject;
```

Because we now have data to manage, we have to be more careful about object allocation and deallocation. At a minimum, we need a deallocation method:

```
static void
Custom_dealloc(PyObject *op)
{
    CustomObject *self = (CustomObject *) op;
    Py_XDECREF(self->first);
    Py_XDECREF(self->last);
    Py_TYPE(self)->tp_free(self);
}
```

which is assigned to the **`tp_dealloc`** member:

```
.tp_dealloc = Custom_dealloc,
```

This method first clears the reference counts of the two Python attributes. **`Py_XDECREF()`** correctly handles the case where its argument is `NULL` (which might happen here if `tp_new` failed midway). It then calls the **`tp_free`** member of the object’s type (computed by `Py_TYPE(self)`) to free the object’s memory. Note that the object’s type might not be **`CustomType`**, because the object may be an instance of a subclass.

Note

The explicit cast to `CustomObject *` above is needed because we defined `Custom_dealloc` to take a `PyObject *` argument, as the `tp_dealloc` function pointer expects to receive a `PyObject *` argument. By assigning to the `tp_dealloc` slot of a type, we declare that it can only be called with instances of our `CustomObject` class, so the cast to `(CustomObject *)` is safe. This is object-oriented polymorphism, in C!

In existing code, or in previous versions of this tutorial, you might see similar functions take a pointer to the subtype object structure (`CustomObject*`) directly, like this:

```
Custom_dealloc(CustomObject *self)
{
    Py_XDECREF(self->first);
    Py_XDECREF(self->last);
    Py_TYPE(self)->tp_free((PyObject *) self);
}
...
.tp_dealloc = (destructor) Custom_dealloc,
```

This does the same thing on all architectures that CPython supports, but according to the C standard, it invokes undefined behavior.

We want to make sure that the first and last names are initialized to empty strings, so we provide a `tp_new` implementation:

```
static PyObject *
Custom_new(PyTypeObject *type, PyObject *args, PyObject *kwds)
{
    CustomObject *self;
    self = (CustomObject *) type->tp_alloc(type, 0);
    if (self != NULL) {
        self->first = PyUnicode_FromString("");
        if (self->first == NULL) {
            Py_DECREF(self);
            return NULL;
        }
        self->last = PyUnicode_FromString("");
        if (self->last == NULL) {
            Py_DECREF(self);
            return NULL;
        }
        self->number = 0;
    }
    return (PyObject *) self;
}
```

and install it in the **`tp_new`** member:

```
.tp_new = Custom_new,
```

The `tp_new` handler is responsible for creating (as opposed to initializing) objects of the type. It is exposed in Python as the `__new__()` method. It is not required to define a `tp_new` member, and indeed many extension types will simply reuse `PyType_GenericNew()` as done in the first version of the **`Custom`** type above. In this case, we use the `tp_new` handler to initialize the `first` and `last` attributes to non-`NULL` default values.

`tp_new` is passed the type being instantiated (not necessarily `CustomType`, if a subclass is instantiated) and any arguments passed when the type was called, and is expected to return the instance created. `tp_new` handlers always accept positional and keyword arguments, but they often ignore the arguments, leaving the argument handling to initializer (a.k.a. `tp_init` in C or `__init__` in Python) methods.

Note

`tp_new` shouldn't call `tp_init` explicitly, as the interpreter will do it itself.

The `tp_new` implementation calls the `tp_alloc` slot to allocate memory:

```
self = (CustomObject *) type->tp_alloc(type, 0);
```

Since memory allocation may fail, we must check the `tp_alloc` result against `NULL` before proceeding.

Note

We didn't fill the `tp_alloc` slot ourselves. Rather `PyType_Ready()` fills it for us by inheriting it from our base class, which is `object` by default. Most types use the default allocation strategy.

Note

If you are creating a co-operative `tp_new` (one that calls a base type's `tp_new` or `__new__()`), you must *not* try to determine what method to call using method resolution order at runtime. Always statically determine what type you are going to call, and call its `tp_new` directly, or via `type->tp_base->tp_new`. If you do not do this, Python subclasses of your type that also inherit from other Python-defined classes may not work correctly. (Specifically, you may not be able to create instances of such subclasses without getting a `TypeError`.)

We also define an initialization function which accepts arguments to provide initial values for our instance:

```
static int
Custom_init(PyObject *op, PyObject *args, PyObject *kwds)
{
    CustomObject *self = (CustomObject *) op;
    static char *kwlist[] = {"first", "last", "number", NULL};
    PyObject *first = NULL, *last = NULL, *tmp;

    if (!PyArg_ParseTupleAndKeywords(args, kwds, "|OOi",
kwlist,
                                     &first, &last,
                                     &self->number))
        return -1;

    if (first) {
        tmp = self->first;
        Py_INCREF(first);
        self->first = first;
        Py_XDECREF(tmp);
    }
    if (last) {
        tmp = self->last;
        Py_INCREF(last);
        self->last = last;
        Py_XDECREF(tmp);
    }
    return 0;
}
```

by filling the `tp_init` slot.

```
.tp_init = Custom_init,
```

The `tp_init` slot is exposed in Python as the `__init__()` method. It is used to initialize an object after it’s created.

Initializers always accept positional and keyword arguments, and they should return either `0` on success or `-1` on error.

Unlike the `tp_new` handler, there is no guarantee that `tp_init` is called at all (for example, the **`pickle`** module by default doesn't call **`__init__()`** on unpickled instances). It can also be called multiple times. Anyone can call the **`__init__()`** method on our objects. For this reason, we have to be extra careful when assigning the new attribute values. We might be tempted, for example to assign the `first` member like this:

```
if (first) {
    Py_XDECREF(self->first);
    Py_INCREF(first);
    self->first = first;
}
```

But this would be risky. Our type doesn't restrict the type of the `first` member, so it could be any kind of object. It could have a destructor that causes code to be executed that tries to access the `first` member; or that destructor could detach the thread state and let arbitrary code run in other threads that accesses and modifies our object.

To be paranoid and protect ourselves against this possibility, we almost always reassign members before decrementing their reference counts. When don't we have to do this?

- when we absolutely know that the reference count is greater than 1;
- when we know that deallocation of the object [[1]] will neither detach the thread state nor cause any calls back into our type's code;
- when decrementing a reference count in a **`tp_dealloc`** handler on a type which doesn't support cyclic garbage collection [[2]].

We want to expose our instance variables as attributes. There are a number of ways to do that. The simplest way is to define member definitions:

```
static PyMemberDef Custom_members[] = {
    {"first", Py_T_OBJECT_EX, offsetof(CustomObject, first), 0,
     "first name"},
    {"last", Py_T_OBJECT_EX, offsetof(CustomObject, last), 0,
     "last name"},
    {"number", Py_T_INT, offsetof(CustomObject, number), 0,
     "custom number"},
    {NULL}  /* Sentinel */
};
```

and put the definitions in the **`tp_members`** slot:

```
.tp_members = Custom_members,
```

Each member definition has a member name, type, offset, access flags and documentation string. See the Generic Attribute Management section below for details.

A disadvantage of this approach is that it doesn’t provide a way to restrict the types of objects that can be assigned to the Python attributes. We expect the first and last names to be strings, but any Python objects can be assigned. Further, the attributes can be deleted, setting the C pointers to `NULL`. Even though we can make sure the members are initialized to non-`NULL` values, the members can be set to `NULL` if the attributes are deleted.

We define a single method, **`Custom.name()`**, that outputs the objects name as the concatenation of the first and last names.

```
static PyObject *
Custom_name(PyObject *op, PyObject *Py_UNUSED(dummy))
{
    CustomObject *self = (CustomObject *) op;
    if (self->first == NULL) {
        PyErr_SetString(PyExc_AttributeError, "first");
        return NULL;
    }
    if (self->last == NULL) {
        PyErr_SetString(PyExc_AttributeError, "last");
        return NULL;
    }
    return PyUnicode_FromFormat("%S %S", self->first, self-
>last);
}
```

The method is implemented as a C function that takes a **`Custom`** (or **`Custom`** subclass) instance as the first argument. Methods always take an instance as the first argument. Methods often take positional and keyword arguments as well, but in this case we don't take any and don't need to accept a positional argument tuple or keyword argument dictionary. This method is equivalent to the Python method:

```
def name(self):
    return "%s %s" % (self.first, self.last)
```

Note that we have to check for the possibility that our **`first`** and **`last`** members are `NULL`. This is because they can be deleted, in which case they are set to `NULL`. It would be better to prevent deletion of these attributes and to restrict the attribute values to be strings. We'll see how to do that in the next section.

Now that we've defined the method, we need to create an array of method definitions:

```
static PyMethodDef Custom_methods[] = {
    {"name", Custom_name, METH_NOARGS,
     "Return the name, combining the first and last name"
    },
    {NULL}  /* Sentinel */
};
```

(note that we used the `METH_NOARGS` flag to indicate that the method is expecting no arguments other than *self*)

and assign it to the `tp_methods` slot:

```
.tp_methods = Custom_methods,
```

Finally, we'll make our type usable as a base class for subclassing. We've written our methods carefully so far so that they don't make any assumptions about the type of the object being created or used, so all we need to do is to add the `Py_TPFLAGS_BASETYPE` to our class flag definition:

```
.tp_flags = Py_TPFLAGS_DEFAULT | Py_TPFLAGS_BASETYPE,
```

We rename **`PyInit_custom()`** to **`PyInit_custom2()`**, update the module name in the `PyModuleDef` struct, and update the full class name in the `PyTypeObject` struct.

Finally, we update our `setup.py` file to include the new module,

```
from setuptools import Extension, setup
setup(ext_modules=[
    Extension("custom", ["custom.c"]),
    Extension("custom2", ["custom2.c"]),
])
```

and then we re-install so that we can `import custom2`:

```
$ python -m pip install .
```

2.3. Providing finer control over data attributes

In this section, we'll provide finer control over how the **`first`** and **`last`** attributes are set in the **`Custom`** example. In the previous version of our module, the instance variables **`first`** and **`last`** could be set to non-string values or even deleted. We want to make sure that these attributes always contain strings.

```
#define PY_SSIZE_T_CLEAN
#include <Python.h>
#include <stddef.h> /* for offsetof() */

typedef struct {
    PyObject_HEAD
    PyObject *first; /* first name */
    PyObject *last;  /* last name */
    int number;
} CustomObject;

static void
Custom_dealloc(PyObject *op)
{
    CustomObject *self = (CustomObject *) op;
    Py_XDECREF(self->first);
    Py_XDECREF(self->last);
    Py_TYPE(self)->tp_free(self);
}

static PyObject *
Custom_new(PyTypeObject *type, PyObject *args, PyObject *kwds)
{
    CustomObject *self;
    self = (CustomObject *) type->tp_alloc(type, 0);
    if (self != NULL) {
        self->first = Py_GetConstant(Py_CONSTANT_EMPTY_STR);
        if (self->first == NULL) {
            Py_DECREF(self);
            return NULL;
        }
        self->last = Py_GetConstant(Py_CONSTANT_EMPTY_STR);
        if (self->last == NULL) {
            Py_DECREF(self);
            return NULL;
        }
        self->number = 0;
    }
    return (PyObject *) self;
}

static int
Custom_init(PyObject *op, PyObject *args, PyObject *kwds)
{
    CustomObject *self = (CustomObject *) op;
    static char *kwlist[] = {"first", "last", "number", NULL};
    PyObject *first = NULL, *last = NULL;

    if (!PyArg_ParseTupleAndKeywords(args, kwds, "|UUi",
kwlist,
                                     &first, &last,
                                     &self->number))
        return -1;

    if (first) {
        Py_SETREF(self->first, Py_NewRef(first));
    }
    if (last) {
        Py_SETREF(self->last, Py_NewRef(last));
    }
    return 0;
}

static PyMemberDef Custom_members[] = {

        return -1;
    }

    if (PyModule_AddObjectRef(m, "Custom", (PyObject *)
&CustomType) < 0) {
        return -1;
    }

    return 0;
}

static PyModuleDef_Slot custom_module_slots[] = {
    {Py_mod_exec, custom_module_exec},
    {Py_mod_multiple_interpreters,
Py_MOD_MULTIPLE_INTERPRETERS_NOT_SUPPORTED},
    {0, NULL}
};

static PyModuleDef custom_module = {
    .m_base = PyModuleDef_HEAD_INIT,
    .m_name = "custom3",
    .m_doc = "Example module that creates an extension type.",
    .m_size = 0,
    .m_slots = custom_module_slots,
};

PyMODINIT_FUNC
PyInit_custom3(void)
{
    return PyModuleDef_Init(&custom_module);
}
```

To provide greater control, over the **`first`** and **`last`** attributes, we’ll use custom getter and setter functions. Here are the functions for getting and setting the **`first`** attribute:

```
static PyObject *
Custom_getfirst(PyObject *op, void *closure)
{
    CustomObject *self = (CustomObject *) op;
    Py_INCREF(self->first);
    return self->first;
}

static int
Custom_setfirst(PyObject *op, PyObject *value, void *closure)
```

```
{
    CustomObject *self = (CustomObject *) op;
    PyObject *tmp;
    if (value == NULL) {
        PyErr_SetString(PyExc_TypeError, "Cannot delete the
first attribute");
        return -1;
    }
    if (!PyUnicode_Check(value)) {
        PyErr_SetString(PyExc_TypeError,
                        "The first attribute value must be a
string");
        return -1;
    }
    tmp = self->first;
    Py_INCREF(value);
    self->first = value;
    Py_DECREF(tmp);
    return 0;
}
```

The getter function is passed a **`Custom`** object and a “closure”, which is a void pointer. In this case, the closure is ignored. (The closure supports an advanced usage in which definition data is passed to the getter and setter. This could, for example, be used to allow a single set of getter and setter functions that decide the attribute to get or set based on data in the closure.)

The setter function is passed the **`Custom`** object, the new value, and the closure. The new value may be `NULL`, in which case the attribute is being deleted. In our setter, we raise an error if the attribute is deleted or if its new value is not a string.

We create an array of **`PyGetSetDef`** structures:

```
static PyGetSetDef Custom_getsetters[] = {
    {"first", Custom_getfirst, Custom_setfirst,
     "first name", NULL},
    {"last", Custom_getlast, Custom_setlast,
     "last name", NULL},
    {NULL}  /* Sentinel */
};
```

and register it in the **`tp_getset`** slot:

```
.tp_getset = Custom_getsetters,
```

The last item in a **`PyGetSetDef`** structure is the “closure” mentioned above. In this case, we aren’t using a closure, so we just pass `NULL`.

We also remove the member definitions for these attributes:

```
static PyMemberDef Custom_members[] = {
    {"number", Py_T_INT, offsetof(CustomObject, number), 0,
     "custom number"},
    {NULL}  /* Sentinel */
};
```

We also need to update the **`tp_init`** handler to only allow strings [[3]] to be passed:

```
static int
Custom_init(PyObject *op, PyObject *args, PyObject *kwds)
{
    CustomObject *self = (CustomObject *) op;
    static char *kwlist[] = {"first", "last", "number", NULL};
    PyObject *first = NULL, *last = NULL, *tmp;

    if (!PyArg_ParseTupleAndKeywords(args, kwds, "|UUi",
kwlist,
                                     &first, &last,
                                     &self->number))
        return -1;

    if (first) {
        tmp = self->first;
        Py_INCREF(first);
        self->first = first;
        Py_DECREF(tmp);
    }
    if (last) {
        tmp = self->last;
        Py_INCREF(last);
        self->last = last;
        Py_DECREF(tmp);
    }
    return 0;
}
```

With these changes, we can assure that the `first` and `last` members are never `NULL` so we can remove checks for `NULL` values in almost all cases. This means that most of the `Py_XDECREF()` calls can be converted to `Py_DECREF()` calls. The only place we can't change these calls is in the `tp_dealloc` implementation, where there is the possibility that the initialization of these members failed in `tp_new`.

We also rename the module initialization function and module name in the initialization function, as we did before, and we add an extra definition to the `setup.py` file.

2.4. Supporting cyclic garbage collection

Python has a cyclic garbage collector (GC) that can identify unneeded objects even when their reference counts are not zero. This can happen when objects are involved in cycles. For example, consider:

```
>>> l = []
>>> l.append(l)
>>> del l
```

In this example, we create a list that contains itself. When we delete it, it still has a reference from itself. Its reference count doesn't drop to zero. Fortunately, Python's cyclic garbage collector will eventually figure out that the list is garbage and free it.

In the second version of the **`Custom`** example, we allowed any kind of object to be stored in the **`first`** or **`last`** attributes [[4]]. Besides, in the second and third versions, we allowed subclassing **`Custom`**, and subclasses may add arbitrary attributes. For any of those two reasons, **`Custom`** objects can participate in cycles:

```
>>> import custom3
>>> class Derived(custom3.Custom): pass
...
>>> n = Derived()
>>> n.some_attribute = n
```

To allow a **`Custom`** instance participating in a reference cycle to be properly detected and collected by the cyclic GC, our **`Custom`** type needs to fill two additional slots and to enable a flag that enables these slots:

```
#define PY_SSIZE_T_CLEAN
#include <Python.h>
#include <stddef.h> /* for offsetof() */

typedef struct {
    PyObject_HEAD
    PyObject *first; /* first name */
    PyObject *last;  /* last name */
    int number;
} CustomObject;

static int
Custom_traverse(PyObject *op, visitproc visit, void *arg)
{
    CustomObject *self = (CustomObject *) op;
    Py_VISIT(self->first);
    Py_VISIT(self->last);
    return 0;
}
```

```
static int
Custom_clear(PyObject *op)
{
    CustomObject *self = (CustomObject *) op;
    Py_CLEAR(self->first);
    Py_CLEAR(self->last);
    return 0;
}

static void
Custom_dealloc(PyObject *op)
{
    PyObject_GC_UnTrack(op);
    (void)Custom_clear(op);
    Py_TYPE(op)->tp_free(op);
}

static PyObject *
Custom_new(PyTypeObject *type, PyObject *args, PyObject *kwds)
{
    CustomObject *self;
    self = (CustomObject *) type->tp_alloc(type, 0);
    if (self != NULL) {
        self->first = Py_GetConstant(Py_CONSTANT_EMPTY_STR);
        if (self->first == NULL) {
            Py_DECREF(self);
            return NULL;
        }
        self->last = Py_GetConstant(Py_CONSTANT_EMPTY_STR);
        if (self->last == NULL) {
            Py_DECREF(self);
            return NULL;
        }
        self->number = 0;
    }
    return (PyObject *) self;
}

static int
Custom_init(PyObject *op, PyObject *args, PyObject *kwds)
{
    CustomObject *self = (CustomObject *) op;
    static char *kwlist[] = {"first", "last", "number", NULL};
    PyObject *first = NULL, *last = NULL;

    if (!PyArg_ParseTupleAndKeywords(args, kwds, "|UUi",
kwlist,
                                     &first, &last,
                                     &self->number))
        return -1;

    if (first) {
        Py_SETREF(self->first, Py_NewRef(first));
    }
    if (last) {
        Py_SETREF(self->last, Py_NewRef(last));
    }
    return 0;
}

static PyMemberDef Custom_members[] = {
    {"number", Py_T_INT, offsetof(CustomObject, number), 0,
     "custom number"},
    {NULL}  /* Sentinel */
};

static PyObject *

    Py_XSETREF(self->last, Py_NewRef(value));
    return 0;
}

static PyGetSetDef Custom_getsetters[] = {
    {"first", Custom_getfirst, Custom_setfirst,
     "first name", NULL},
    {"last", Custom_getlast, Custom_setlast,
     "last name", NULL},
    {NULL}  /* Sentinel */
};

static PyObject *
Custom_name(PyObject *op, PyObject *Py_UNUSED(dummy))
```

```
{
    CustomObject *self = (CustomObject *) op;
    return PyUnicode_FromFormat("%S %S", self->first, self-
>last);
}

static PyMethodDef Custom_methods[] = {
    {"name", Custom_name, METH_NOARGS,
     "Return the name, combining the first and last name"
    },
    {NULL}  /* Sentinel */
};

static PyTypeObject CustomType = {
    .ob_base = PyVarObject_HEAD_INIT(NULL, 0)
    .tp_name = "custom4.Custom",
    .tp_doc = PyDoc_STR("Custom objects"),
    .tp_basicsize = sizeof(CustomObject),
    .tp_itemsize = 0,
    .tp_flags = Py_TPFLAGS_DEFAULT | Py_TPFLAGS_BASETYPE |
Py_TPFLAGS_HAVE_GC,
    .tp_new = Custom_new,
    .tp_init = Custom_init,
    .tp_dealloc = Custom_dealloc,
    .tp_traverse = Custom_traverse,
    .tp_clear = Custom_clear,
    .tp_members = Custom_members,
    .tp_methods = Custom_methods,
    .tp_getset = Custom_getsetters,
};

static int
custom_module_exec(PyObject *m)
{
    if (PyType_Ready(&CustomType) < 0) {
        return -1;
    }

    if (PyModule_AddObjectRef(m, "Custom", (PyObject *)
&CustomType) < 0) {
        return -1;
    }
    return 0;
}

static PyModuleDef_Slot custom_module_slots[] = {
    {Py_mod_exec, custom_module_exec},
    {Py_mod_multiple_interpreters,
Py_MOD_MULTIPLE_INTERPRETERS_NOT_SUPPORTED},
    {0, NULL}
};

static PyModuleDef custom_module = {
    .m_base = PyModuleDef_HEAD_INIT,
    .m_name = "custom4",
    .m_doc = "Example module that creates an extension type.",
    .m_size = 0,
    .m_slots = custom_module_slots,
};

PyMODINIT_FUNC
PyInit_custom4(void)
{
    return PyModuleDef_Init(&custom_module);
}
```

First, the traversal method lets the cyclic GC know about subobjects that could participate in cycles:

```
static int
Custom_traverse(PyObject *op, visitproc visit, void *arg)
{
    CustomObject *self = (CustomObject *) op;
    int vret;
    if (self->first) {
        vret = visit(self->first, arg);
        if (vret != 0)
            return vret;
    }
    if (self->last) {
        vret = visit(self->last, arg);
        if (vret != 0)
            return vret;
    }
    return 0;
}
```

For each subobject that can participate in cycles, we need to call the **`visit()`** function, which is passed to the traversal method. The **`visit()`** function takes as arguments the subobject and the extra argument *arg* passed to the traversal method. It returns an integer value that must be returned if it is non-zero.

Python provides a **`Py_VISIT()`** macro that automates calling visit functions. With **`Py_VISIT()`**, we can minimize the amount of boilerplate in `Custom_traverse`:

```
static int
Custom_traverse(PyObject *op, visitproc visit, void *arg)
{
    CustomObject *self = (CustomObject *) op;
    Py_VISIT(self->first);
    Py_VISIT(self->last);
    return 0;
}
```

Note

The **`tp_traverse`** implementation must name its arguments exactly *visit* and *arg* in order to use **`Py_VISIT()`**.

Second, we need to provide a method for clearing any subobjects that can participate in cycles:

```
static int
Custom_clear(PyObject *op)
{
    CustomObject *self = (CustomObject *) op;
    Py_CLEAR(self->first);
    Py_CLEAR(self->last);
    return 0;
}
```

Notice the use of the `Py_CLEAR()` macro. It is the recommended and safe way to clear data attributes of arbitrary types while decrementing their reference counts. If you were to call `Py_XDECREF()` instead on the attribute before setting it to `NULL`, there is a possibility that the attribute's destructor would call back into code that reads the attribute again (*especially* if there is a reference cycle).

Note

You could emulate `Py_CLEAR()` by writing:

```
PyObject *tmp;
tmp = self->first;
self->first = NULL;
Py_XDECREF(tmp);
```

Nevertheless, it is much easier and less error-prone to always use `Py_CLEAR()` when deleting an attribute. Don't try to micro-optimize at the expense of robustness!

The deallocator `Custom_dealloc` may call arbitrary code when clearing attributes. It means the circular GC can be triggered inside the function. Since the GC assumes reference count is not zero, we need to untrack the object from the GC by calling `PyObject_GC_UnTrack()` before clearing members. Here is our reimplemented deallocator using `PyObject_GC_UnTrack()` and `Custom_clear`:

```
static void
Custom_dealloc(PyObject *op)
{
    PyObject_GC_UnTrack(op);
    (void)Custom_clear(op);
    Py_TYPE(op)->tp_free(op);
}
```

Finally, we add the `Py_TPFLAGS_HAVE_GC` flag to the class flags:

```
.tp_flags = Py_TPFLAGS_DEFAULT | Py_TPFLAGS_BASETYPE |
Py_TPFLAGS_HAVE_GC,
```

That’s pretty much it. If we had written custom `tp_alloc` or `tp_free` handlers, we’d need to modify them for cyclic garbage collection. Most extensions will use the versions automatically provided.

2.5. Subclassing other types

It is possible to create new extension types that are derived from existing types. It is easiest to inherit from the built in types, since an extension can easily use the `PyTypeObject` it needs. It can be difficult to share these `PyTypeObject` structures between extension modules.

In this example we will create a **`SubList`** type that inherits from the built-in `list` type. The new type will be completely compatible with regular lists, but will have an additional **`increment()`** method that increases an internal counter:

```
>>> import sublist
>>> s = sublist.SubList(range(3))
>>> s.extend(s)
>>> print(len(s))
6
>>> print(s.increment())
1
>>> print(s.increment())
2
```

```
#define PY_SSIZE_T_CLEAN
#include <Python.h>
```

```
typedef struct {
    PyListObject list;
    int state;
} SubListObject;

static PyObject *
SubList_increment(PyObject *op, PyObject *Py_UNUSED(dummy))
{
    SubListObject *self = (SubListObject *) op;
    self->state++;
    return PyLong_FromLong(self->state);
}

static PyMethodDef SubList_methods[] = {
    {"increment", SubList_increment, METH_NOARGS,
     PyDoc_STR("increment state counter")},
    {NULL},
};

static int
SubList_init(PyObject *op, PyObject *args, PyObject *kwds)
{
    SubListObject *self = (SubListObject *) op;
    if (PyList_Type.tp_init(op, args, kwds) < 0)
        return -1;
    self->state = 0;
    return 0;
}

static PyTypeObject SubListType = {
    .ob_base = PyVarObject_HEAD_INIT(NULL, 0)
    .tp_name = "sublist.SubList",
    .tp_doc = PyDoc_STR("SubList objects"),
    .tp_basicsize = sizeof(SubListObject),
    .tp_itemsize = 0,
    .tp_flags = Py_TPFLAGS_DEFAULT | Py_TPFLAGS_BASETYPE,
    .tp_init = SubList_init,
    .tp_methods = SubList_methods,
};

static int
sublist_module_exec(PyObject *m)
{
    SubListType.tp_base = &PyList_Type;
    if (PyType_Ready(&SubListType) < 0) {
        return -1;
    }

    if (PyModule_AddObjectRef(m, "SubList", (PyObject *)
&SubListType) < 0) {
        return -1;
    }

    return 0;
}

static PyModuleDef_Slot sublist_module_slots[] = {
    {Py_mod_exec, sublist_module_exec},
    {Py_mod_multiple_interpreters,
Py_MOD_MULTIPLE_INTERPRETERS_NOT_SUPPORTED},
    {0, NULL}
};

static PyModuleDef sublist_module = {
    .m_base = PyModuleDef_HEAD_INIT,
    .m_name = "sublist",
    .m_doc = "Example module that creates an extension type.",
    .m_size = 0,
    .m_slots = sublist_module_slots,
};

PyMODINIT_FUNC
PyInit_sublist(void)
{
    return PyModuleDef_Init(&sublist_module);
}
```

As you can see, the source code closely resembles the **`Custom`** examples in previous sections. We will break down the main differences between them.

```
typedef struct {
    PyListObject list;
    int state;
} SubListObject;
```

The primary difference for derived type objects is that the base type’s object structure must be the first value. The base type will already include the `PyObject_HEAD()` at the beginning of its structure.

When a Python object is a **`SubList`** instance, its `PyObject *` pointer can be safely cast to both `PyListObject *` and `SubListObject *`:

```
static int
SubList_init(PyObject *op, PyObject *args, PyObject *kwds)
{
    SubListObject *self = (SubListObject *) op;
    if (PyList_Type.tp_init(op, args, kwds) < 0)
        return -1;
    self->state = 0;
    return 0;
}
```

We see above how to call through to the `__init__()` method of the base type.

This pattern is important when writing a type with custom `tp_new` and `tp_dealloc` members. The `tp_new` handler should not actually create the memory for the object with its `tp_alloc`, but let the base class handle it by calling its own `tp_new`.

The `PyTypeObject` struct supports a `tp_base` specifying the type’s concrete base class. Due to cross-platform compiler issues, you can’t fill that field directly with a reference to `PyList_Type`; it should be done in the `Py_mod_exec` function:

```
static int
sublist_module_exec(PyObject *m)
{
    SubListType.tp_base = &PyList_Type;
    if (PyType_Ready(&SubListType) < 0) {
        return -1;
    }

    if (PyModule_AddObjectRef(m, "SubList", (PyObject *)
&SubListType) < 0) {
        return -1;
    }

    return 0;
}
```

Before calling `PyType_Ready()`, the type structure must have the `tp_base` slot filled in. When we are deriving an existing type, it is not necessary to fill out the `tp_alloc` slot with `PyType_GenericNew()` – the allocation function from the base type will be inherited.

After that, calling `PyType_Ready()` and adding the type object to the module is the same as with the basic **`Custom`** examples.

Footnotes

[1]

This is true when we know that the object is a basic type, like a string or a float.

[2]

We relied on this in the `tp_dealloc` handler in this example, because our type doesn't support garbage collection.

[3]

We now know that the first and last members are strings, so perhaps we could be less careful about decrementing their reference counts, however, we accept instances of string subclasses. Even though deallocating normal strings won't

call back into our objects, we can’t guarantee that deallocating an instance of a string subclass won’t call back into our objects.
[4]

Also, even with our attributes restricted to strings instances, the user could pass arbitrary `str` subclasses and therefore still create reference cycles.

3. Defining Extension Types: Assorted Topics

This section aims to give a quick fly-by on the various type methods you can implement and what they do.

Here is the definition of **`PyTypeObject`**, with some fields only used in debug builds omitted:

```
typedef struct _typeobject {
    PyObject_VAR_HEAD
    const char *tp_name; /* For printing, in format "<module>.
<name>" */
    Py_ssize_t tp_basicsize, tp_itemsize; /* For allocation */

    /* Methods to implement standard operations */

    destructor tp_dealloc;
    Py_ssize_t tp_vectorcall_offset;
    getattrfunc tp_getattr;
    setattrfunc tp_setattr;
    PyAsyncMethods *tp_as_async; /* formerly known as
tp_compare (Python 2)
                                    or tp_reserved (Python 3)
*/
    reprfunc tp_repr;

    /* Method suites for standard classes */

    PyNumberMethods *tp_as_number;
    PySequenceMethods *tp_as_sequence;
    PyMappingMethods *tp_as_mapping;

    /* More standard operations (here for binary compatibility)
*/

    hashfunc tp_hash;
    ternaryfunc tp_call;
    reprfunc tp_str;
    getattrofunc tp_getattro;
    setattrofunc tp_setattro;

    /* Functions to access object as input/output buffer */
    PyBufferProcs *tp_as_buffer;

    /* Flags to define presence of optional/expanded features
*/
    unsigned long tp_flags;

    const char *tp_doc; /* Documentation string */

    /* Assigned meaning in release 2.0 */
    /* call function for all accessible objects */
    traverseproc tp_traverse;

    /* delete references to contained objects */
    inquiry tp_clear;

    /* Assigned meaning in release 2.1 */
    /* rich comparisons */
    richcmpfunc tp_richcompare;

    /* weak reference enabler */
    Py_ssize_t tp_weaklistoffset;

    /* Iterators */
    getiterfunc tp_iter;
    iternextfunc tp_iternext;

    /* Attribute descriptor and subclassing stuff */
    PyMethodDef *tp_methods;
    PyMemberDef *tp_members;
    PyGetSetDef *tp_getset;
    // Strong reference on a heap type, borrowed reference on a
static type
    PyTypeObject *tp_base;
    PyObject *tp_dict;
    descrgetfunc tp_descr_get;
    descrsetfunc tp_descr_set;
    Py_ssize_t tp_dictoffset;
    initproc tp_init;
    allocfunc tp_alloc;
    newfunc tp_new;
    freefunc tp_free; /* Low-level free-memory routine */
    inquiry tp_is_gc; /* For PyObject_IS_GC */
    PyObject *tp_bases;
    PyObject *tp_mro; /* method resolution order */
    PyObject *tp_cache; /* no longer used */
    void *tp_subclasses;  /* for static builtin types this is
an index */
    PyObject *tp_weaklist; /* not used for static builtin types
*/
    destructor tp_del;

    /* Type attribute cache version tag. Added in version 2.6.
     * If zero, the cache is invalid and must be initialized.
     */
    unsigned int tp_version_tag;

    destructor tp_finalize;
    vectorcallfunc tp_vectorcall;

    /* bitset of which type-watchers care about this type */
    unsigned char tp_watched;

    /* Number of tp_version_tag values used.
     * Set to _Py_ATTR_CACHE_UNUSED if the attribute cache is
     * disabled for this type (e.g. due to custom MRO entries).
     * Otherwise, limited to MAX_VERSIONS_PER_CLASS (defined
elsewhere).
     */
    uint16_t tp_versions_used;
} PyTypeObject;
```

Now that’s a *lot* of methods. Don’t worry too much though – if you have a type you want to define, the chances are very good that you will only implement a handful of these.

As you probably expect by now, we’re going to go over this and give more information about the various handlers. We won’t go in the order they are defined in the structure, because there is a lot of historical baggage that impacts the ordering of the fields. It’s often easiest to find an example that includes the fields you need and then change the values to suit your new type.

```
const char *tp_name; /* For printing */
```

The name of the type – as mentioned in the previous chapter, this will appear in various places, almost entirely for diagnostic purposes. Try to choose something that will be helpful in such a situation!

```
Py_ssize_t tp_basicsize, tp_itemsize; /* For allocation */
```

These fields tell the runtime how much memory to allocate when new objects of this type are created. Python has some built-in support for variable length structures (think: strings, tuples) which is where the `tp_itemsize` field comes in. This will be dealt with later.

```
const char *tp_doc;
```

Here you can put a string (or its address) that you want returned when the Python script references `obj.__doc__` to retrieve the doc string.

Now we come to the basic type methods – the ones most extension types will implement.

3.1. Finalization and De-allocation

```
destructor tp_dealloc;
```

This function is called when the reference count of the instance of your type is reduced to zero and the Python interpreter wants to reclaim it. If your type has memory to free or other clean-up to perform, you can put it here. The object itself needs to be freed here as well. Here is an example of this function:

```
static void
newdatatype_dealloc(PyObject *op)
{
    newdatatypeobject *self = (newdatatypeobject *) op;
    free(self->obj_UnderlyingDatatypePtr);
    Py_TYPE(self)->tp_free(self);
}
```

If your type supports garbage collection, the destructor should call `PyObject_GC_UnTrack()` before clearing any member fields:

```
static void
newdatatype_dealloc(PyObject *op)
{
    newdatatypeobject *self = (newdatatypeobject *) op;
    PyObject_GC_UnTrack(op);
    Py_CLEAR(self->other_obj);
    ...
    Py_TYPE(self)->tp_free(self);
}
```

One important requirement of the deallocator function is that it leaves any pending exceptions alone. This is important since deallocators are frequently called as the interpreter unwinds the Python stack; when the stack is unwound due to an exception (rather than normal returns), nothing is done to protect the deallocators from seeing that an exception has already been set. Any actions which a deallocator performs which may cause additional Python code to be executed may detect that an exception has been set. This can lead to misleading errors from the interpreter. The proper way to protect against this is to save a pending exception before performing the unsafe action, and restoring it when done. This can be done using the `PyErr_Fetch()` and `PyErr_Restore()` functions:

```
static void
my_dealloc(PyObject *obj)
{
    MyObject *self = (MyObject *) obj;
    PyObject *cbresult;

    if (self->my_callback != NULL) {
        PyObject *err_type, *err_value, *err_traceback;

        /* This saves the current exception state */
        PyErr_Fetch(&err_type, &err_value, &err_traceback);

        cbresult = PyObject_CallNoArgs(self->my_callback);
        if (cbresult == NULL) {
           PyErr_WriteUnraisable(self->my_callback);
        }
        else {
            Py_DECREF(cbresult);
        }

        /* This restores the saved exception state */
        PyErr_Restore(err_type, err_value, err_traceback);

        Py_DECREF(self->my_callback);
    }
    Py_TYPE(self)->tp_free(self);
}
```

Note

There are limitations to what you can safely do in a deallocator function. First, if your type supports garbage collection (using `tp_traverse` and/or `tp_clear`), some of the object's members can have been cleared or finalized by the time `tp_dealloc` is called. Second, in `tp_dealloc`, your object is in an unstable state: its reference count is equal to zero. Any call to a non-trivial object or API (as in the example above) might end up calling `tp_dealloc` again, causing a double free and a crash.

Starting with Python 3.4, it is recommended not to put any complex finalization code in `tp_dealloc`, and instead use the new `tp_finalize` type method.

See also

PEP 442 [https://peps.python.org/pep-0442/] explains the new finalization scheme.

3.2. Object Presentation

In Python, there are two ways to generate a textual representation of an object: the `repr()` function, and the `str()` function. (The `print()` function just calls `str()`.) These handlers are both optional.

```
reprfunc tp_repr;
reprfunc tp_str;
```

The `tp_repr` handler should return a string object containing a representation of the instance for which it is called. Here is a simple example:

```
static PyObject *
newdatatype_repr(PyObject *op)
{
    newdatatypeobject *self = (newdatatypeobject *) op;
    return PyUnicode_FromFormat("Repr-
ified_newdatatype{{size:%d}}",
                                self-
>obj_UnderlyingDatatypePtr->size);
}
```

If no `tp_repr` handler is specified, the interpreter will supply a representation that uses the type’s `tp_name` and a uniquely identifying value for the object.

The `tp_str` handler is to `str()` what the `tp_repr` handler described above is to `repr()`; that is, it is called when Python code calls `str()` on an instance of your object. Its implementation is very similar to the `tp_repr` function, but the resulting string is intended for human consumption. If `tp_str` is not specified, the `tp_repr` handler is used instead.

Here is a simple example:

```
static PyObject *
newdatatype_str(PyObject *op)
{
    newdatatypeobject *self = (newdatatypeobject *) op;
    return
PyUnicode_FromFormat("Stringified_newdatatype{{size:%d}}",
                                self-
>obj_UnderlyingDatatypePtr->size);
}
```

3.3. Attribute Management

For every object which can support attributes, the corresponding type must provide the functions that control how the attributes are resolved. There needs to be a function which can retrieve attributes (if any are defined), and another to set attributes (if setting attributes is allowed). Removing an attribute is a special case, for which the new value passed to the handler is `NULL`.

Python supports two pairs of attribute handlers; a type that supports attributes only needs to implement the functions for one pair. The difference is that one pair takes the name of the attribute as a char*, while the other accepts a PyObject*. Each type can use whichever pair makes more sense for the implementation’s convenience.

```
getattrfunc  tp_getattr;        /* char * version */
setattrfunc  tp_setattr;
```

```
/* ... */
getattrofunc tp_getattro;       /* PyObject * version */
setattrofunc tp_setattro;
```

If accessing attributes of an object is always a simple operation (this will be explained shortly), there are generic implementations which can be used to provide the PyObject* version of the attribute management functions. The actual need for type-specific attribute handlers almost completely disappeared starting with Python 2.2, though there are many examples which have not been updated to use some of the new generic mechanism that is available.

3.3.1. Generic Attribute Management

Most extension types only use *simple* attributes. So, what makes the attributes simple? There are only a couple of conditions that must be met:

1. The name of the attributes must be known when **`PyType_Ready()`** is called.
2. No special processing is needed to record that an attribute was looked up or set, nor do actions need to be taken based on the value.

Note that this list does not place any restrictions on the values of the attributes, when the values are computed, or how relevant data is stored.

When **`PyType_Ready()`** is called, it uses three tables referenced by the type object to create descriptors which are placed in the dictionary of the type object. Each descriptor controls access to one attribute of the instance object. Each of the tables is optional; if all three are `NULL`, instances of the type will only have attributes that are inherited from their base type, and should leave the **`tp_getattro`** and **`tp_setattro`** fields `NULL` as well, allowing the base type to handle attributes.

The tables are declared as three fields of the type object:

```
struct PyMethodDef *tp_methods;
struct PyMemberDef *tp_members;
struct PyGetSetDef *tp_getset;
```

If **`tp_methods`** is not `NULL`, it must refer to an array of **`PyMethodDef`** structures. Each entry in the table is an instance of this structure:

```
typedef struct PyMethodDef {
    const char  *ml_name;       /* method name */
    PyCFunction  ml_meth;       /* implementation function */
    int          ml_flags;      /* flags */
    const char  *ml_doc;        /* docstring */
} PyMethodDef;
```

One entry should be defined for each method provided by the type; no entries are needed for methods inherited from a base type. One additional entry is needed at the end; it is a sentinel that marks the end of the array. The **`ml_name`** field of the sentinel must be `NULL`.

The second table is used to define attributes which map directly to data stored in the instance. A variety of primitive C types are supported, and access may be read-only or read-write. The structures in the table are defined as:

```
typedef struct PyMemberDef {
    const char *name;
    int         type;
    int         offset;
    int         flags;
    const char *doc;
} PyMemberDef;
```

For each entry in the table, a descriptor will be constructed and added to the type which will be able to extract a value from the instance structure. The **`type`** field should contain a type code like `Py_T_INT` or `Py_T_DOUBLE`; the value will be used to determine how to convert Python values to and from C values. The `flags` field is used to store flags which control how the attribute can be accessed: you can set it to `Py_READONLY` to prevent Python code from setting it.

An interesting advantage of using the `tp_members` table to build descriptors that are used at runtime is that any attribute defined this way can have an associated doc string simply by providing the text in the table. An application can use the introspection API to retrieve the descriptor from the class object, and get the doc string using its `__doc__` attribute.

As with the `tp_methods` table, a sentinel entry with a `ml_name` value of `NULL` is required.

3.3.2. Type-specific Attribute Management

For simplicity, only the char* version will be demonstrated here; the type of the name parameter is the only difference between the char* and PyObject* flavors of the interface. This example effectively does the same thing as the generic example above, but does not use the generic support added in Python 2.2. It explains how the handler functions are called, so that if you do need to extend their functionality, you'll understand what needs to be done.

The `tp_getattr` handler is called when the object requires an attribute look-up. It is called in the same situations where the `__getattr__()` method of a class would be called.

Here is an example:

```
static PyObject *
newdatatype_getattr(PyObject *op, char *name)
{
    newdatatypeobject *self = (newdatatypeobject *) op;
    if (strcmp(name, "data") == 0) {
        return PyLong_FromLong(self->data);
    }

    PyErr_Format(PyExc_AttributeError,
                 "'%.100s' object has no attribute '%.400s'",
                 Py_TYPE(self)->tp_name, name);
    return NULL;
}
```

The **`tp_setattr`** handler is called when the `__setattr__()` or `__delattr__()` method of a class instance would be called. When an attribute should be deleted, the third parameter will be `NULL`. Here is an example that simply raises an exception; if this were really all you wanted, the **`tp_setattr`** handler should be set to `NULL`.

```
static int
newdatatype_setattr(PyObject *op, char *name, PyObject *v)
{
    PyErr_Format(PyExc_RuntimeError, "Read-only attribute: %s",
name);
    return -1;
}
```

3.4. Object Comparison

```
richcmpfunc tp_richcompare;
```

The **`tp_richcompare`** handler is called when comparisons are needed. It is analogous to the rich comparison methods, like **`__lt__()`**, and also called by **`PyObject_RichCompare()`** and **`PyObject_RichCompareBool()`**.

This function is called with two Python objects and the operator as arguments, where the operator is one of `Py_EQ`, `Py_NE`, `Py_LE`, `Py_GE`, `Py_LT` or `Py_GT`. It should compare the two objects with respect to the specified operator and return

`Py_True` or `Py_False` if the comparison is successful, `Py_NotImplemented` to indicate that comparison is not implemented and the other object's comparison method should be tried, or `NULL` if an exception was set.

Here is a sample implementation, for a datatype that is considered equal if the size of an internal pointer is equal:

```
static PyObject *
newdatatype_richcmp(PyObject *lhs, PyObject *rhs, int op)
{
    newdatatypeobject *obj1 = (newdatatypeobject *) lhs;
    newdatatypeobject *obj2 = (newdatatypeobject *) rhs;
    PyObject *result;
    int c, size1, size2;

    /* code to make sure that both arguments are of type
       newdatatype omitted */

    size1 = obj1->obj_UnderlyingDatatypePtr->size;
    size2 = obj2->obj_UnderlyingDatatypePtr->size;

    switch (op) {
    case Py_LT: c = size1 <  size2; break;
    case Py_LE: c = size1 <= size2; break;
    case Py_EQ: c = size1 == size2; break;
    case Py_NE: c = size1 != size2; break;
    case Py_GT: c = size1 >  size2; break;
    case Py_GE: c = size1 >= size2; break;
    }
    result = c ? Py_True : Py_False;
    return Py_NewRef(result);
 }
```

3.5. Abstract Protocol Support

Python supports a variety of *abstract* 'protocols;' the specific interfaces provided to use these interfaces are documented in Abstract Objects Layer.

A number of these abstract interfaces were defined early in the development of the Python implementation. In particular, the number, mapping, and sequence protocols have been part of Python since the beginning. Other protocols have been added over time. For protocols which depend on several handler routines from the type implementation, the older protocols have been defined as optional blocks of handlers referenced by the type object. For newer protocols there are additional slots in the main type object, with a flag bit being set to indicate that the slots are present and should be checked by the interpreter. (The flag bit does not indicate that the slot values are non-`NULL`. The flag may be set to indicate the presence of a slot, but a slot may still be unfilled.)

```
PyNumberMethods   *tp_as_number;
PySequenceMethods *tp_as_sequence;
PyMappingMethods  *tp_as_mapping;
```

If you wish your object to be able to act like a number, a sequence, or a mapping object, then you place the address of a structure that implements the C type **`PyNumberMethods`**, **`PySequenceMethods`**, or **`PyMappingMethods`**, respectively. It is up to you to fill in this structure with appropriate values. You can find examples of the use of each of these in the `Objects` directory of the Python source distribution.

```
hashfunc tp_hash;
```

This function, if you choose to provide it, should return a hash number for an instance of your data type. Here is a simple example:

```
static Py_hash_t
newdatatype_hash(PyObject *op)
{
    newdatatypeobject *self = (newdatatypeobject *) op;
    Py_hash_t result;
    result = self->some_size + 32767 * self->some_number;
    if (result == -1) {
        result = -2;
    }
    return result;
}
```

`Py_hash_t` is a signed integer type with a platform-varying width. Returning `-1` from `tp_hash` indicates an error, which is why you should be careful to avoid returning it when hash computation is successful, as seen above.

```
ternaryfunc tp_call;
```

This function is called when an instance of your data type is “called”, for example, if `obj1` is an instance of your data type and the Python script contains `obj1('hello')`, the `tp_call` handler is invoked.

This function takes three arguments:

1. *self* is the instance of the data type which is the subject of the call. If the call is `obj1('hello')`, then *self* is `obj1`.
2. *args* is a tuple containing the arguments to the call. You can use `PyArg_ParseTuple()` to extract the arguments.
3. *kwds* is a dictionary of keyword arguments that were passed. If this is non-`NULL` and you support keyword arguments, use `PyArg_ParseTupleAndKeywords()` to extract the arguments. If you do not want to support keyword arguments and this is non-`NULL`, raise a `TypeError` with a message saying that keyword arguments are not supported.

Here is a toy `tp_call` implementation:

```
static PyObject *
newdatatype_call(PyObject *op, PyObject *args, PyObject *kwds)
{
    newdatatypeobject *self = (newdatatypeobject *) op;
    PyObject *result;
    const char *arg1;
    const char *arg2;
    const char *arg3;

    if (!PyArg_ParseTuple(args, "sss:call", &arg1, &arg2,
&arg3)) {
        return NULL;
    }
    result = PyUnicode_FromFormat(
        "Returning -- value: [%d] arg1: [%s] arg2: [%s] arg3:
[%s]\n",
        self->obj_UnderlyingDatatypePtr->size,
        arg1, arg2, arg3);
    return result;
}
```

```
/* Iterators */
getiterfunc tp_iter;
iternextfunc tp_iternext;
```

These functions provide support for the iterator protocol. Both handlers take exactly one parameter, the instance for which they are being called, and return a new reference. In the case of an error, they should set an exception and return `NULL`. **`tp_iter`** corresponds to the Python **`__iter__()`** method, while **`tp_iternext`** corresponds to the Python **`__next__()`** method.

Any iterable object must implement the **`tp_iter`** handler, which must return an iterator object. Here the same guidelines apply as for Python classes:

- For collections (such as lists and tuples) which can support multiple independent iterators, a new iterator should be created and returned by each call to **`tp_iter`**.
- Objects which can only be iterated over once (usually due to side effects of iteration, such as file objects) can implement **`tp_iter`** by returning a new reference to

themselves – and should also therefore implement the **`tp_iternext`** handler.

Any iterator object should implement both **`tp_iter`** and **`tp_iternext`**. An iterator's **`tp_iter`** handler should return a new reference to the iterator. Its **`tp_iternext`** handler should return a new reference to the next object in the iteration, if there is one. If the iteration has reached the end, **`tp_iternext`** may return `NULL` without setting an exception, or it may set **`StopIteration`** *in addition* to returning `NULL`; avoiding the exception can yield slightly better performance. If an actual error occurs, **`tp_iternext`** should always set an exception and return `NULL`.

3.6. Weak Reference Support

One of the goals of Python's weak reference implementation is to allow any type to participate in the weak reference mechanism without incurring the overhead on performance-critical objects (such as numbers).

See also

Documentation for the **`weakref`** module.

For an object to be weakly referenceable, the extension type must set the `Py_TPFLAGS_MANAGED_WEAKREF` bit of the **`tp_flags`** field. The legacy **`tp_weaklistoffset`** field should be left as zero.

Concretely, here is how the statically declared type object would look:

```
static PyTypeObject TrivialType = {
    PyVarObject_HEAD_INIT(NULL, 0)
    /* ... other members omitted for brevity ... */
    .tp_flags = Py_TPFLAGS_MANAGED_WEAKREF | ...,
};
```

The only further addition is that `tp_dealloc` needs to clear any weak references (by calling **`PyObject_ClearWeakRefs()`**):

```
static void
Trivial_dealloc(PyObject *op)
{
    /* Clear weakrefs first before calling any destructors */
    PyObject_ClearWeakRefs(op);
    /* ... remainder of destruction code omitted for brevity
... */
    Py_TYPE(op)->tp_free(op);
}
```

3.7. More Suggestions

In order to learn how to implement any specific method for your new data type, get the CPython source code. Go to the `Objects` directory, then search the C source files for `tp_` plus the function you want (for example, `tp_richcompare`). You will find examples of the function you want to implement.

When you need to verify that an object is a concrete instance of the type you are implementing, use the **`PyObject_TypeCheck()`** function. A sample of its use might be something like the following:

```
if (!PyObject_TypeCheck(some_object, &MyType)) {
    PyErr_SetString(PyExc_TypeError, "arg #1 not a mything");
    return NULL;
}
```

4. Building C and C++ Extensions

A C extension for CPython is a shared library (for example, a `.so` file on Linux, `.pyd` on Windows), which exports an *initialization function*.

See Defining extension modules for details.

4.1. Building C and C++ Extensions with setuptools

Building, packaging and distributing extension modules is best done with third-party tools, and is out of scope of this document. One suitable tool is Setuptools, whose documentation can be found at https://setuptools.pypa.io/en/latest/setuptools.html.

The **`distutils`** module, which was included in the standard library until Python 3.12, is now maintained as part of Setuptools.

5. Building C and C++ Extensions on Windows

This chapter briefly explains how to create a Windows extension module for Python using Microsoft Visual C++, and follows with more detailed background information on how it works. The explanatory material is useful for both the Windows programmer learning to build Python extensions and the Unix programmer interested in producing software which can be successfully built on both Unix and Windows.

Module authors are encouraged to use the distutils approach for building extension modules, instead of the one described in this section. You will still need the C compiler that was used to build Python; typically Microsoft Visual C++.

Note

This chapter mentions a number of filenames that include an encoded Python version number. These filenames are represented with the version number shown as XY; in practice, `'X'` will be the major version number and `'Y'` will be the minor version number of the Python release you’re working with. For example, if you are using Python 2.2.1, XY will actually be 22.

5.1. A Cookbook Approach

There are two approaches to building extension modules on Windows, just as there are on Unix: use the `setuptools` package to control the build process, or do things manually. The setuptools approach works well for most extensions; documentation on using `setuptools` to build and package extension modules is available in Building C and C++ Extensions with setuptools. If you find you really need to do things manually, it may be instructive to study the project file for the winsound [https://github.com/python/cpython/tree/3.14/PCbuild/winsound.vcxproj] standard library module.

5.2. Differences Between Unix and Windows

Unix and Windows use completely different paradigms for run-time loading of code. Before you try to build a module that can be dynamically loaded, be aware of how your system works.

In Unix, a shared object (`.so`) file contains code to be used by the program, and also the names of functions and data that it expects to find in the program. When the file is joined to the program, all references to those functions and data in the file's code are changed to point to the actual locations in the program where the functions and data are placed in memory. This is basically a link operation.

In Windows, a dynamic-link library (`.dll`) file has no dangling references. Instead, an access to functions or data goes through a lookup table. So the DLL code does not have to be fixed up at runtime to refer to the program's memory;

instead, the code already uses the DLL's lookup table, and the lookup table is modified at runtime to point to the functions and data.

In Unix, there is only one type of library file (`.a`) which contains code from several object files (`.o`). During the link step to create a shared object file (`.so`), the linker may find that it doesn't know where an identifier is defined. The linker will look for it in the object files in the libraries; if it finds it, it will include all the code from that object file.

In Windows, there are two types of library, a static library and an import library (both called `.lib`). A static library is like a Unix `.a` file; it contains code to be included as necessary. An import library is basically used only to reassure the linker that a certain identifier is legal, and will be present in the program when the DLL is loaded. So the linker uses the information from the import library to build the lookup table for using identifiers that are not included in the DLL. When an application or a DLL is linked, an import library may be generated, which will need to be used for all future DLLs that depend on the symbols in the application or DLL.

Suppose you are building two dynamic-load modules, B and C, which should share another block of code A. On Unix, you would *not* pass `A.a` to the linker for `B.so` and `C.so`; that would cause it to be included twice, so that B and C would each have their own copy. In Windows, building `A.dll` will also build `A.lib`. You *do* pass `A.lib` to the linker for B and C. `A.lib` does not contain code; it just contains information which will be used at runtime to access A's code.

In Windows, using an import library is sort of like using `import spam`; it gives you access to spam's names, but does not create a separate copy. On Unix, linking with a library is more like `from spam import *`; it does create a separate copy.

Py_NO_LINK_LIB

Turn off the implicit, `#pragma`-based linkage with the Python library, performed inside CPython header files.

Added in version 3.14.

5.3. Using DLLs in Practice

Windows Python is built in Microsoft Visual C++; using other compilers may or may not work. The rest of this section is MSVC++ specific.

When creating DLLs in Windows, you can use the CPython library in two ways:

1. By default, inclusion of `PC/pyconfig.h` directly or via `Python.h` triggers an implicit, configure-aware link with the library. The header file chooses `pythonXY_d.lib` for Debug, `pythonXY.lib` for Release, and `pythonX.lib` for Release with the Limited API enabled.

   To build two DLLs, spam and ni (which uses C functions found in spam), you could use these commands:

   ```
   cl /LD /I/python/include spam.c
   cl /LD /I/python/include ni.c spam.lib
   ```

   The first command created three files: `spam.obj`, `spam.dll` and `spam.lib`. `Spam.dll` does not contain any Python functions (such as **`PyArg_ParseTuple()`**), but it does know how to find the Python code thanks to the implicitly linked `pythonXY.lib`.

The second command created `ni.dll` (and `.obj` and `.lib`), which knows how to find the necessary functions from spam, and also from the Python executable.

2. Manually by defining `Py_NO_LINK_LIB` macro before including `Python.h`. You must pass `pythonXY.lib` to the linker.

   To build two DLLs, spam and ni (which uses C functions found in spam), you could use these commands:

   ```
   cl /LD /DPy_NO_LINK_LIB /I/python/include spam.c
   ../libs/pythonXY.lib
   cl /LD /DPy_NO_LINK_LIB /I/python/include ni.c spam.lib
   ../libs/pythonXY.lib
   ```

   The first command created three files: `spam.obj`, `spam.dll` and `spam.lib`. `Spam.dll` does not contain any Python functions (such as `PyArg_ParseTuple()`), but it does know how to find the Python code thanks to `pythonXY.lib`.

   The second command created `ni.dll` (and `.obj` and `.lib`), which knows how to find the necessary functions from spam, and also from the Python executable.

Not every identifier is exported to the lookup table. If you want any other modules (including Python) to be able to see your identifiers, you have to say `_declspec(dllexport)`, as in `void _declspec(dllexport) initspam(void)` or `PyObject _declspec(dllexport) *NiGetSpamData(void)`.

Developer Studio will throw in a lot of import libraries that you do not really need, adding about 100K to your executable. To get rid of them, use the Project Settings dialog, Link tab, to specify *ignore default libraries*. Add the correct `msvcrtxx.lib` to the list of libraries.

1. Embedding Python in Another Application

The previous chapters discussed how to extend Python, that is, how to extend the functionality of Python by attaching a library of C functions to it. It is also possible to do it the other way around: enrich your C/C++ application by embedding Python in it. Embedding provides your application with the ability to implement some of the functionality of your application in Python rather than C or C++. This can be used for many purposes; one example would be to allow users to tailor the application to their needs by writing some scripts in Python. You can also use it yourself if some of the functionality can be written in Python more easily.

Embedding Python is similar to extending it, but not quite. The difference is that when you extend Python, the main program of the application is still the Python interpreter, while if you embed Python, the main program may have nothing to do with Python — instead, some parts of the application occasionally call the Python interpreter to run some Python code.

So if you are embedding Python, you are providing your own main program. One of the things this main program has to do is initialize the Python interpreter. At the very least, you have to call the function `Py_Initialize()`. There are optional calls to pass command line arguments to Python. Then later you can call the interpreter from any part of the application.

There are several different ways to call the interpreter: you can pass a string containing Python statements to

`PyRun_SimpleString()`, or you can pass a stdio file pointer and a file name (for identification in error messages only) to `PyRun_SimpleFile()`. You can also call the lower-level operations described in the previous chapters to construct and use Python objects.

See also

Python/C API Reference Manual
The details of Python's C interface are given in this manual. A great deal of necessary information can be found here.

1.1. Very High Level Embedding

The simplest form of embedding Python is the use of the very high level interface. This interface is intended to execute a Python script without needing to interact with the application directly. This can for example be used to perform some operation on a file.

```
#define PY_SSIZE_T_CLEAN
#include <Python.h>

int
main(int argc, char *argv[])
{
    PyStatus status;
    PyConfig config;
    PyConfig_InitPythonConfig(&config);

    /* optional but recommended */
    status = PyConfig_SetBytesString(&config,
&config.program_name, argv[0]);
    if (PyStatus_Exception(status)) {
        goto exception;
    }
    status = Py_InitializeFromConfig(&config);
    if (PyStatus_Exception(status)) {
        goto exception;
    }
    PyConfig_Clear(&config);

    PyRun_SimpleString("from time import time,ctime\n"
                       "print('Today is', ctime(time()))\n");
    if (Py_FinalizeEx() < 0) {
        exit(120);
    }
    return 0;

  exception:
     PyConfig_Clear(&config);
     Py_ExitStatusException(status);
}
```

Note

`#define PY_SSIZE_T_CLEAN` was used to indicate that `Py_ssize_t` should be used in some APIs instead of `int`. It is not necessary since Python 3.13, but we keep it here for backward compatibility. See Strings and buffers for a description of this macro.

Setting `PyConfig.program_name` should be called before `Py_InitializeFromConfig()` to inform the interpreter about paths to Python run-time libraries. Next, the Python interpreter is initialized with `Py_Initialize()`, followed by the execution of a hard-coded Python script that prints the date and time. Afterwards, the `Py_FinalizeEx()` call shuts the interpreter down, followed by the end of the program. In a real program, you may want to get the Python script from another source, perhaps a text-editor routine, a file, or a database. Getting the Python code from a file can better be done by using the `PyRun_SimpleFile()` function, which saves you the trouble of allocating memory space and loading the file contents.

1.2. Beyond Very High Level Embedding: An overview

The high level interface gives you the ability to execute arbitrary pieces of Python code from your application, but exchanging data values is quite cumbersome to say the least. If you want that, you should use lower level calls. At the cost of having to write more C code, you can achieve almost anything.

It should be noted that extending Python and embedding Python is quite the same activity, despite the different intent. Most topics discussed in the previous chapters are still valid. To show this, consider what the extension code from Python to C really does:

1. Convert data values from Python to C,
2. Perform a function call to a C routine using the converted values, and
3. Convert the data values from the call from C to Python.

When embedding Python, the interface code does:

1. Convert data values from C to Python,
2. Perform a function call to a Python interface routine using the converted values, and
3. Convert the data values from the call from Python to C.

As you can see, the data conversion steps are simply swapped to accommodate the different direction of the cross-language transfer. The only difference is the routine that you call between both data conversions. When extending, you call a C routine, when embedding, you call a Python routine.

This chapter will not discuss how to convert data from Python to C and vice versa. Also, proper use of references and dealing with errors is assumed to be understood. Since these aspects do not differ from extending the interpreter, you can refer to earlier chapters for the required information.

1.3. Pure Embedding

The first program aims to execute a function in a Python script. Like in the section about the very high level interface, the Python interpreter does not directly interact with the application (but that will change in the next section).

The code to run a function defined in a Python script is:

```
#define PY_SSIZE_T_CLEAN
#include <Python.h>

int
main(int argc, char *argv[])
{
    PyObject *pName, *pModule, *pFunc;
    PyObject *pArgs, *pValue;
    int i;

    if (argc < 3) {
        fprintf(stderr,"Usage: call pythonfile funcname
[args]\n");
        return 1;
    }

    Py_Initialize();
    pName = PyUnicode_DecodeFSDefault(argv[1]);
    /* Error checking of pName left out */
    pModule = PyImport_Import(pName);
    Py_DECREF(pName);

    if (pModule != NULL) {
        pFunc = PyObject_GetAttrString(pModule, argv[2]);
        /* pFunc is a new reference */

        if (pFunc && PyCallable_Check(pFunc)) {
            pArgs = PyTuple_New(argc - 3);
            for (i = 0; i < argc - 3; ++i) {
                pValue = PyLong_FromLong(atoi(argv[i + 3]));
                if (!pValue) {
                    Py_DECREF(pArgs);
                    Py_DECREF(pModule);
                    fprintf(stderr, "Cannot convert
argument\n");
                    return 1;
                }
                /* pValue reference stolen here: */
                PyTuple_SetItem(pArgs, i, pValue);
            }
            pValue = PyObject_CallObject(pFunc, pArgs);
            Py_DECREF(pArgs);
            if (pValue != NULL) {
                printf("Result of call: %ld\n",
PyLong_AsLong(pValue));
                Py_DECREF(pValue);
            }
            else {
                Py_DECREF(pFunc);
                Py_DECREF(pModule);
                PyErr_Print();
                fprintf(stderr,"Call failed\n");
                return 1;
            }
        }
        else {
            if (PyErr_Occurred())
                PyErr_Print();
            fprintf(stderr, "Cannot find function \"%s\"\n",
argv[2]);
        }
        Py_XDECREF(pFunc);
        Py_DECREF(pModule);
    }
    else {
        PyErr_Print();
        fprintf(stderr, "Failed to load \"%s\"\n", argv[1]);
        return 1;
    }
    if (Py_FinalizeEx() < 0) {
        return 120;
    }
    return 0;
}
```

This code loads a Python script using `argv[1]`, and calls the function named in `argv[2]`. Its integer arguments are the other values of the `argv` array. If you compile and link this program (let’s call the finished executable **call**), and use it to execute a Python script, such as:

```
def multiply(a,b):
    print("Will compute", a, "times", b)
    c = 0
    for i in range(0, a):
        c = c + b
    return c
```

then the result should be:

```
$ call multiply multiply 3 2
Will compute 3 times 2
Result of call: 6
```

Although the program is quite large for its functionality, most of the code is for data conversion between Python and C, and for error reporting. The interesting part with respect to embedding Python starts with

```
Py_Initialize();
pName = PyUnicode_DecodeFSDefault(argv[1]);
/* Error checking of pName left out */
pModule = PyImport_Import(pName);
```

After initializing the interpreter, the script is loaded using `PyImport_Import()`. This routine needs a Python string as its argument, which is constructed using the `PyUnicode_DecodeFSDefault()` data conversion routine.

```
pFunc = PyObject_GetAttrString(pModule, argv[2]);
/* pFunc is a new reference */

if (pFunc && PyCallable_Check(pFunc)) {
    ...
}
Py_XDECREF(pFunc);
```

Once the script is loaded, the name we’re looking for is retrieved using `PyObject_GetAttrString()`. If the name exists, and the object returned is callable, you can safely assume that it is a function. The program then proceeds by constructing a tuple of arguments as normal. The call to the Python function is then made with:

```
pValue = PyObject_CallObject(pFunc, pArgs);
```

Upon return of the function, `pValue` is either `NULL` or it contains a reference to the return value of the function. Be sure to release the reference after examining the value.

1.4. Extending Embedded Python

Until now, the embedded Python interpreter had no access to functionality from the application itself. The Python API allows this by extending the embedded interpreter. That is, the embedded interpreter gets extended with routines provided by the application. While it sounds complex, it is not so bad. Simply forget for a while that the application starts the Python interpreter. Instead, consider the application to be a set of subroutines, and write some glue code that gives Python access to those routines, just like you would write a normal Python extension. For example:

```
static int numargs=0;

/* Return the number of arguments of the application command
line */
static PyObject*
emb_numargs(PyObject *self, PyObject *args)
{
    if(!PyArg_ParseTuple(args, ":numargs"))
        return NULL;
    return PyLong_FromLong(numargs);
}

static PyMethodDef emb_module_methods[] = {
    {"numargs", emb_numargs, METH_VARARGS,
     "Return the number of arguments received by the
process."},
    {NULL, NULL, 0, NULL}
};

static struct PyModuleDef emb_module = {
    .m_base = PyModuleDef_HEAD_INIT,
    .m_name = "emb",
    .m_size = 0,
    .m_methods = emb_module_methods,
};

static PyObject*
PyInit_emb(void)
{
    return PyModuleDef_Init(&emb_module);
}
```

Insert the above code just above the **`main()`** function. Also, insert the following two statements before the call to **`Py_Initialize()`**:

```
numargs = argc;
PyImport_AppendInittab("emb", &PyInit_emb);
```

These two lines initialize the `numargs` variable, and make the **`emb.numargs()`** function accessible to the embedded Python interpreter. With these extensions, the Python script can do things like

```
import emb
print("Number of arguments", emb.numargs())
```

In a real application, the methods will expose an API of the application to Python.

1.5. Embedding Python in C++

It is also possible to embed Python in a C++ program; precisely how this is done will depend on the details of the C++ system used; in general you will need to write the main program in C++, and use the C++ compiler to compile and link your program. There is no need to recompile Python itself using C++.

1.6. Compiling and Linking under Unix-like systems

It is not necessarily trivial to find the right flags to pass to your compiler (and linker) in order to embed the Python interpreter into your application, particularly because Python needs to load library modules implemented as C dynamic extensions (`.so` files) linked against it.

To find out the required compiler and linker flags, you can execute the `python`*`X.Y`*`-config` script which is generated as part of the installation process (a `python3-config` script may also be available). This script has several options, of which the following will be directly useful to you:

- `pythonX.Y-config --cflags` will give you the recommended flags when compiling:

  ```
  $ /opt/bin/python3.11-config --cflags
  -I/opt/include/python3.11 -I/opt/include/python3.11 -Wsign-compare  -DNDEBUG -g -fwrapv -O3 -Wall
  ```

- `pythonX.Y-config --ldflags --embed` will give you the recommended flags when linking:

  ```
  $ /opt/bin/python3.11-config --ldflags --embed
  -L/opt/lib/python3.11/config-3.11-x86_64-linux-gnu -L/opt/lib -lpython3.11 -lpthread -ldl  -lutil -lm
  ```

Note

To avoid confusion between several Python installations (and especially between the system Python and your own compiled Python), it is recommended that you use the absolute path to `python`*`X.Y`*`-config`, as in the above example.

If this procedure doesn't work for you (it is not guaranteed to work for all Unix-like platforms; however, we welcome bug reports) you will have to read your system's documentation about dynamic linking and/or examine Python's `Makefile` (use **`sysconfig.get_makefile_filename()`** to find its location) and compilation options. In this case, the **`sysconfig`** module is a useful tool to programmatically extract the configuration values that you will want to combine together. For example:

```
>>> import sysconfig
>>> sysconfig.get_config_var('LIBS')
'-lpthread -ldl  -lutil'
>>> sysconfig.get_config_var('LINKFORSHARED')
'-Xlinker -export-dynamic'
```

Python/C API Reference Manual

This manual documents the API used by C and C++ programmers who want to write extension modules or embed Python. It is a companion to Extending and Embedding the Python Interpreter, which describes the general principles of extension writing but does not document the API functions in detail.

- Introduction

Introduction

The Application Programmer's Interface to Python gives C and C++ programmers access to the Python interpreter at a variety of levels. The API is equally usable from C++, but for brevity it is generally referred to as the Python/C API. There are two fundamentally different reasons for using the Python/C API. The first reason is to write *extension modules* for specific purposes; these are C modules that extend the Python interpreter. This is probably the most common use. The second reason is to use Python as a component in a larger application; this technique is generally referred to as *embedding* Python in an application.

Writing an extension module is a relatively well-understood process, where a "cookbook" approach works well. There are several tools that automate the process to some extent. While people have embedded Python in other applications since its early existence, the process of embedding Python is less straightforward than writing an extension.

Many API functions are useful independent of whether you're embedding or extending Python; moreover, most applications that embed Python will need to provide a custom extension as well, so it's probably a good idea to become familiar with writing an extension before attempting to embed Python in a real application.

Language version compatibility

Python's C API is compatible with C11 and C++11 versions of C and C++.

This is a lower limit: the C API does not require features from later C/C++ versions. You do *not* need to enable your compiler's "c11 mode".

Coding standards

If you're writing C code for inclusion in CPython, you **must** follow the guidelines and standards defined in **PEP 7** [https://peps.python.org/pep-0007/]. These guidelines apply regardless of the version of Python you are contributing to. Following these conventions is not necessary for your own third party extension modules, unless you eventually expect to contribute them to Python.

Include Files

All function, type and macro definitions needed to use the Python/C API are included in your code by the following line:

```
#define PY_SSIZE_T_CLEAN
#include <Python.h>
```

This implies inclusion of the following standard headers: `<stdio.h>`, `<string.h>`, `<errno.h>`, `<limits.h>`, `<assert.h>` and `<stdlib.h>` (if available).

Note

Since Python may define some pre-processor definitions which affect the standard headers on some systems, you *must* include `Python.h` before any standard headers are included.

It is recommended to always define `PY_SSIZE_T_CLEAN` before including `Python.h`. See Parsing arguments and building values for a description of this macro.

All user visible names defined by Python.h (except those defined by the included standard headers) have one of the prefixes `Py` or `_Py`. Names beginning with `_Py` are for internal use by the Python implementation and should not be used by extension writers. Structure member names do not have a reserved prefix.

Note

User code should never define names that begin with `Py` or `_Py`. This confuses the reader, and jeopardizes the portability of the user code to future Python versions, which may define additional names beginning with one of these prefixes.

The header files are typically installed with Python. On Unix, these are located in the directories `prefix/include/pythonversion/` and `exec_prefix/include/pythonversion/`, where **`prefix`** and **`exec_prefix`** are defined by the corresponding parameters to Python's **configure** script and *version* is `'%d.%d' % sys.version_info[:2]`. On Windows, the headers are installed in `prefix/include`, where `prefix` is the installation directory specified to the installer.

To include the headers, place both directories (if different) on your compiler's search path for includes. Do *not* place the parent directories on the search path and then use `#include <pythonX.Y/Python.h>`; this will break on multi-platform builds since the platform independent headers under `prefix` include the platform specific headers from `exec_prefix`.

C++ users should note that although the API is defined entirely using C, the header files properly declare the entry points to be `extern "C"`. As a result, there is no need to do anything special to use the API from C++.

Useful macros

Several useful macros are defined in the Python header files. Many are defined closer to where they are useful (for example, `Py_RETURN_NONE`, `PyMODINIT_FUNC`). Others of a more general utility are defined here. This is not necessarily a complete listing.

Py_ABS(x)

Return the absolute value of `x`.

If the result cannot be represented (for example, if `x` has **`INT_MIN`** value for int type), the behavior is undefined.

Added in version 3.3.

Py_ALWAYS_INLINE

Ask the compiler to always inline a static inline function. The compiler can ignore it and decide to not inline the function.

It can be used to inline performance critical static inline functions when building Python in debug mode with function inlining disabled. For example, MSC disables function inlining when building in debug mode.

Marking blindly a static inline function with Py_ALWAYS_INLINE can result in worse performances (due to increased code size for example). The compiler is usually smarter than the developer for the cost/benefit analysis.

If Python is built in debug mode (if the **`Py_DEBUG`** macro is defined), the **`Py_ALWAYS_INLINE`** macro does nothing.

It must be specified before the function return type. Usage:

```
static inline Py_ALWAYS_INLINE int random(void) { return 4;
}
```

Added in version 3.11.

Py_CHARMASK(c)

Argument must be a character or an integer in the range [-128, 127] or [0, 255]. This macro returns `c` cast to an `unsigned char`.

Py_DEPRECATED(version)

Use this for deprecated declarations. The macro must be placed before the symbol name.

Example:

```
Py_DEPRECATED(3.8) PyAPI_FUNC(int) Py_OldFunction(void);
```

Changed in version 3.8: MSVC support was added.

Py_GETENV(s)

Like `getenv(s)`, but returns `NULL` if **`-E`** was passed on the command line (see **`PyConfig.use_environment`**).

Py_LOCAL(type)

Declare a function returning the specified *type* using a fast-calling qualifier for functions that are local to the current file. Semantically, this is equivalent to `static type`.

Py_LOCAL_INLINE(type)

Equivalent to **`Py_LOCAL`** but additionally requests the function be inlined.

Py_LOCAL_SYMBOL

Macro used to declare a symbol as local to the shared library (hidden). On supported platforms, it ensures the symbol is not exported.

On compatible versions of GCC/Clang, it expands to `__attribute__((visibility("hidden")))`.

Py_MAX(x, y)

Return the maximum value between `x` and `y`.

Added in version 3.3.

Py_MEMBER_SIZE(type, member)

Return the size of a structure (`type`) `member` in bytes.

Added in version 3.6.

Py_MEMCPY(dest, src, n)

This is a soft deprecated alias to **`memcpy()`**. Use **`memcpy()`** directly instead.

Deprecated since version 3.14: The macro is soft deprecated.

Py_MIN(x, y)

Return the minimum value between `x` and `y`.

Added in version 3.3.

Py_NO_INLINE

Disable inlining on a function. For example, it reduces the C stack consumption: useful on LTO+PGO builds which heavily inline code (see bpo-33720 [https://bugs.python.org/issue?@action=redirect&bpo=33720]).

Usage:

```
Py_NO_INLINE static int random(void) { return 4; }
```

Added in version 3.11.

Py_STRINGIFY(x)

Convert `x` to a C string. E.g. `Py_STRINGIFY(123)` returns `"123"`.

Added in version 3.4.

Py_UNREACHABLE()

Use this when you have a code path that cannot be reached by design. For example, in the `default:` clause in a `switch` statement for which all possible values are covered in `case` statements. Use this in places where you might be tempted to put an `assert(0)` or `abort()` call.

In release mode, the macro helps the compiler to optimize the code, and avoids a warning about unreachable code. For example, the macro is implemented with `__builtin_unreachable()` on GCC in release mode.

A use for `Py_UNREACHABLE()` is following a call a function that never returns but that is not declared **`_Py_NO_RETURN`**.

If a code path is very unlikely code but can be reached under exceptional case, this macro must not be used. For example, under low memory condition or if a system call returns a value out of the expected range. In this case, it's better to report the error to the caller. If the error cannot be reported to caller, `Py_FatalError()` can be used.

Added in version 3.7.

Py_UNUSED(arg)

Use this for unused arguments in a function definition to silence compiler warnings. Example: `int func(int a, int Py_UNUSED(b)) { return a; }`.

Added in version 3.4.

Py_BUILD_ASSERT(cond)

Asserts a compile-time condition *cond*, as a statement. The build will fail if the condition is false or cannot be evaluated at compile time.

For example:

```
Py_BUILD_ASSERT(sizeof(PyTime_t) == sizeof(int64_t));
```

Added in version 3.3.

Py_BUILD_ASSERT_EXPR(cond)

Asserts a compile-time condition *cond*, as an expression that evaluates to `0`. The build will fail if the condition is false or cannot be evaluated at compile time.

For example:

```
#define foo_to_char(foo) \
    ((char *)(foo) + Py_BUILD_ASSERT_EXPR(offsetof(struct
foo, string) == 0))
```

Added in version 3.3.

PyDoc_STRVAR(name, str)

Creates a variable with name *name* that can be used in docstrings. If Python is built without docstrings, the value will be empty.

Use **`PyDoc_STRVAR`** for docstrings to support building Python without docstrings, as specified in **PEP 7** [https://peps.python.org/pep-0007/].

Example:

```
PyDoc_STRVAR(pop_doc, "Remove and return the rightmost
element.");

static PyMethodDef deque_methods[] = {
    // ...
    {"pop", (PyCFunction)deque_pop, METH_NOARGS, pop_doc},
    // ...
}
```

PyDoc_STR(str)

Creates a docstring for the given input string or an empty string if docstrings are disabled.

Use **`PyDoc_STR`** in specifying docstrings to support building Python without docstrings, as specified in **PEP 7** [https://peps.python.org/pep-0007/].

Example:

```
static PyMethodDef pysqlite_row_methods[] = {
    {"keys", (PyCFunction)pysqlite_row_keys, METH_NOARGS,
        PyDoc_STR("Returns the keys of the row.")},
    {NULL, NULL}
};
```

PyDoc_VAR(name)

Declares a static character array variable with the given name *name*.

For example:

```
PyDoc_VAR(python_doc) = PyDoc_STR("A genus of constricting
snakes in the Pythonidae family native "
                                  "to the tropics and
subtropics of the Eastern Hemisphere.");
```

Py_ARRAY_LENGTH(array)

Compute the length of a statically allocated C array at compile time.

The *array* argument must be a C array with a size known at compile time. Passing an array with an unknown size, such as a heap-allocated array, will result in a compilation error on some compilers, or otherwise produce incorrect results.

This is roughly equivalent to:

```
sizeof(array) / sizeof((array)[0])
```

Py_EXPORTED_SYMBOL

Macro used to declare a symbol (function or data) as exported. On Windows, this expands to `__declspec(dllexport)`. On compatible versions of GCC/Clang, it expands to `__attribute__((visibility("default")))`. This macro is for defining the C API itself; extension modules should not use it.

Py_IMPORTED_SYMBOL

Macro used to declare a symbol as imported. On Windows, this expands to `__declspec(dllimport)`. This macro is for defining the C API itself; extension modules should not use it.

PyAPI_FUNC(type)

Macro used by CPython to declare a function as part of the C API. Its expansion depends on the platform and build configuration. This macro is intended for defining CPython's C API itself; extension modules should not use it for their own symbols.

PyAPI_DATA(type)

Macro used by CPython to declare a public global variable as part of the C API. Its expansion depends on the platform and build configuration. This macro is intended for defining CPython's C API itself; extension modules should not use it for their own symbols.

Objects, Types and Reference Counts

Most Python/C API functions have one or more arguments as well as a return value of type PyObject*. This type is a pointer to an opaque data type representing an arbitrary Python object. Since all Python object types are treated the same way by the Python language in most situations (e.g., assignments, scope rules, and argument passing), it is only fitting that they should be represented by a single C type. Almost all Python objects live on the heap: you never declare an automatic or static variable of type **`PyObject`**, only pointer variables of type PyObject* can be declared. The sole exception are the type objects; since these must never be deallocated, they are typically static **`PyTypeObject`** objects.

All Python objects (even Python integers) have a *type* and a *reference count*. An object's type determines what kind of object it is (e.g., an integer, a list, or a user-defined function; there are many more as explained in The standard type hierarchy). For each of the well-known types there is a macro to check whether an object is of that type; for instance, `PyList_Check(a)` is true if (and only if) the object pointed to by *a* is a Python list.

Reference Counts

The reference count is important because today's computers have a finite (and often severely limited) memory size; it counts how many different places there are that have a strong reference to an object. Such a place could be another object, or a global (or static) C variable, or a local variable in some C function. When the last strong reference to an object is released (i.e. its reference count becomes zero), the object is deallocated. If it contains references to other objects, those references are released. Those other objects may be deallocated in turn, if there are no more references to them, and so on. (There's an obvious problem with objects that reference each other here; for now, the solution is "don't do that.")

Reference counts are always manipulated explicitly. The normal way is to use the macro **`Py_INCREF()`** to take a new reference to an object (i.e. increment its reference count by one), and **`Py_DECREF()`** to release that reference (i.e. decrement the reference count by one). The **`Py_DECREF()`** macro is considerably more complex than the incref one, since it must check whether the reference count becomes zero and then cause the object's deallocator to be called. The deallocator is a function pointer contained in the object's type structure. The type-specific deallocator takes care of releasing references for other objects contained in the object if this is a compound object type, such as a list, as well as performing any additional finalization that's needed. There's no chance that the reference count can overflow; at least as many bits are used to hold the reference count as there are distinct memory locations in virtual memory (assuming `sizeof(Py_ssize_t) >=`

`sizeof(void*)`). Thus, the reference count increment is a simple operation.

It is not necessary to hold a strong reference (i.e. increment the reference count) for every local variable that contains a pointer to an object. In theory, the object’s reference count goes up by one when the variable is made to point to it and it goes down by one when the variable goes out of scope. However, these two cancel each other out, so at the end the reference count hasn’t changed. The only real reason to use the reference count is to prevent the object from being deallocated as long as our variable is pointing to it. If we know that there is at least one other reference to the object that lives at least as long as our variable, there is no need to take a new strong reference (i.e. increment the reference count) temporarily. An important situation where this arises is in objects that are passed as arguments to C functions in an extension module that are called from Python; the call mechanism guarantees to hold a reference to every argument for the duration of the call.

However, a common pitfall is to extract an object from a list and hold on to it for a while without taking a new reference. Some other operation might conceivably remove the object from the list, releasing that reference, and possibly deallocating it. The real danger is that innocent-looking operations may invoke arbitrary Python code which could do this; there is a code path which allows control to flow back to the user from a **`Py_DECREF()`**, so almost any operation is potentially dangerous.

A safe approach is to always use the generic operations (functions whose name begins with `PyObject_`, `PyNumber_`, `PySequence_` or `PyMapping_`). These operations always create a new strong reference (i.e. increment the reference count) of the object they return. This leaves the caller with the responsibility to call `Py_DECREF()` when they are done with the result; this soon becomes second nature.

Reference Count Details

The reference count behavior of functions in the Python/C API is best explained in terms of *ownership of references*. Ownership pertains to references, never to objects (objects are not owned: they are always shared). “Owning a reference” means being responsible for calling Py_DECREF on it when the reference is no longer needed. Ownership can also be transferred, meaning that the code that receives ownership of the reference then becomes responsible for eventually releasing it by calling `Py_DECREF()` or `Py_XDECREF()` when it’s no longer needed—or passing on this responsibility (usually to its caller). When a function passes ownership of a reference on to its caller, the caller is said to receive a *new* reference. When no ownership is transferred, the caller is said to *borrow* the reference. Nothing needs to be done for a borrowed reference.

Conversely, when a calling function passes in a reference to an object, there are two possibilities: the function *steals* a reference to the object, or it does not. *Stealing a reference* means that when you pass a reference to a function, that function assumes that it now owns that reference, and you are not responsible for it any longer.

Few functions steal references; the two notable exceptions are `PyList_SetItem()` and `PyTuple_SetItem()`, which steal a reference to the item (but not to the tuple or list into which the item is put!). These functions were designed to steal a reference because of a common idiom for populating a tuple or list with newly created objects; for example, the code to create the tuple `(1, 2, "three")` could look like this (forgetting about error handling for the moment; a better way to code this is shown below):

```
PyObject *t;

t = PyTuple_New(3);
PyTuple_SetItem(t, 0, PyLong_FromLong(1L));
PyTuple_SetItem(t, 1, PyLong_FromLong(2L));
PyTuple_SetItem(t, 2, PyUnicode_FromString("three"));
```

Here, `PyLong_FromLong()` returns a new reference which is immediately stolen by `PyTuple_SetItem()`. When you want to keep using an object although the reference to it will be stolen, use `Py_INCREF()` to grab another reference before calling the reference-stealing function.

Incidentally, `PyTuple_SetItem()` is the *only* way to set tuple items; `PySequence_SetItem()` and `PyObject_SetItem()` refuse to do this since tuples are an immutable data type. You should only use `PyTuple_SetItem()` for tuples that you are creating yourself.

Equivalent code for populating a list can be written using `PyList_New()` and `PyList_SetItem()`.

However, in practice, you will rarely use these ways of creating and populating a tuple or list. There’s a generic function, `Py_BuildValue()`, that can create most common objects from C values, directed by a *format string*. For example, the above two blocks of code could be replaced by the following (which also takes care of the error checking):

```
PyObject *tuple, *list;

tuple = Py_BuildValue("(iis)", 1, 2, "three");
list = Py_BuildValue("[iis]", 1, 2, "three");
```

It is much more common to use **`PyObject_SetItem()`** and friends with items whose references you are only borrowing, like arguments that were passed in to the function you are writing. In that case, their behaviour regarding references is much saner, since you don't have to take a new reference just so you can give that reference away ("have it be stolen"). For example, this function sets all items of a list (actually, any mutable sequence) to a given item:

```
int
set_all(PyObject *target, PyObject *item)
{
    Py_ssize_t i, n;

    n = PyObject_Length(target);
    if (n < 0)
        return -1;
    for (i = 0; i < n; i++) {
        PyObject *index = PyLong_FromSsize_t(i);
        if (!index)
            return -1;
        if (PyObject_SetItem(target, index, item) < 0) {
            Py_DECREF(index);
            return -1;
        }
        Py_DECREF(index);
    }
    return 0;
}
```

The situation is slightly different for function return values. While passing a reference to most functions does not change your ownership responsibilities for that reference, many functions that return a reference to an object give you ownership of the reference. The reason is simple: in many cases, the returned object is created on the fly, and the reference you get is the only reference to the object. Therefore, the generic functions that return object references, like **`PyObject_GetItem()`** and **`PySequence_GetItem()`**, always return a new reference (the caller becomes the owner of the reference).

It is important to realize that whether you own a reference returned by a function depends on which function you call only — *the plumage* (the type of the object passed as an argument to the function) *doesn’t enter into it!* Thus, if you extract an item from a list using `PyList_GetItem()`, you don’t own the reference — but if you obtain the same item from the same list using `PySequence_GetItem()` (which happens to take exactly the same arguments), you do own a reference to the returned object.

Here is an example of how you could write a function that computes the sum of the items in a list of integers; once using `PyList_GetItem()`, and once using `PySequence_GetItem()`.

```
long
sum_list(PyObject *list)
{
    Py_ssize_t i, n;
    long total = 0, value;
    PyObject *item;

    n = PyList_Size(list);
    if (n < 0)
        return -1; /* Not a list */
    for (i = 0; i < n; i++) {
        item = PyList_GetItem(list, i); /* Can't fail */
        if (!PyLong_Check(item)) continue; /* Skip non-integers
*/
        value = PyLong_AsLong(item);
        if (value == -1 && PyErr_Occurred())
            /* Integer too big to fit in a C long, bail out */
            return -1;
        total += value;
    }
    return total;
}
```

```
long
sum_sequence(PyObject *sequence)
{
    Py_ssize_t i, n;
    long total = 0, value;
    PyObject *item;
    n = PySequence_Length(sequence);
    if (n < 0)
        return -1; /* Has no length */
    for (i = 0; i < n; i++) {
        item = PySequence_GetItem(sequence, i);
        if (item == NULL)
            return -1; /* Not a sequence, or other failure */
        if (PyLong_Check(item)) {
            value = PyLong_AsLong(item);
            Py_DECREF(item);
            if (value == -1 && PyErr_Occurred())
                /* Integer too big to fit in a C long, bail out
*/
                return -1;
            total += value;
        }
        else {
            Py_DECREF(item); /* Discard reference ownership */
        }
    }
    return total;
}
```

Types

There are few other data types that play a significant role in the Python/C API; most are simple C types such as int, long, double and char*. A few structure types are used to describe static tables used to list the functions exported by a module or the data attributes of a new object type, and another is used to describe the value of a complex number. These will be discussed together with the functions that use them.

type Py_ssize_t

Part of the Stable ABI.

A signed integral type such that `sizeof(Py_ssize_t) == sizeof(size_t)`. C99 doesn't define such a thing directly (size_t is an unsigned integral type). See **PEP 353** [https://peps.python.org/pep-0353/] for details. `PY_SSIZE_T_MAX` is the largest positive value of type `Py_ssize_t`.

Exceptions

The Python programmer only needs to deal with exceptions if specific error handling is required; unhandled exceptions are automatically propagated to the caller, then to the caller's caller, and so on, until they reach the top-level interpreter, where they are reported to the user accompanied by a stack traceback.

For C programmers, however, error checking always has to be explicit. All functions in the Python/C API can raise exceptions, unless an explicit claim is made otherwise in a function's documentation. In general, when a function encounters an error, it sets an exception, discards any object references that it owns, and returns an error indicator. If not documented otherwise, this indicator is either `NULL` or `-1`, depending on the function's return type. A few functions return a Boolean true/false result, with false indicating an error. Very few functions return no explicit error indicator or have an ambiguous return value, and require explicit testing for errors with `PyErr_Occurred()`. These exceptions are always explicitly documented.

Exception state is maintained in per-thread storage (this is equivalent to using global storage in an unthreaded application). A thread can be in one of two states: an exception has occurred, or not. The function `PyErr_Occurred()`

can be used to check for this: it returns a borrowed reference to the exception type object when an exception has occurred, and `NULL` otherwise. There are a number of functions to set the exception state: **`PyErr_SetString()`** is the most common (though not the most general) function to set the exception state, and **`PyErr_Clear()`** clears the exception state.

The full exception state consists of three objects (all of which can be `NULL`): the exception type, the corresponding exception value, and the traceback. These have the same meanings as the Python result of `sys.exc_info()`; however, they are not the same: the Python objects represent the last exception being handled by a Python **`try`** … **`except`** statement, while the C level exception state only exists while an exception is being passed on between C functions until it reaches the Python bytecode interpreter's main loop, which takes care of transferring it to `sys.exc_info()` and friends.

Note that starting with Python 1.5, the preferred, thread-safe way to access the exception state from Python code is to call the function **`sys.exc_info()`**, which returns the per-thread exception state for Python code. Also, the semantics of both ways to access the exception state have changed so that a function which catches an exception will save and restore its thread's exception state so as to preserve the exception state of its caller. This prevents common bugs in exception handling code caused by an innocent-looking function overwriting the exception being handled; it also reduces the often unwanted lifetime extension for objects that are referenced by the stack frames in the traceback.

As a general principle, a function that calls another function to perform some task should check whether the called function raised an exception, and if so, pass the exception state on to its caller. It should discard any object references that it owns, and return an error indicator, but it should *not* set another exception — that would overwrite the exception that was just raised, and lose important information about the exact cause of the error.

A simple example of detecting exceptions and passing them on is shown in the **`sum_sequence()`** example above. It so happens that this example doesn't need to clean up any owned references when it detects an error. The following example function shows some error cleanup. First, to remind you why you like Python, we show the equivalent Python code:

```
def incr_item(dict, key):
    try:
        item = dict[key]
    except KeyError:
        item = 0
    dict[key] = item + 1
```

Here is the corresponding C code, in all its glory:

```
int
incr_item(PyObject *dict, PyObject *key)
{
    /* Objects all initialized to NULL for Py_XDECREF */
    PyObject *item = NULL, *const_one = NULL, *incremented_item
= NULL;
    int rv = -1; /* Return value initialized to -1 (failure) */

    item = PyObject_GetItem(dict, key);
    if (item == NULL) {
        /* Handle KeyError only: */
        if (!PyErr_ExceptionMatches(PyExc_KeyError))
            goto error;

        /* Clear the error and use zero: */
        PyErr_Clear();
        item = PyLong_FromLong(0L);
        if (item == NULL)
            goto error;
    }
    const_one = PyLong_FromLong(1L);
    if (const_one == NULL)
        goto error;

    incremented_item = PyNumber_Add(item, const_one);
    if (incremented_item == NULL)
        goto error;

    if (PyObject_SetItem(dict, key, incremented_item) < 0)
        goto error;
    rv = 0; /* Success */
    /* Continue with cleanup code */

 error:
    /* Cleanup code, shared by success and failure path */

    /* Use Py_XDECREF() to ignore NULL references */
    Py_XDECREF(item);
    Py_XDECREF(const_one);
    Py_XDECREF(incremented_item);

    return rv; /* -1 for error, 0 for success */
}
```

This example represents an endorsed use of the `goto` statement in C! It illustrates the use of **`PyErr_ExceptionMatches()`** and **`PyErr_Clear()`** to handle specific exceptions, and the use of **`Py_XDECREF()`** to dispose of owned references that may be `NULL` (note the `'X'` in the name; **`Py_DECREF()`** would crash when confronted with a `NULL` reference). It is important that the variables used to hold owned references are initialized to `NULL` for this to work; likewise, the proposed return value is initialized to `-1` (failure) and only set to success after the final call made is successful.

Embedding Python

The one important task that only embedders (as opposed to extension writers) of the Python interpreter have to worry about is the initialization, and possibly the finalization, of the Python interpreter. Most functionality of the interpreter can only be used after the interpreter has been initialized.

The basic initialization function is **`Py_Initialize()`**. This initializes the table of loaded modules, and creates the fundamental modules **`builtins`**, **`__main__`**, and **`sys`**. It also initializes the module search path (`sys.path`).

`Py_Initialize()` does not set the “script argument list” (`sys.argv`). If this variable is needed by Python code that will be executed later, setting **`PyConfig.argv`** and **`PyConfig.parse_argv`** must be set: see Python Initialization Configuration.

On most systems (in particular, on Unix and Windows, although the details are slightly different), **`Py_Initialize()`** calculates the module search path based upon its best guess for the location of the standard Python interpreter executable, assuming that the Python library is found in a fixed location relative to the Python interpreter executable. In particular, it looks for a directory named `lib/python`*`X.Y`* relative to the parent directory where the executable named `python` is found on the shell command search path (the environment variable **`PATH`**).

For instance, if the Python executable is found in `/usr/local/bin/python`, it will assume that the libraries are in `/usr/local/lib/python`*`X.Y`*. (In fact, this particular path is also the “fallback” location, used when no executable file named `python` is found along **`PATH`**.) The user can override this behavior by setting the environment variable **`PYTHONHOME`**, or insert additional directories in front of the standard path by setting **`PYTHONPATH`**.

The embedding application can steer the search by setting `PyConfig.program_name` *before* calling `Py_InitializeFromConfig()`. Note that `PYTHONHOME` still overrides this and `PYTHONPATH` is still inserted in front of the standard path. An application that requires total control has to provide its own implementation of `Py_GetPath()`, `Py_GetPrefix()`, `Py_GetExecPrefix()`, and `Py_GetProgramFullPath()` (all defined in `Modules/getpath.c`).

Sometimes, it is desirable to “uninitialize” Python. For instance, the application may want to start over (make another call to `Py_Initialize()`) or the application is simply done with its use of Python and wants to free memory allocated by Python. This can be accomplished by calling `Py_FinalizeEx()`. The function `Py_IsInitialized()` returns true if Python is currently in the initialized state. More information about these functions is given in a later chapter. Notice that `Py_FinalizeEx()` does *not* free all memory allocated by the Python interpreter, e.g. memory allocated by extension modules currently cannot be released.

Debugging Builds

Python can be built with several macros to enable extra checks of the interpreter and extension modules. These checks tend to add a large amount of overhead to the runtime so they are not enabled by default.

A full list of the various types of debugging builds is in the file `Misc/SpecialBuilds.txt` in the Python source distribution. Builds are available that support tracing of reference counts, debugging the memory allocator, or low-level profiling of the main interpreter loop. Only the most frequently used builds will be described in the remainder of this section.

Py_DEBUG

Compiling the interpreter with the **`Py_DEBUG`** macro defined produces what is generally meant by a debug build of Python. **`Py_DEBUG`** is enabled in the Unix build by adding **`--with-pydebug`** to the `./configure` command. It is also implied by the presence of the not-Python-specific **`_DEBUG`** macro. When **`Py_DEBUG`** is enabled in the Unix build, compiler optimization is disabled.

In addition to the reference count debugging described below, extra checks are performed, see Python Debug Build.

Defining **`Py_TRACE_REFS`** enables reference tracing (see the **`configure --with-trace-refs option`**). When defined, a circular doubly linked list of active objects is maintained by adding two extra fields to every **`PyObject`**. Total allocations are tracked as well. Upon exit, all existing references are printed. (In interactive mode this happens after every statement run by the interpreter.)

Please refer to `Misc/SpecialBuilds.txt` in the Python source distribution for more detailed information.

Recommended third party tools

The following third party tools offer both simpler and more sophisticated approaches to creating C, C++ and Rust extensions for Python:

- Cython [https://cython.org/]
- cffi [https://cffi.readthedocs.io]
- HPy [https://hpyproject.org/]
- nanobind [https://github.com/wjakob/nanobind] (C++)
- Numba [https://numba.pydata.org/]
- pybind11 [https://pybind11.readthedocs.io/] (C++)
- PyO3 [https://pyo3.rs/] (Rust)
- SWIG [https://www.swig.org]

Using tools such as these can help avoid writing code that is tightly bound to a particular version of CPython, avoid reference counting errors, and focus more on your own code than on using the CPython API. In general, new versions of Python can be supported by updating the tool, and your code will often use newer and more efficient APIs automatically. Some tools also support compiling for other implementations of Python from a single set of sources.

These projects are not supported by the same people who maintain Python, and issues need to be raised with the projects directly. Remember to check that the project is still maintained and supported, as the list above may become outdated.

Python Packaging User Guide: Binary Extensions

[https://packaging.python.org/guides/packaging-binary-extensions/]

The Python Packaging User Guide not only covers several available tools that simplify the creation of binary extensions, but also discusses the various reasons why creating an extension module may be desirable in the first place.

C API Stability

Unless documented otherwise, Python’s C API is covered by the Backwards Compatibility Policy, **PEP 387** [https://peps.python.org/pep-0387/]. Most changes to it are source-compatible (typically by only adding new API). Changing existing API or removing API is only done after a deprecation period or to fix serious issues.

CPython’s Application Binary Interface (ABI) is forward- and backwards-compatible across a minor release (if these are compiled the same way; see Platform Considerations below). So, code compiled for Python 3.10.0 will work on 3.10.8 and vice versa, but will need to be compiled separately for 3.9.x and 3.11.x.

There are two tiers of C API with different stability expectations:

- Unstable API, may change in minor versions without a deprecation period. It is marked by the `PyUnstable` prefix in names.
- Limited API, is compatible across several minor releases. When **`Py_LIMITED_API`** is defined, only this subset is exposed from `Python.h`.

These are discussed in more detail below.

Names prefixed by an underscore, such as `_Py_InternalState`, are private API that can change without notice even in patch releases. If you need to use this API, consider reaching out to CPython developers [https://discuss.python.org/c/core-dev/c-api/30] to discuss adding public API for your use case.

Unstable C API

Any API named with the `PyUnstable` prefix exposes CPython implementation details, and may change in every minor release (e.g. from 3.9 to 3.10) without any deprecation warnings. However, it will not change in a bugfix release (e.g. from 3.10.0 to 3.10.1).

It is generally intended for specialized, low-level tools like debuggers.

Projects that use this API are expected to follow CPython development and spend extra effort adjusting to changes.

Stable Application Binary Interface

For simplicity, this document talks about *extensions*, but the Limited API and Stable ABI work the same way for all uses of the API – for example, embedding Python.

Limited C API

Python 3.2 introduced the *Limited API*, a subset of Python's C API. Extensions that only use the Limited API can be compiled once and be loaded on multiple versions of Python. Contents of the Limited API are listed below.

Py_LIMITED_API

Define this macro before including `Python.h` to opt in to only use the Limited API, and to select the Limited API version.

Define `Py_LIMITED_API` to the value of **`PY_VERSION_HEX`** corresponding to the lowest Python version your extension supports. The extension will be ABI-compatible with all Python 3 releases from the specified one onward, and can use Limited API introduced up to that version.

Rather than using the `PY_VERSION_HEX` macro directly, hardcode a minimum minor version (e.g. `0x030A0000` for Python 3.10) for stability when compiling with future Python versions.

You can also define `Py_LIMITED_API` to `3`. This works the same as `0x03020000` (Python 3.2, the version that introduced Limited API).

Stable ABI

To enable this, Python provides a *Stable ABI*: a set of symbols that will remain ABI-compatible across Python 3.x versions.

Note

The Stable ABI prevents ABI issues, like linker errors due to missing symbols or data corruption due to changes in structure layouts or function signatures. However, other changes in Python can change the *behavior* of extensions. See Python's Backwards Compatibility Policy (**PEP 387** [https://peps.python.org/pep-0387/]) for details.

The Stable ABI contains symbols exposed in the Limited API, but also other ones – for example, functions necessary to support older versions of the Limited API.

On Windows, extensions that use the Stable ABI should be linked against `python3.dll` rather than a version-specific library such as `python39.dll`.

On some platforms, Python will look for and load shared library files named with the `abi3` tag (e.g. `mymodule.abi3.so`). It does not check if such extensions conform to a Stable ABI. The user (or their packaging tools) need to ensure that, for example, extensions built with the 3.10+ Limited API are not installed for lower versions of Python.

All functions in the Stable ABI are present as functions in Python’s shared library, not solely as macros. This makes them usable from languages that don’t use the C preprocessor.

Limited API Scope and Performance

The goal for the Limited API is to allow everything that is possible with the full C API, but possibly with a performance penalty.

For example, while `PyList_GetItem()` is available, its “unsafe” macro variant `PyList_GET_ITEM()` is not. The macro can be faster because it can rely on version-specific implementation details of the list object.

Without `Py_LIMITED_API` defined, some C API functions are inlined or replaced by macros. Defining `Py_LIMITED_API` disables this inlining, allowing stability as Python’s data structures are improved, but possibly reducing performance.

By leaving out the `Py_LIMITED_API` definition, it is possible to compile a Limited API extension with a version-specific ABI. This can improve performance for that Python version, but will limit compatibility. Compiling with `Py_LIMITED_API` will then yield an extension that can be distributed where a version-specific one is not available – for example, for prereleases of an upcoming Python version.

Limited API Caveats

Note that compiling with `Py_LIMITED_API` is *not* a complete guarantee that code conforms to the Limited API or the Stable ABI. `Py_LIMITED_API` only covers definitions, but an API also includes other issues, such as expected semantics.

One issue that `Py_LIMITED_API` does not guard against is calling a function with arguments that are invalid in a lower Python version. For example, consider a function that starts accepting `NULL` for an argument. In Python 3.9, `NULL` now selects a default behavior, but in Python 3.8, the argument will be used directly, causing a `NULL` dereference and crash. A similar argument works for fields of structs.

Another issue is that some struct fields are currently not hidden when `Py_LIMITED_API` is defined, even though they're part of the Limited API.

For these reasons, we recommend testing an extension with *all* minor Python versions it supports, and preferably to build with the *lowest* such version.

We also recommend reviewing documentation of all used API to check if it is explicitly part of the Limited API. Even with `Py_LIMITED_API` defined, a few private declarations are exposed for technical reasons (or even unintentionally, as bugs).

Also note that the Limited API is not necessarily stable: compiling with `Py_LIMITED_API` with Python 3.8 means that the extension will run with Python 3.12, but it will not necessarily *compile* with Python 3.12. In particular, parts of the Limited API may be deprecated and removed, provided that the Stable ABI stays stable.

Platform Considerations

ABI stability depends not only on Python, but also on the compiler used, lower-level libraries and compiler options. For the purposes of the Stable ABI, these details define a “platform”. They usually depend on the OS type and processor architecture

It is the responsibility of each particular distributor of Python to ensure that all Python versions on a particular platform are built in a way that does not break the Stable ABI. This is the case with Windows and macOS releases from `python.org` and many third-party distributors.

Contents of Limited API

Currently, the Limited API includes the following items:

- `METH_CLASS`
- `METH_COEXIST`
- `METH_FASTCALL`
- `METH_METHOD`
- `METH_NOARGS`
- `METH_O`
- `METH_STATIC`
- `METH_VARARGS`
- `PY_VECTORCALL_ARGUMENTS_OFFSET`
- `PyAIter_Check()`
- `PyArg_Parse()`
- `PyArg_ParseTuple()`
- `PyArg_ParseTupleAndKeywords()`
- `PyArg_UnpackTuple()`
- `PyArg_VaParse()`
- `PyArg_VaParseTupleAndKeywords()`
- `PyArg_ValidateKeywordArguments()`

The Very High Level Layer

The functions in this chapter will let you execute Python source code given in a file or a buffer, but they will not let you interact in a more detailed way with the interpreter.

Several of these functions accept a start symbol from the grammar as a parameter. The available start symbols are `Py_eval_input`, `Py_file_input`, `Py_single_input`, and `Py_func_type_input`. These are described following the functions which accept them as parameters.

Note also that several of these functions take FILE* parameters. One particular issue which needs to be handled carefully is that the `FILE` structure for different C libraries can be different and incompatible. Under Windows (at least), it is possible for dynamically linked extensions to actually use different libraries, so care should be taken that FILE* parameters are only passed to these functions if it is certain that they were created by the same library that the Python runtime is using.

int PyRun_AnyFile(FILE *fp, const char *filename)

This is a simplified interface to `PyRun_AnyFileExFlags()` below, leaving *closeit* set to `0` and *flags* set to `NULL`.

int PyRun_AnyFileFlags(FILE *fp, const char *filename, PyCompilerFlags *flags)

This is a simplified interface to `PyRun_AnyFileExFlags()` below, leaving the *closeit* argument set to `0`.

int PyRun_AnyFileEx(FILE *fp, const char *filename, int closeit)

This is a simplified interface to `PyRun_AnyFileExFlags()` below, leaving the *flags* argument set to `NULL`.

int PyRun_AnyFileExFlags(FILE *fp, const char *filename, int closeit, PyCompilerFlags *flags)

If *fp* refers to a file associated with an interactive device (console or terminal input or Unix pseudo-terminal), return the value of `PyRun_InteractiveLoop()`, otherwise return the result of `PyRun_SimpleFile()`. *filename* is decoded from the filesystem encoding (`sys.getfilesystemencoding()`). If *filename* is `NULL`, this function uses `"???"` as the filename. If *closeit* is true, the file is closed before `PyRun_SimpleFileExFlags()` returns.

int PyRun_SimpleString(const char *command)

This is a simplified interface to `PyRun_SimpleStringFlags()` below, leaving the `PyCompilerFlags`* argument set to `NULL`.

int PyRun_SimpleStringFlags(const char *command, PyCompilerFlags *flags)

Executes the Python source code from *command* in the `__main__` module according to the *flags* argument. If `__main__` does not already exist, it is created. Returns `0` on success or `-1` if an exception was raised. If there was an error, there is no way to get the exception information. For the meaning of *flags*, see below.

Note that if an otherwise unhandled `SystemExit` is raised, this function will not return `-1`, but exit the process, as long as `PyConfig.inspect` is zero.

int PyRun_SimpleFile(FILE *fp, const char *filename)

This is a simplified interface to `PyRun_SimpleFileExFlags()` below, leaving *closeit* set to `0` and *flags* set to `NULL`.

int PyRun_SimpleFileEx(FILE *fp, const char *filename, int closeit)

This is a simplified interface to **`PyRun_SimpleFileExFlags()`** below, leaving *flags* set to `NULL`.

int PyRun_SimpleFileExFlags(FILE *fp, const char *filename, int closeit, PyCompilerFlags *flags)

Similar to **`PyRun_SimpleStringFlags()`**, but the Python source code is read from *fp* instead of an in-memory string. *filename* should be the name of the file, it is decoded from filesystem encoding and error handler. If *closeit* is true, the file is closed before `PyRun_SimpleFileExFlags()` returns.

Note

On Windows, *fp* should be opened as binary mode (e.g. `fopen(filename, "rb")`). Otherwise, Python may not handle script file with LF line ending correctly.

int PyRun_InteractiveOneObject(FILE *fp, PyObject *filename, PyCompilerFlags *flags)

Read and execute a single statement from a file associated with an interactive device according to the *flags* argument. The user will be prompted using `sys.ps1` and `sys.ps2`. *filename* must be a Python **`str`** object.

Returns `0` when the input was executed successfully, `-1` if there was an exception, or an error code from the `errcode.h` include file distributed as part of Python if there was a parse error. (Note that `errcode.h` is not included by `Python.h`, so must be included specifically if needed.)

int PyRun_InteractiveOne(FILE *fp, const char *filename)

This is a simplified interface to **`PyRun_InteractiveOneFlags()`** below, leaving *flags* set to `NULL`.

int PyRun_InteractiveOneFlags(FILE *fp, const char *filename, PyCompilerFlags *flags)

Similar to **`PyRun_InteractiveOneObject()`**, but *filename* is a const char*, which is decoded from the filesystem encoding and error handler.

int PyRun_InteractiveLoop(FILE *fp, const char *filename)

This is a simplified interface to **`PyRun_InteractiveLoopFlags()`** below, leaving *flags* set to `NULL`.

int PyRun_InteractiveLoopFlags(FILE *fp, const char *filename, PyCompilerFlags *flags)

Read and execute statements from a file associated with an interactive device until EOF is reached. The user will be prompted using `sys.ps1` and `sys.ps2`. *filename* is decoded from the filesystem encoding and error handler. Returns `0` at EOF or a negative number upon failure.

int (*PyOS_InputHook)(void)

Part of the Stable ABI.

Can be set to point to a function with the prototype `int func(void)`. The function will be called when Python’s interpreter prompt is about to become idle and wait for user input from the terminal. The return value is ignored. Overriding this hook can be used to integrate the interpreter’s prompt with other event loops, as done in `Modules/_tkinter.c` in the Python source code.

Changed in version 3.12: This function is only called from the main interpreter.

char *(*PyOS_ReadlineFunctionPointer)(FILE*, FILE*, const char*)

Can be set to point to a function with the prototype `char *func(FILE *stdin, FILE *stdout, char *prompt)`, overriding the default function used to read a single line of input at the interpreter's prompt. The function is expected to output the string *prompt* if it's not `NULL`, and then read a line of input from the provided standard input file, returning the resulting string. For example, The **`readline`** module sets this hook to provide line-editing and tab-completion features.

The result must be a string allocated by **`PyMem_RawMalloc()`** or **`PyMem_RawRealloc()`**, or `NULL` if an error occurred.

Changed in version 3.4: The result must be allocated by **`PyMem_RawMalloc()`** or **`PyMem_RawRealloc()`**, instead of being allocated by **`PyMem_Malloc()`** or **`PyMem_Realloc()`**.

Changed in version 3.12: This function is only called from the main interpreter.

PyObject *PyRun_String(const char *str, int start, PyObject *globals, PyObject *locals)

Return value: New reference.
This is a simplified interface to **`PyRun_StringFlags()`** below, leaving *flags* set to `NULL`.

PyObject *PyRun_StringFlags(const char *str, int start, PyObject *globals, PyObject *locals, PyCompilerFlags *flags)

Return value: New reference.
Execute Python source code from *str* in the context specified by the objects *globals* and *locals* with the compiler flags specified by *flags*. *globals* must be a dictionary; *locals* can be any object that implements the

mapping protocol. The parameter *start* specifies the start symbol and must one of the available start symbols.

Returns the result of executing the code as a Python object, or `NULL` if an exception was raised.

PyObject *PyRun_File(FILE *fp, const char *filename, int start, PyObject *globals, PyObject *locals)

Return value: New reference.
This is a simplified interface to **`PyRun_FileExFlags()`** below, leaving *closeit* set to `0` and *flags* set to `NULL`.

PyObject *PyRun_FileEx(FILE *fp, const char *filename, int start, PyObject *globals, PyObject *locals, int closeit)

Return value: New reference.
This is a simplified interface to **`PyRun_FileExFlags()`** below, leaving *flags* set to `NULL`.

PyObject *PyRun_FileFlags(FILE *fp, const char *filename, int start, PyObject *globals, PyObject *locals, PyCompilerFlags *flags)

Return value: New reference.
This is a simplified interface to **`PyRun_FileExFlags()`** below, leaving *closeit* set to `0`.

PyObject *PyRun_FileExFlags(FILE *fp, const char *filename, int start, PyObject *globals, PyObject *locals, int closeit, PyCompilerFlags *flags)

Return value: New reference.
Similar to **`PyRun_StringFlags()`**, but the Python source code is read from *fp* instead of an in-memory string. *filename* should be the name of the file, it is decoded from the filesystem encoding and error handler. If *closeit* is true, the file is closed before **`PyRun_FileExFlags()`** returns.

PyObject *Py_CompileString(const char *str, const char *filename, int start)

Return value: New reference. Part of the Stable ABI.
This is a simplified interface to **`Py_CompileStringFlags()`** below, leaving *flags* set to `NULL`.

PyObject *Py_CompileStringFlags(const char *str, const char *filename, int start, PyCompilerFlags *flags)

Return value: New reference.
This is a simplified interface to **`Py_CompileStringExFlags()`** below, with *optimize* set to `-1`.

PyObject *Py_CompileStringObject(const char *str, PyObject *filename, int start, PyCompilerFlags *flags, int optimize)

Return value: New reference.
Parse and compile the Python source code in *str*, returning the resulting code object. The start symbol is given by *start*; this can be used to constrain the code which can be compiled and should be available start symbols. The filename specified by *filename* is used to construct the code object and may appear in tracebacks or **`SyntaxError`** exception messages. This returns `NULL` if the code cannot be parsed or compiled.

The integer *optimize* specifies the optimization level of the compiler; a value of `-1` selects the optimization level of the interpreter as given by **`-O`** options. Explicit levels are `0` (no optimization; `__debug__` is true), `1` (asserts are removed, `__debug__` is false) or `2` (docstrings are removed too).

Added in version 3.4.

PyObject *Py_CompileStringExFlags(const char *str, const char *filename, int start, PyCompilerFlags *flags, int optimize)

Return value: New reference.
Like `Py_CompileStringObject()`, but *filename* is a byte string decoded from the filesystem encoding and error handler.

Added in version 3.2.

PyObject *PyEval_EvalCode(PyObject *co, PyObject *globals, PyObject *locals)

Return value: New reference. Part of the Stable ABI.
This is a simplified interface to `PyEval_EvalCodeEx()`, with just the code object, and global and local variables. The other arguments are set to `NULL`.

PyObject *PyEval_EvalCodeEx(PyObject *co, PyObject *globals, PyObject *locals, PyObject *const *args, int argcount, PyObject *const *kws, int kwcount, PyObject *const *defs, int defcount, PyObject *kwdefs, PyObject *closure)

Return value: New reference. Part of the Stable ABI.
Evaluate a precompiled code object, given a particular environment for its evaluation. This environment consists of a dictionary of global variables, a mapping object of local variables, arrays of arguments, keywords and defaults, a dictionary of default values for keyword-only arguments and a closure tuple of cells.

PyObject *PyEval_EvalFrame(PyFrameObject *f)

Return value: New reference. Part of the Stable ABI.
Evaluate an execution frame. This is a simplified interface to `PyEval_EvalFrameEx()`, for backward compatibility.

PyObject *PyEval_EvalFrameEx(PyFrameObject *f, int throwflag)

Return value: New reference. Part of the Stable ABI.
This is the main, unvarnished function of Python interpretation. The code object associated with the execution frame *f* is executed, interpreting bytecode and executing calls as needed. The additional *throwflag* parameter can mostly be ignored - if true, then it causes an exception to immediately be thrown; this is used for the **`throw()`** methods of generator objects.

Changed in version 3.4: This function now includes a debug assertion to help ensure that it does not silently discard an active exception.

int PyEval_MergeCompilerFlags(PyCompilerFlags *cf)

This function changes the flags of the current evaluation frame, and returns true on success, false on failure.

struct PyCompilerFlags

This is the structure used to hold compiler flags. In cases where code is only being compiled, it is passed as `int flags`, and in cases where code is being executed, it is passed as `PyCompilerFlags *flags`. In this case, `from __future__ import` can modify *flags*.

Whenever `PyCompilerFlags *flags` is `NULL`, **`cf_flags`** is treated as equal to `0`, and any modification due to `from __future__ import` is discarded.

int cf_flags

Compiler flags.

int cf_feature_version

cf_feature_version is the minor Python version. It should be initialized to `PY_MINOR_VERSION`.

The field is ignored by default, it is used if and only if `PyCF_ONLY_AST` flag is set in **`cf_flags`**.

Changed in version 3.8: Added *cf_feature_version* field.

The available compiler flags are accessible as macros:

PyCF_ALLOW_TOP_LEVEL_AWAIT
PyCF_ONLY_AST
PyCF_OPTIMIZED_AST
PyCF_TYPE_COMMENTS

See compiler flags in documentation of the **`ast`** Python module, which exports these constants under the same names.

The "`PyCF`" flags above can be combined with "`CO_FUTURE`" flags such as **`CO_FUTURE_ANNOTATIONS`** to enable features normally selectable using future statements. See Code Object Flags for a complete list.

Available start symbols

int Py_eval_input

The start symbol from the Python grammar for isolated expressions; for use with **`Py_CompileString()`**.

int Py_file_input

The start symbol from the Python grammar for sequences of statements as read from a file or other source; for use with **`Py_CompileString()`**. This is the symbol to use when compiling arbitrarily long Python source code.

int Py_single_input

The start symbol from the Python grammar for a single statement; for use with **`Py_CompileString()`**. This is the symbol used for the interactive interpreter loop.

int Py_func_type_input

The start symbol from the Python grammar for a function type; for use with `Py_CompileString()`. This is used to parse “signature type comments” from **PEP 484** [https://peps.python.org/pep-0484/].

This requires the `PyCF_ONLY_AST` flag to be set.

See also

- `ast.FunctionType`
- **PEP 484** [https://peps.python.org/pep-0484/]

Added in version 3.8.

Stack Effects

See also

`dis.stack_effect()`

PY_INVALID_STACK_EFFECT

Sentinel value representing an invalid stack effect.

This is currently equivalent to `INT_MAX`.

Added in version 3.8.

int PyCompile_OpcodeStackEffect(int opcode, int oparg)

Compute the stack effect of *opcode* with argument *oparg*.

On success, this function returns the stack effect; on failure, this returns `PY_INVALID_STACK_EFFECT`.

Added in version 3.4.

int PyCompile_OpcodeStackEffectWithJump(int opcode, int oparg, int jump)

Similar to `PyCompile_OpcodeStackEffect()`, but don't include the stack effect of jumping if *jump* is zero.

If *jump* is `0`, this will not include the stack effect of jumping, but if *jump* is `1` or `-1`, this will include it.

On success, this function returns the stack effect; on failure, this returns `PY_INVALID_STACK_EFFECT`.

Added in version 3.8.

Reference Counting

The functions and macros in this section are used for managing reference counts of Python objects.

Py_ssize_t Py_REFCNT(PyObject *o)

Part of the Stable ABI since version 3.14.
Get the reference count of the Python object *o*.

Note that the returned value may not actually reflect how many references to the object are actually held. For example, some objects are immortal and have a very high refcount that does not reflect the actual number of references. Consequently, do not rely on the returned value to be accurate, other than a value of 0 or 1.

Use the `Py_SET_REFCNT()` function to set an object reference count.

Note

On free threaded builds of Python, returning 1 isn’t sufficient to determine if it’s safe to treat *o* as having no access by other threads. Use `PyUnstable_Object_IsUniquelyReferenced()` for that instead.

See also the function `PyUnstable_Object_IsUniqueReferencedTemporary()`.

Changed in version 3.10: `Py_REFCNT()` is changed to the inline static function.

Changed in version 3.11: The parameter type is no longer const PyObject*.

void Py_SET_REFCNT(PyObject *o, Py_ssize_t refcnt)

Set the object *o* reference counter to *refcnt*.

On Python build with Free Threading, if *refcnt* is larger than `UINT32_MAX`, the object is made immortal.

This function has no effect on immortal objects.

Added in version 3.9.

Changed in version 3.12: Immortal objects are not modified.

void Py_INCREF(PyObject *o)

Indicate taking a new strong reference to object *o*, indicating it is in use and should not be destroyed.

This function has no effect on immortal objects.

This function is usually used to convert a borrowed reference to a strong reference in-place. The **`Py_NewRef()`** function can be used to create a new strong reference.

When done using the object, release is by calling **`Py_DECREF()`**.

The object must not be `NULL`; if you aren't sure that it isn't `NULL`, use **`Py_XINCREF()`**.

Do not expect this function to actually modify *o* in any way. For at least **some objects** [https://peps.python.org/pep-0683/], this function has no effect.

Changed in version 3.12: Immortal objects are not modified.

void Py_XINCREF(PyObject *o)

Similar to **`Py_INCREF()`**, but the object *o* can be `NULL`, in which case this has no effect.

See also **`Py_XNewRef()`**.

PyObject *Py_NewRef(PyObject *o)

Part of the Stable ABI since version 3.10.
Create a new strong reference to an object: call **`Py_INCREF()`** on *o* and return the object *o*.

When the strong reference is no longer needed, **`Py_DECREF()`** should be called on it to release the reference.

The object *o* must not be `NULL`; use **`Py_XNewRef()`** if *o* can be `NULL`.

For example:

```
Py_INCREF(obj);
self->attr = obj;
```

can be written as:

```
self->attr = Py_NewRef(obj);
```

See also **`Py_INCREF()`**.

Added in version 3.10.

PyObject *Py_XNewRef(PyObject *o)

Part of the Stable ABI since version 3.10.
Similar to **`Py_NewRef()`**, but the object *o* can be NULL.

If the object *o* is `NULL`, the function just returns `NULL`.

Added in version 3.10.

void Py_DECREF(PyObject *o)

Release a strong reference to object *o*, indicating the reference is no longer used.

This function has no effect on immortal objects.

Once the last strong reference is released (i.e. the object's reference count reaches 0), the object's type's deallocation function (which must not be `NULL`) is invoked.

This function is usually used to delete a strong reference before exiting its scope.

The object must not be `NULL`; if you aren't sure that it isn't `NULL`, use **`Py_XDECREF()`**.

Do not expect this function to actually modify *o* in any way. For at least **some objects** [https://peps.python.org/pep-0683/], this function has no effect.

Warning

The deallocation function can cause arbitrary Python code to be invoked (e.g. when a class instance with a **`__del__()`** method is deallocated). While exceptions in such code are not propagated, the executed code has free access to all Python global variables. This means that any object that is reachable from a global variable should be in a consistent state before **`Py_DECREF()`** is invoked. For example, code to delete an object from a list should copy a reference to the deleted object in a temporary variable, update the list data structure, and then call **`Py_DECREF()`** for the temporary variable.

Changed in version 3.12: Immortal objects are not modified.

void Py_XDECREF(PyObject *o)

Similar to **`Py_DECREF()`**, but the object *o* can be `NULL`, in which case this has no effect. The same warning from **`Py_DECREF()`** applies here as well.

void Py_CLEAR(PyObject *o)

Release a strong reference for object *o*. The object may be `NULL`, in which case the macro has no effect; otherwise the effect is the same as for **`Py_DECREF()`**, except that the argument is also set to `NULL`. The warning for **`Py_DECREF()`** does not apply with respect to the object passed because the macro carefully uses a temporary variable and sets the argument to `NULL` before releasing the reference.

It is a good idea to use this macro whenever releasing a reference to an object that might be traversed during garbage collection.

Changed in version 3.12: The macro argument is now only evaluated once. If the argument has side effects, these are no longer duplicated.

void Py_IncRef(PyObject *o)

Part of the Stable ABI.
Indicate taking a new strong reference to object *o*. A function version of **`Py_XINCREF()`**. It can be used for runtime dynamic embedding of Python.

void Py_DecRef(PyObject *o)

Part of the Stable ABI.
Release a strong reference to object *o*. A function version of **`Py_XDECREF()`**. It can be used for runtime dynamic embedding of Python.

Py_SETREF(dst, src)

Macro safely releasing a strong reference to object *dst* and setting *dst* to *src*.

As in case of `Py_CLEAR()`, “the obvious” code can be deadly:

```
Py_DECREF(dst);
dst = src;
```

The safe way is:

```
Py_SETREF(dst, src);
```

That arranges to set *dst* to *src* *before* releasing the reference to the old value of *dst*, so that any code triggered as a side-effect of *dst* getting torn down no longer believes *dst* points to a valid object.

Added in version 3.6.

Changed in version 3.12: The macro arguments are now only evaluated once. If an argument has side effects, these are no longer duplicated.

Py_XSETREF(dst, src)

Variant of `Py_SETREF` macro that uses `Py_XDECREF()` instead of `Py_DECREF()`.

Added in version 3.6.

Changed in version 3.12: The macro arguments are now only evaluated once. If an argument has side effects, these are no longer duplicated.

Exception Handling

The functions described in this chapter will let you handle and raise Python exceptions. It is important to understand some of the basics of Python exception handling. It works somewhat like the POSIX **`errno`** variable: there is a global indicator (per thread) of the last error that occurred. Most C API functions don’t clear this on success, but will set it to indicate the cause of the error on failure. Most C API functions also return an error indicator, usually `NULL` if they are supposed to return a pointer, or `-1` if they return an integer (exception: the `PyArg_*` functions return `1` for success and `0` for failure).

Concretely, the error indicator consists of three object pointers: the exception’s type, the exception’s value, and the traceback object. Any of those pointers can be `NULL` if non-set (although some combinations are forbidden, for example you can’t have a non-`NULL` traceback if the exception type is `NULL`).

When a function must fail because some function it called failed, it generally doesn’t set the error indicator; the function it called already set it. It is responsible for either handling the error and clearing the exception or returning after cleaning up any resources it holds (such as object references or memory allocations); it should *not* continue normally if it is not prepared to handle the error. If returning due to an error, it is important to indicate to the caller that an error has been set. If the error is not handled or carefully propagated, additional calls into the Python/C API may not behave as intended and may fail in mysterious ways.

Note

The error indicator is **not** the result of `sys.exc_info()`. The former corresponds to an exception that is not yet caught (and is therefore still propagating), while the latter returns an exception after it is caught (and has therefore stopped propagating).

Printing and clearing

void PyErr_Clear()

Part of the Stable ABI.
Clear the error indicator. If the error indicator is not set, there is no effect.

void PyErr_PrintEx(int set_sys_last_vars)

Part of the Stable ABI.
Print a standard traceback to `sys.stderr` and clear the error indicator. **Unless** the error is a `SystemExit`, in that case no traceback is printed and the Python process will exit with the error code specified by the `SystemExit` instance.

Call this function **only** when the error indicator is set. Otherwise it will cause a fatal error!

If *set_sys_last_vars* is nonzero, the variable `sys.last_exc` is set to the printed exception. For backwards compatibility, the deprecated variables `sys.last_type`, `sys.last_value` and `sys.last_traceback` are also set to the type, value and traceback of this exception, respectively.

Changed in version 3.12: The setting of `sys.last_exc` was added.

void PyErr_Print()

Part of the Stable ABI.
Alias for `PyErr_PrintEx(1)`.

void PyErr_WriteUnraisable(PyObject *obj)

Part of the Stable ABI.

Call `sys.unraisablehook()` using the current exception and *obj* argument.

This utility function prints a warning message to `sys.stderr` when an exception has been set but it is impossible for the interpreter to actually raise the exception. It is used, for example, when an exception occurs in an `__del__()` method.

The function is called with a single argument *obj* that identifies the context in which the unraisable exception occurred. If possible, the repr of *obj* will be printed in the warning message. If *obj* is `NULL`, only the traceback is printed.

An exception must be set when calling this function.

Changed in version 3.4: Print a traceback. Print only traceback if *obj* is `NULL`.

Changed in version 3.8: Use `sys.unraisablehook()`.

void PyErr_FormatUnraisable(const char *format, ...)

Similar to `PyErr_WriteUnraisable()`, but the *format* and subsequent parameters help format the warning message; they have the same meaning and values as in `PyUnicode_FromFormat()`. `PyErr_WriteUnraisable(obj)` is roughly equivalent to `PyErr_FormatUnraisable("Exception ignored in: %R", obj)`. If *format* is `NULL`, only the traceback is printed.

Added in version 3.13.

void PyErr_DisplayException(PyObject *exc)

Part of the Stable ABI since version 3.12.

Print the standard traceback display of `exc` to `sys.stderr`, including chained exceptions and notes.

Added in version 3.12.

Raising exceptions

These functions help you set the current thread's error indicator. For convenience, some of these functions will always return a `NULL` pointer for use in a `return` statement.

void PyErr_SetString(PyObject *type, const char *message)

Part of the Stable ABI.
This is the most common way to set the error indicator. The first argument specifies the exception type; it is normally one of the standard exceptions, e.g. **`PyExc_RuntimeError`**. You need not create a new strong reference to it (e.g. with **`Py_INCREF()`**). The second argument is an error message; it is decoded from `'utf-8'`.

void PyErr_SetObject(PyObject *type, PyObject *value)

Part of the Stable ABI.
This function is similar to **`PyErr_SetString()`** but lets you specify an arbitrary Python object for the "value" of the exception.

PyObject *PyErr_Format(PyObject *exception, const char *format, ...)

Return value: Always NULL. Part of the Stable ABI.
This function sets the error indicator and returns `NULL`. *exception* should be a Python exception class. The *format* and subsequent parameters help format the error message; they have the same meaning and values as in **`PyUnicode_FromFormat()`**. *format* is an ASCII-encoded string.

PyObject *PyErr_FormatV(PyObject *exception, const char *format, va_list vargs)

Return value: Always NULL. Part of the Stable ABI since version 3.5.
Same as **`PyErr_Format()`**, but taking a **`va_list`** argument rather than a variable number of arguments.

Added in version 3.5.

void PyErr_SetNone(PyObject *type)

Part of the Stable ABI.
This is a shorthand for `PyErr_SetObject(type, Py_None)`.

int PyErr_BadArgument()

Part of the Stable ABI.
This is a shorthand for `PyErr_SetString(PyExc_TypeError, message)`, where *message* indicates that a built-in operation was invoked with an illegal argument. It is mostly for internal use.

PyObject *PyErr_NoMemory()

Return value: Always NULL. Part of the Stable ABI.
This is a shorthand for `PyErr_SetNone(PyExc_MemoryError)`; it returns `NULL` so an object allocation function can write `return PyErr_NoMemory();` when it runs out of memory.

PyObject *PyErr_SetFromErrno(PyObject *type)

Return value: Always NULL. Part of the Stable ABI.
This is a convenience function to raise an exception when a C library function has returned an error and set the C variable **`errno`**. It constructs a tuple object whose first item is the integer **`errno`** value and whose second item is the corresponding error message (gotten from **`strerror()`**), and then calls `PyErr_SetObject(type, object)`. On Unix, when the **`errno`** value is **`EINTR`**, indicating an interrupted system call, this calls **`PyErr_CheckSignals()`**, and if that set the error

indicator, leaves it set to that. The function always returns `NULL`, so a wrapper function around a system call can write `return PyErr_SetFromErrno(type);` when the system call returns an error.

PyObject *PyErr_SetFromErrnoWithFilenameObject(PyObject *type, PyObject *filenameObject)

Return value: Always NULL. Part of the Stable ABI.
Similar to **`PyErr_SetFromErrno()`**, with the additional behavior that if *filenameObject* is not `NULL`, it is passed to the constructor of *type* as a third parameter. In the case of **`OSError`** exception, this is used to define the **`filename`** attribute of the exception instance.

PyObject *PyErr_SetFromErrnoWithFilenameObjects(PyObject *type, PyObject *filenameObject, PyObject *filenameObject2)

Return value: Always NULL. Part of the Stable ABI since version 3.7.
Similar to **`PyErr_SetFromErrnoWithFilenameObject()`**, but takes a second filename object, for raising errors when a function that takes two filenames fails.

Added in version 3.4.

PyObject *PyErr_SetFromErrnoWithFilename(PyObject *type, const char *filename)

Return value: Always NULL. Part of the Stable ABI.
Similar to **`PyErr_SetFromErrnoWithFilenameObject()`**, but the filename is given as a C string. *filename* is decoded from the filesystem encoding and error handler.

PyObject *PyErr_SetFromWindowsErr(int ierr)

Return value: Always NULL. Part of the Stable ABI on Windows since version 3.7.
This is a convenience function to raise **`OSError`**. If called with *ierr* of `0`, the error code returned by a call to

`GetLastError()` is used instead. It calls the Win32 function **`FormatMessage()`** to retrieve the Windows description of error code given by *ierr* or **`GetLastError()`**, then it constructs a **`OSError`** object with the **`winerror`** attribute set to the error code, the **`strerror`** attribute set to the corresponding error message (gotten from **`FormatMessage()`**), and then calls `PyErr_SetObject(PyExc_OSError, object)`. This function always returns `NULL`.

Availability: Windows.

PyObject *PyErr_SetExcFromWindowsErr(PyObject *type, int ierr)

Return value: Always NULL. Part of the Stable ABI on Windows since version 3.7.
Similar to **`PyErr_SetFromWindowsErr()`**, with an additional parameter specifying the exception type to be raised.

Availability: Windows.

PyObject *PyErr_SetFromWindowsErrWithFilename(int ierr, const char *filename)

Return value: Always NULL. Part of the Stable ABI on Windows since version 3.7.
Similar to **`PyErr_SetFromWindowsErr()`**, with the additional behavior that if *filename* is not `NULL`, it is decoded from the filesystem encoding (**`os.fsdecode()`**) and passed to the constructor of **`OSError`** as a third parameter to be used to define the **`filename`** attribute of the exception instance.

Availability: Windows.

PyObject *PyErr_SetExcFromWindowsErrWithFilenameObject(PyObject *type, int ierr, PyObject *filename)

Return value: Always NULL. Part of the Stable ABI on Windows since version 3.7.
Similar to `PyErr_SetExcFromWindowsErr()`, with the additional behavior that if *filename* is not `NULL`, it is passed to the constructor of `OSError` as a third parameter to be used to define the **`filename`** attribute of the exception instance.

Availability: Windows.

PyObject *PyErr_SetExcFromWindowsErrWithFilenameObjects(PyObject *type, int ierr, PyObject *filename, PyObject *filename2)

Return value: Always NULL. Part of the Stable ABI on Windows since version 3.7.
Similar to `PyErr_SetExcFromWindowsErrWithFilenameObject()`, but accepts a second filename object.

Availability: Windows.

Added in version 3.4.

PyObject *PyErr_SetExcFromWindowsErrWithFilename(PyObject *type, int ierr, const char *filename)

Return value: Always NULL. Part of the Stable ABI on Windows since version 3.7.
Similar to `PyErr_SetFromWindowsErrWithFilename()`, with an additional parameter specifying the exception type to be raised.

Availability: Windows.

PyObject *PyErr_SetImportError(PyObject *msg, PyObject *name, PyObject *path)

Return value: Always NULL. Part of the Stable ABI since version 3.7.

This is a convenience function to raise `ImportError`. *msg* will be set as the exception's message string. *name* and *path*, both of which can be `NULL`, will be set as the `ImportError`'s respective `name` and `path` attributes.

Added in version 3.3.

PyObject *PyErr_SetImportErrorSubclass(PyObject *exception, PyObject *msg, PyObject *name, PyObject *path)

Return value: Always NULL. Part of the Stable ABI since version 3.6.

Much like `PyErr_SetImportError()` but this function allows for specifying a subclass of `ImportError` to raise.

Added in version 3.6.

void PyErr_SyntaxLocationObject(PyObject *filename, int lineno, int col_offset)

Set file, line, and offset information for the current exception. If the current exception is not a `SyntaxError`, then it sets additional attributes, which make the exception printing subsystem think the exception is a `SyntaxError`.

Added in version 3.4.

void PyErr_RangedSyntaxLocationObject(PyObject *filename, int lineno, int col_offset, int end_lineno, int end_col_offset)

Similar to `PyErr_SyntaxLocationObject()`, but also sets the *end_lineno* and *end_col_offset* information for the current exception.

Added in version 3.10.

void PyErr_SyntaxLocationEx(const char *filename, int lineno, int col_offset)

Part of the Stable ABI since version 3.7.
Like **`PyErr_SyntaxLocationObject()`**, but *filename* is a byte string decoded from the filesystem encoding and error handler.

Added in version 3.2.

void PyErr_SyntaxLocation(const char *filename, int lineno)

Part of the Stable ABI.
Like **`PyErr_SyntaxLocationEx()`**, but the *col_offset* parameter is omitted.

void PyErr_BadInternalCall()

Part of the Stable ABI.
This is a shorthand for `PyErr_SetString(PyExc_SystemError, message)`, where *message* indicates that an internal operation (e.g. a Python/C API function) was invoked with an illegal argument. It is mostly for internal use.

PyObject *PyErr_ProgramTextObject(PyObject *filename, int lineno)

Get the source line in *filename* at line *lineno*. *filename* should be a Python **`str`** object.

On success, this function returns a Python string object with the found line. On failure, this function returns `NULL` without an exception set.

PyObject *PyErr_ProgramText(const char *filename, int lineno)

Part of the Stable ABI.
Similar to **`PyErr_ProgramTextObject()`**, but *filename* is a const char*, which is decoded with the filesystem encoding and error handler, instead of a Python object reference.

Issuing warnings

Use these functions to issue warnings from C code. They mirror similar functions exported by the Python **`warnings`** module. They normally print a warning message to *sys.stderr*; however, it is also possible that the user has specified that warnings are to be turned into errors, and in that case they will raise an exception. It is also possible that the functions raise an exception because of a problem with the warning machinery. The return value is `0` if no exception is raised, or `-1` if an exception is raised. (It is not possible to determine whether a warning message is actually printed, nor what the reason is for the exception; this is intentional.) If an exception is raised, the caller should do its normal exception handling (for example, **`Py_DECREF()`** owned references and return an error value).

int PyErr_WarnEx(PyObject *category, const char *message, Py_ssize_t stack_level)

Part of the Stable ABI.

Issue a warning message. The *category* argument is a warning category (see below) or `NULL`; the *message* argument is a UTF-8 encoded string. *stack_level* is a positive number giving a number of stack frames; the warning will be issued from the currently executing line of code in that stack frame. A *stack_level* of 1 is the function calling **`PyErr_WarnEx()`**, 2 is the function above that, and so forth.

Warning categories must be subclasses of **`PyExc_Warning`**; **`PyExc_Warning`** is a subclass of **`PyExc_Exception`**; the default warning category is **`PyExc_RuntimeWarning`**. The standard Python warning categories are available as global variables whose names are enumerated at Warning types.

For information about warning control, see the documentation for the **`warnings`** module and the **`-W`** option in the command line documentation. There is no C API for warning control.

int PyErr_WarnExplicitObject(PyObject *category, PyObject *message, PyObject *filename, int lineno, PyObject *module, PyObject *registry)

Issue a warning message with explicit control over all warning attributes. This is a straightforward wrapper around the Python function **`warnings.warn_explicit()`**; see there for more information. The *module* and *registry* arguments may be set to `NULL` to get the default effect described there.

Added in version 3.4.

int PyErr_WarnExplicit(PyObject *category, const char *message, const char *filename, int lineno, const char *module, PyObject *registry)

Part of the Stable ABI.
Similar to **`PyErr_WarnExplicitObject()`** except that *message* and *module* are UTF-8 encoded strings, and *filename* is decoded from the filesystem encoding and error handler.

int PyErr_WarnFormat(PyObject *category, Py_ssize_t stack_level, const char *format, ...)

Part of the Stable ABI.
Function similar to **`PyErr_WarnEx()`**, but use **`PyUnicode_FromFormat()`** to format the warning message. *format* is an ASCII-encoded string.

Added in version 3.2.

int PyErr_WarnExplicitFormat(PyObject *category, const char *filename, int lineno, const char *module, PyObject *registry, const char *format, ...)

Similar to `PyErr_WarnExplicit()`, but uses `PyUnicode_FromFormat()` to format the warning message. *format* is an ASCII-encoded string.

Added in version 3.2.

int PyErr_ResourceWarning(PyObject *source, Py_ssize_t stack_level, const char *format, ...)

Part of the Stable ABI since version 3.6.
Function similar to `PyErr_WarnFormat()`, but *category* is `ResourceWarning` and it passes *source* to **`warnings.WarningMessage`**.

Added in version 3.6.

Querying the error indicator

PyObject *PyErr_Occurred()

Return value: Borrowed reference. Part of the Stable ABI.
Test whether the error indicator is set. If set, return the exception *type* (the first argument to the last call to one of the `PyErr_Set*` functions or to `PyErr_Restore()`). If not set, return `NULL`. You do not own a reference to the return value, so you do not need to `Py_DECREF()` it.

The caller must have an attached thread state.

Note

Do not compare the return value to a specific exception; use `PyErr_ExceptionMatches()` instead, shown below. (The comparison could easily fail since the exception may be an instance instead of a class, in the case of a class exception, or it may be a subclass of the expected exception.)

int PyErr_ExceptionMatches(PyObject *exc)

Part of the Stable ABI.

Equivalent to `PyErr_GivenExceptionMatches(PyErr_Occurred(), exc)`. This should only be called when an exception is actually set; a memory access violation will occur if no exception has been raised.

int PyErr_GivenExceptionMatches(PyObject *given, PyObject *exc)

Part of the Stable ABI.

Return true if the *given* exception matches the exception type in *exc*. If *exc* is a class object, this also returns true when *given* is an instance of a subclass. If *exc* is a tuple, all exception types in the tuple (and recursively in subtuples) are searched for a match.

PyObject *PyErr_GetRaisedException(void)

Return value: New reference. Part of the Stable ABI since version 3.12.

Return the exception currently being raised, clearing the error indicator at the same time. Return `NULL` if the error indicator is not set.

This function is used by code that needs to catch exceptions, or code that needs to save and restore the error indicator temporarily.

For example:

```
{
   PyObject *exc = PyErr_GetRaisedException();

   /* ... code that might produce other errors ... */

   PyErr_SetRaisedException(exc);
}
```

See also

[`PyErr_GetHandledException()`], to save the exception currently being handled.

Added in version 3.12.

void PyErr_SetRaisedException(PyObject *exc)

Part of the Stable ABI since version 3.12.
Set *exc* as the exception currently being raised, clearing the existing exception if one is set.

Warning

This call steals a reference to *exc*, which must be a valid exception.

Added in version 3.12.

void PyErr_Fetch(PyObject **ptype, PyObject **pvalue, PyObject **ptraceback)

Part of the Stable ABI.
Deprecated since version 3.12: Use `PyErr_GetRaisedException()` instead.

Retrieve the error indicator into three variables whose addresses are passed. If the error indicator is not set, set all three variables to `NULL`. If it is set, it will be cleared and you own a reference to each object retrieved. The value and traceback object may be `NULL` even when the type object is not.

Note

This function is normally only used by legacy code that needs to catch exceptions or save and restore the error indicator temporarily.

For example:

```
{
   PyObject *type, *value, *traceback;
   PyErr_Fetch(&type, &value, &traceback);

   /* ... code that might produce other errors ... */

   PyErr_Restore(type, value, traceback);
}
```

void PyErr_Restore(PyObject *type, PyObject *value, PyObject *traceback)

Part of the Stable ABI.
Deprecated since version 3.12: Use `PyErr_SetRaisedException()` instead.

Set the error indicator from the three objects, *type*, *value*, and *traceback*, clearing the existing exception if one is set. If the objects are `NULL`, the error indicator is cleared. Do not pass a `NULL` type and non-`NULL` value or traceback. The exception type should be a class. Do not pass an invalid exception type or value. (Violating these rules will cause subtle problems later.) This call takes away a reference to each object: you must own a reference to each object before the call and after the call you no longer own these references. (If you don't understand this, don't use this function. I warned you.)

Note

This function is normally only used by legacy code that needs to save and restore the error indicator temporarily. Use `PyErr_Fetch()` to save the current error indicator.

void PyErr_NormalizeException(PyObject **exc, PyObject **val, PyObject **tb)

Part of the Stable ABI.

Deprecated since version 3.12: Use **`PyErr_GetRaisedException()`** instead, to avoid any possible de-normalization.

Under certain circumstances, the values returned by **`PyErr_Fetch()`** below can be “unnormalized”, meaning that `*exc` is a class object but `*val` is not an instance of the same class. This function can be used to instantiate the class in that case. If the values are already normalized, nothing happens. The delayed normalization is implemented to improve performance.

Note

This function *does not* implicitly set the **`__traceback__`** attribute on the exception value. If setting the traceback appropriately is desired, the following additional snippet is needed:

```
if (tb != NULL) {
  PyException_SetTraceback(val, tb);
}
```

PyObject *PyErr_GetHandledException(void)

Part of the Stable ABI since version 3.11.

Retrieve the active exception instance, as would be returned by **`sys.exception()`**. This refers to an exception that was *already caught*, not to an exception that was freshly raised. Returns a new reference to the exception or `NULL`. Does not modify the interpreter’s exception state.

Note

This function is not normally used by code that wants to handle exceptions. Rather, it can be used when code needs to save and restore the exception state temporarily. Use **`PyErr_SetHandledException()`** to restore or clear the exception state.

Added in version 3.11.

void PyErr_SetHandledException(PyObject *exc)

Part of the Stable ABI since version 3.11.

Set the active exception, as known from `sys.exception()`. This refers to an exception that was *already caught*, not to an exception that was freshly raised. To clear the exception state, pass `NULL`.

Note

This function is not normally used by code that wants to handle exceptions. Rather, it can be used when code needs to save and restore the exception state temporarily. Use **`PyErr_GetHandledException()`** to get the exception state.

Added in version 3.11.

void PyErr_GetExcInfo(PyObject **ptype, PyObject **pvalue, PyObject **ptraceback)

Part of the Stable ABI since version 3.7.

Retrieve the old-style representation of the exception info, as known from **`sys.exc_info()`**. This refers to an exception that was *already caught*, not to an exception that was freshly raised. Returns new references for the three objects, any of which may be `NULL`. Does not modify the exception info state. This function is kept for backwards compatibility. Prefer using **`PyErr_GetHandledException()`**.

Note

This function is not normally used by code that wants to handle exceptions. Rather, it can be used when code needs to save and restore the exception state temporarily. Use **`PyErr_SetExcInfo()`** to restore or clear the exception state.

Added in version 3.3.

void PyErr_SetExcInfo(PyObject *type, PyObject *value, PyObject *traceback)

Part of the Stable ABI since version 3.7.

Set the exception info, as known from `sys.exc_info()`. This refers to an exception that was *already caught*, not to an exception that was freshly raised. This function steals the references of the arguments. To clear the exception state, pass `NULL` for all three arguments. This function is kept for backwards compatibility. Prefer using **`PyErr_SetHandledException()`**.

Note

This function is not normally used by code that wants to handle exceptions. Rather, it can be used when code needs to save and restore the exception state temporarily. Use **`PyErr_GetExcInfo()`** to read the exception state.

Added in version 3.3.

Changed in version 3.11: The `type` and `traceback` arguments are no longer used and can be NULL. The interpreter now derives them from the exception instance (the `value` argument). The function still steals references of all three arguments.

Signal Handling

int PyErr_CheckSignals()

Part of the Stable ABI.

This function interacts with Python’s signal handling.

If the function is called from the main thread and under the main Python interpreter, it checks whether a signal has been sent to the processes and if so, invokes the corresponding signal handler. If the **`signal`** module is supported, this can invoke a signal handler written in Python.

The function attempts to handle all pending signals, and then returns `0`. However, if a Python signal handler raises an exception, the error indicator is set and the function returns `-1` immediately (such that other pending signals may not have been handled yet: they will be on the next **`PyErr_CheckSignals()`** invocation).

If the function is called from a non-main thread, or under a non-main Python interpreter, it does nothing and returns `0`.

This function can be called by long-running C code that wants to be interruptible by user requests (such as by pressing Ctrl-C).

Note

The default Python signal handler for **`SIGINT`** raises the **`KeyboardInterrupt`** exception.

void PyErr_SetInterrupt()

Part of the Stable ABI.

Simulate the effect of a **`SIGINT`** signal arriving. This is equivalent to `PyErr_SetInterruptEx(SIGINT)`.

Note

This function is async-signal-safe. It can be called without an attached thread state and from a C signal handler.

int PyErr_SetInterruptEx(int signum)

Part of the Stable ABI since version 3.10.
Simulate the effect of a signal arriving. The next time `PyErr_CheckSignals()` is called, the Python signal handler for the given signal number will be called.

This function can be called by C code that sets up its own signal handling and wants Python signal handlers to be invoked as expected when an interruption is requested (for example when the user presses Ctrl-C to interrupt an operation).

If the given signal isn't handled by Python (it was set to `signal.SIG_DFL` or `signal.SIG_IGN`), it will be ignored.

If *signum* is outside of the allowed range of signal numbers, `-1` is returned. Otherwise, `0` is returned. The error indicator is never changed by this function.

Note

This function is async-signal-safe. It can be called without an attached thread state and from a C signal handler.

Added in version 3.10.

int PySignal_SetWakeupFd(int fd)

This utility function specifies a file descriptor to which the signal number is written as a single byte whenever a signal is received. *fd* must be non-blocking. It returns the previous such file descriptor.

The value `-1` disables the feature; this is the initial state. This is equivalent to **`signal.set_wakeup_fd()`** in Python, but without any error checking. *fd* should be a valid file descriptor. The function should only be called from the main thread.

Changed in version 3.5: On Windows, the function now also supports socket handles.

Exception Classes

PyObject *PyErr_NewException(const char *name, PyObject *base, PyObject *dict)

Return value: New reference. Part of the Stable ABI.
This utility function creates and returns a new exception class. The *name* argument must be the name of the new exception, a C string of the form `module.classname`. The *base* and *dict* arguments are normally `NULL`. This creates a class object derived from **`Exception`** (accessible in C as **`PyExc_Exception`**).

The **`__module__`** attribute of the new class is set to the first part (up to the last dot) of the *name* argument, and the class name is set to the last part (after the last dot). The *base* argument can be used to specify alternate base classes; it can either be only one class or a tuple of classes. The *dict* argument can be used to specify a dictionary of class variables and methods.

PyObject *PyErr_NewExceptionWithDoc(const char *name, const char *doc, PyObject *base, PyObject *dict)

Return value: New reference. Part of the Stable ABI.
Same as **`PyErr_NewException()`**, except that the new exception class can easily be given a docstring: If *doc* is non-`NULL`, it will be used as the docstring for the exception class.

Added in version 3.2.

int PyExceptionClass_Check(PyObject *ob)

Return non-zero if *ob* is an exception class, zero otherwise. This function always succeeds.

const char *PyExceptionClass_Name(PyObject *ob)

Part of the Stable ABI since version 3.8.
Return **`tp_name`** of the exception class *ob*.

Exception Objects

int PyExceptionInstance_Check(PyObject *op)

Return true if *op* is an instance of **`BaseException`**, false otherwise. This function always succeeds.

PyExceptionInstance_Class(op)

Equivalent to **`Py_TYPE(op)`**.

PyObject *PyException_GetTraceback(PyObject *ex)

Return value: New reference. Part of the Stable ABI.
Return the traceback associated with the exception as a new reference, as accessible from Python through the **`__traceback__`** attribute. If there is no traceback associated, this returns `NULL`.

int PyException_SetTraceback(PyObject *ex, PyObject *tb)

Part of the Stable ABI.
Set the traceback associated with the exception to *tb*. Use `Py_None` to clear it.

PyObject *PyException_GetContext(PyObject *ex)

Return value: New reference. Part of the Stable ABI.
Return the context (another exception instance during whose handling *ex* was raised) associated with the

exception as a new reference, as accessible from Python through the `__context__` attribute. If there is no context associated, this returns `NULL`.

void PyException_SetContext(PyObject *ex, PyObject *ctx)

Part of the Stable ABI.
Set the context associated with the exception to *ctx*. Use `NULL` to clear it. There is no type check to make sure that *ctx* is an exception instance. This steals a reference to *ctx*.

PyObject *PyException_GetCause(PyObject *ex)

Return value: New reference. Part of the Stable ABI.
Return the cause (either an exception instance, or `None`, set by `raise ... from ...`) associated with the exception as a new reference, as accessible from Python through the `__cause__` attribute.

void PyException_SetCause(PyObject *ex, PyObject *cause)

Part of the Stable ABI.
Set the cause associated with the exception to *cause*. Use `NULL` to clear it. There is no type check to make sure that *cause* is either an exception instance or `None`. This steals a reference to *cause*.

The `__suppress_context__` attribute is implicitly set to `True` by this function.

PyObject *PyException_GetArgs(PyObject *ex)

Return value: New reference. Part of the Stable ABI since version 3.12.
Return `args` of exception *ex*.

void PyException_SetArgs(PyObject *ex, PyObject *args)

Part of the Stable ABI since version 3.12.
Set `args` of exception *ex* to *args*.

PyObject *PyUnstable_Exc_PrepReraiseStar(PyObject *orig, PyObject *excs)

This is Unstable API. It may change without warning in minor releases.

Implement part of the interpreter's implementation of **`except*`**. *orig* is the original exception that was caught, and *excs* is the list of the exceptions that need to be raised. This list contains the unhandled part of *orig*, if any, as well as the exceptions that were raised from the **`except*`** clauses (so they have a different traceback from *orig*) and those that were reraised (and have the same traceback as *orig*). Return the **`ExceptionGroup`** that needs to be reraised in the end, or `None` if there is nothing to reraise.

Added in version 3.12.

Unicode Exception Objects

The following functions are used to create and modify Unicode exceptions from C.

PyObject *PyUnicodeDecodeError_Create(const char *encoding, const char *object, Py_ssize_t length, Py_ssize_t start, Py_ssize_t end, const char *reason)

Return value: New reference. Part of the Stable ABI.
Create a **`UnicodeDecodeError`** object with the attributes *encoding*, *object*, *length*, *start*, *end* and *reason*. *encoding* and *reason* are UTF-8 encoded strings.

PyObject *PyUnicodeDecodeError_GetEncoding(PyObject *exc)
PyObject *PyUnicodeEncodeError_GetEncoding(PyObject *exc)

Return value: New reference. Part of the Stable ABI.

Return the *encoding* attribute of the given exception object.

PyObject *PyUnicodeDecodeError_GetObject(PyObject *exc)
PyObject *PyUnicodeEncodeError_GetObject(PyObject *exc)
PyObject *PyUnicodeTranslateError_GetObject(PyObject *exc)

Return value: New reference. Part of the Stable ABI.
Return the *object* attribute of the given exception object.

int PyUnicodeDecodeError_GetStart(PyObject *exc, Py_ssize_t *start)
int PyUnicodeEncodeError_GetStart(PyObject *exc, Py_ssize_t *start)
int PyUnicodeTranslateError_GetStart(PyObject *exc, Py_ssize_t *start)

Part of the Stable ABI.
Get the *start* attribute of the given exception object and place it into **start*. *start* must not be `NULL`. Return `0` on success, `-1` on failure.

If the **`UnicodeError.object`** is an empty sequence, the resulting *start* is `0`. Otherwise, it is clipped to `[0, len(object) - 1]`.

See also

`UnicodeError.start`

int PyUnicodeDecodeError_SetStart(PyObject *exc, Py_ssize_t start)
int PyUnicodeEncodeError_SetStart(PyObject *exc, Py_ssize_t start)
int PyUnicodeTranslateError_SetStart(PyObject *exc, Py_ssize_t start)

Part of the Stable ABI.
Set the *start* attribute of the given exception object to *start*. Return `0` on success, `-1` on failure.

Note

While passing a negative *start* does not raise an exception, the corresponding getters will not consider it as a relative offset.

int PyUnicodeDecodeError_GetEnd(PyObject *exc, Py_ssize_t *end)
int PyUnicodeEncodeError_GetEnd(PyObject *exc, Py_ssize_t *end)
int PyUnicodeTranslateError_GetEnd(PyObject *exc, Py_ssize_t *end)

Part of the Stable ABI.
Get the *end* attribute of the given exception object and place it into **end*. *end* must not be `NULL`. Return `0` on success, `-1` on failure.

If the **`UnicodeError.object`** is an empty sequence, the resulting *end* is `0`. Otherwise, it is clipped to `[1, len(object)]`.

int PyUnicodeDecodeError_SetEnd(PyObject *exc, Py_ssize_t end)
int PyUnicodeEncodeError_SetEnd(PyObject *exc, Py_ssize_t end)
int PyUnicodeTranslateError_SetEnd(PyObject *exc, Py_ssize_t end)

Part of the Stable ABI.
Set the *end* attribute of the given exception object to *end*. Return `0` on success, `-1` on failure.

See also

`UnicodeError.end`

PyObject *PyUnicodeDecodeError_GetReason(PyObject *exc)
PyObject *PyUnicodeEncodeError_GetReason(PyObject *exc)
PyObject *PyUnicodeTranslateError_GetReason(PyObject *exc)

Return value: New reference. Part of the Stable ABI.
Return the *reason* attribute of the given exception object.

int PyUnicodeDecodeError_SetReason(PyObject *exc, const char *reason)
int PyUnicodeEncodeError_SetReason(PyObject *exc, const char *reason)
int PyUnicodeTranslateError_SetReason(PyObject *exc, const char *reason)

Part of the Stable ABI.
Set the *reason* attribute of the given exception object to *reason*. Return `0` on success, `-1` on failure.

Recursion Control

These two functions provide a way to perform safe recursive calls at the C level, both in the core and in extension modules. They are needed if the recursive code does not necessarily invoke Python code (which tracks its recursion depth automatically). They are also not needed for *tp_call* implementations because the call protocol takes care of recursion handling.

int Py_EnterRecursiveCall(const char *where)

Part of the Stable ABI since version 3.9.

Marks a point where a recursive C-level call is about to be performed.

The function then checks if the stack limit is reached. If this is the case, a `RecursionError` is set and a nonzero value is returned. Otherwise, zero is returned.

where should be a UTF-8 encoded string such as `" in instance check"` to be concatenated to the `RecursionError` message caused by the recursion depth limit.

See also

The `PyUnstable_ThreadState_SetStackProtection()` function.

Changed in version 3.9: This function is now also available in the limited API.

void Py_LeaveRecursiveCall(void)

Part of the Stable ABI since version 3.9.

Ends a `Py_EnterRecursiveCall()`. Must be called once for each *successful* invocation of `Py_EnterRecursiveCall()`.

Changed in version 3.9: This function is now also available in the limited API.

Properly implementing `tp_repr` for container types requires special recursion handling. In addition to protecting the stack, `tp_repr` also needs to track objects to prevent cycles. The following two functions facilitate this functionality. Effectively, these are the C equivalent to `reprlib.recursive_repr()`.

int Py_ReprEnter(PyObject *object)

Part of the Stable ABI.

Called at the beginning of the `tp_repr` implementation to detect cycles.

If the object has already been processed, the function returns a positive integer. In that case the `tp_repr` implementation should return a string object indicating a cycle. As examples, `dict` objects return `{...}` and `list` objects return `[...]`.

The function will return a negative integer if the recursion limit is reached. In that case the `tp_repr` implementation should typically return `NULL`.

Otherwise, the function returns zero and the `tp_repr` implementation can continue normally.

void Py_ReprLeave(PyObject *object)

Part of the Stable ABI.
Ends a `Py_ReprEnter()`. Must be called once for each invocation of `Py_ReprEnter()` that returns zero.

int Py_GetRecursionLimit(void)

Part of the Stable ABI.
Get the recursion limit for the current interpreter. It can be set with `Py_SetRecursionLimit()`. The recursion limit prevents the Python interpreter stack from growing infinitely.

This function cannot fail, and the caller must hold an attached thread state.

See also

`sys.getrecursionlimit()`

void Py_SetRecursionLimit(int new_limit)

Part of the Stable ABI.
Set the recursion limit for the current interpreter.

This function cannot fail, and the caller must hold an attached thread state.

See also

`sys.setrecursionlimit()`

Exception and warning types

All standard Python exceptions and warning categories are available as global variables whose names are `PyExc_` followed by the Python exception name. These have the type PyObject*; they are all class objects.

For completeness, here are all the variables:

Exception types

C name	Python name
PyObject *PyExc_BaseException *Part of the Stable ABI.*	`BaseException`
PyObject *PyExc_BaseExceptionGroup *Part of the Stable ABI since version 3.11.*	`BaseExceptionGroup`
PyObject *PyExc_Exception *Part of the Stable ABI.*	`Exception`
PyObject *PyExc_ArithmeticError	`ArithmeticError`

C name	**Python name**
Part of the Stable ABI.	
PyObject *PyExc_AssertionError *Part of the Stable ABI.*	`AssertionError`
PyObject *PyExc_AttributeError *Part of the Stable ABI.*	`AttributeError`
PyObject *PyExc_BlockingIOError *Part of the Stable ABI since version 3.7.*	`BlockingIOError`
PyObject *PyExc_BrokenPipeError *Part of the Stable ABI since version 3.7.*	`BrokenPipeError`
PyObject *PyExc_BufferError *Part of the Stable ABI.*	`BufferError`
PyObject *PyExc_ChildProcessError *Part of the Stable ABI since version 3.7.*	`ChildProcessError`
PyObject *PyExc_ConnectionAbortedError *Part of the Stable ABI since version 3.7.*	`ConnectionAbortedError`

C name	Python name
PyObject *PyExc_ConnectionError *Part of the Stable ABI since version 3.7.*	`ConnectionError`
PyObject *PyExc_ConnectionRefusedError *Part of the Stable ABI since version 3.7.*	`ConnectionRefusedError`
PyObject *PyExc_ConnectionResetError *Part of the Stable ABI since version 3.7.*	`ConnectionResetError`
PyObject *PyExc_EOFError *Part of the Stable ABI.*	`EOFError`
PyObject *PyExc_FileExistsError *Part of the Stable ABI since version 3.7.*	`FileExistsError`
PyObject *PyExc_FileNotFoundError *Part of the Stable ABI since version 3.7.*	`FileNotFoundError`
PyObject *PyExc_FloatingPointError *Part of the Stable ABI.*	`FloatingPointError`

C name	Python name
PyObject *PyExc_GeneratorExit *Part of the Stable ABI.*	`GeneratorExit`
PyObject *PyExc_ImportError *Part of the Stable ABI.*	`ImportError`
PyObject *PyExc_IndentationError *Part of the Stable ABI.*	`IndentationError`
PyObject *PyExc_IndexError *Part of the Stable ABI.*	`IndexError`
PyObject *PyExc_InterruptedError *Part of the Stable ABI since version 3.7.*	`InterruptedError`
PyObject *PyExc_IsADirectoryError *Part of the Stable ABI since version 3.7.*	`IsADirectoryError`
PyObject *PyExc_KeyError *Part of the Stable ABI.*	`KeyError`
PyObject *PyExc_KeyboardInterrupt *Part of the Stable ABI.*	`KeyboardInterrupt`
PyObject *PyExc_LookupError	`LookupError`

C name	**Python name**
Part of the Stable ABI.	
PyObject *PyExc_MemoryError *Part of the Stable ABI.*	`MemoryError`
PyObject *PyExc_ModuleNotFoundError *Part of the Stable ABI since version 3.6.*	`ModuleNotFoundError`
PyObject *PyExc_NameError *Part of the Stable ABI.*	`NameError`
PyObject *PyExc_NotADirectoryError *Part of the Stable ABI since version 3.7.*	`NotADirectoryError`
PyObject *PyExc_NotImplementedError *Part of the Stable ABI.*	`NotImplementedError`
PyObject *PyExc_OSError *Part of the Stable ABI.*	`OSError`
PyObject *PyExc_OverflowError *Part of the Stable ABI.*	`OverflowError`
PyObject *PyExc_PermissionError	`PermissionError`

C name	**Python name**
Part of the Stable ABI since version 3.7.	
PyObject *PyExc_ProcessLookupError *Part of the Stable ABI since version 3.7.*	`ProcessLookupError`
PyObject *PyExc_PythonFinalizationError	`PythonFinalizationError`
PyObject *PyExc_RecursionError *Part of the Stable ABI since version 3.7.*	`RecursionError`
PyObject *PyExc_ReferenceError *Part of the Stable ABI.*	`ReferenceError`
PyObject *PyExc_RuntimeError *Part of the Stable ABI.*	`RuntimeError`
PyObject *PyExc_StopAsyncIteration *Part of the Stable ABI since version 3.7.*	`StopAsyncIteration`
PyObject *PyExc_StopIteration *Part of the Stable ABI.*	`StopIteration`
PyObject *PyExc_SyntaxError	`SyntaxError`

C name	Python name
Part of the Stable ABI.	
PyObject *PyExc_SystemError *Part of the Stable ABI.*	`SystemError`
PyObject *PyExc_SystemExit *Part of the Stable ABI.*	`SystemExit`
PyObject *PyExc_TabError *Part of the Stable ABI.*	`TabError`
PyObject *PyExc_TimeoutError *Part of the Stable ABI since version 3.7.*	`TimeoutError`
PyObject *PyExc_TypeError *Part of the Stable ABI.*	`TypeError`
PyObject *PyExc_UnboundLocalError *Part of the Stable ABI.*	`UnboundLocalError`
PyObject *PyExc_UnicodeDecodeError *Part of the Stable ABI.*	`UnicodeDecodeError`
PyObject *PyExc_UnicodeEncodeError *Part of the Stable ABI.*	`UnicodeEncodeError`

C name	Python name
PyObject *PyExc_UnicodeError *Part of the Stable ABI.*	`UnicodeError`
PyObject *PyExc_UnicodeTranslateError *Part of the Stable ABI.*	`UnicodeTranslateError`
PyObject *PyExc_ValueError *Part of the Stable ABI.*	`ValueError`
PyObject *PyExc_ZeroDivisionError *Part of the Stable ABI.*	`ZeroDivisionError`

Added in version 3.3: `PyExc_BlockingIOError`, `PyExc_BrokenPipeError`, `PyExc_ChildProcessError`, `PyExc_ConnectionError`, `PyExc_ConnectionAbortedError`, `PyExc_ConnectionRefusedError`, `PyExc_ConnectionResetError`, `PyExc_FileExistsError`, `PyExc_FileNotFoundError`, `PyExc_InterruptedError`, `PyExc_IsADirectoryError`, `PyExc_NotADirectoryError`, `PyExc_PermissionError`, `PyExc_ProcessLookupError` and `PyExc_TimeoutError` were introduced following **PEP 3151** [https://peps.python.org/pep-3151/].

Added in version 3.5: `PyExc_StopAsyncIteration` and `PyExc_RecursionError`.

Added in version 3.6: `PyExc_ModuleNotFoundError`.

Added in version 3.11: `PyExc_BaseExceptionGroup`.

OSError aliases

The following are a compatibility aliases to `PyExc_OSError`.

Changed in version 3.3: These aliases used to be separate exception types.

C name	Python name	Notes
PyObject *PyExc_EnvironmentError *Part of the Stable ABI.*	`OSError`	
PyObject *PyExc_IOError *Part of the Stable ABI.*	`OSError`	
PyObject *PyExc_WindowsError *Part of the Stable ABI on Windows since version 3.7.*	`OSError`	[win]

Notes:

[win]

`PyExc_WindowsError` is only defined on Windows; protect code that uses this by testing that the preprocessor macro `MS_WINDOWS` is defined.

Warning types

C name	Python name
PyObject *PyExc_Warning *Part of the Stable ABI.*	`Warning`
PyObject *PyExc_BytesWarning *Part of the Stable ABI.*	`BytesWarning`
PyObject *PyExc_DeprecationWarning *Part of the Stable ABI.*	`DeprecationWarning`
PyObject *PyExc_EncodingWarning *Part of the Stable ABI since version 3.10.*	`EncodingWarning`
PyObject *PyExc_FutureWarning *Part of the Stable ABI.*	`FutureWarning`
PyObject *PyExc_ImportWarning *Part of the Stable ABI.*	`ImportWarning`
PyObject *PyExc_PendingDeprecationWarning *Part of the Stable ABI.*	`PendingDeprecationWarning`
PyObject *PyExc_ResourceWarning *Part of the Stable ABI since version 3.7.*	`ResourceWarning`

C name	**Python name**
PyObject *PyExc_RuntimeWarning *Part of the Stable ABI.*	`RuntimeWarning`
PyObject *PyExc_SyntaxWarning *Part of the Stable ABI.*	`SyntaxWarning`
PyObject *PyExc_UnicodeWarning *Part of the Stable ABI.*	`UnicodeWarning`
PyObject *PyExc_UserWarning *Part of the Stable ABI.*	`UserWarning`

Added in version 3.2: `PyExc_ResourceWarning`.

Added in version 3.10: `PyExc_EncodingWarning`.

Tracebacks

PyTypeObject PyTraceBack_Type

Part of the Stable ABI.

Type object for traceback objects. This is available as `types.TracebackType` in the Python layer.

int PyTraceBack_Check(PyObject *op)

Return true if *op* is a traceback object, false otherwise. This function does not account for subtypes.

int PyTraceBack_Here(PyFrameObject *f)

Part of the Stable ABI.

Replace the `__traceback__` attribute on the current exception with a new traceback prepending *f* to the existing chain.

Calling this function without an exception set is undefined behavior.

This function returns `0` on success, and returns `-1` with an exception set on failure.

int PyTraceBack_Print(PyObject *tb, PyObject *f)

Part of the Stable ABI.
Write the traceback *tb* into the file *f*.

This function returns `0` on success, and returns `-1` with an exception set on failure.

Defining extension modules

A C extension for CPython is a shared library (for example, a `.so` file on Linux, `.pyd` DLL on Windows), which is loadable into the Python process (for example, it is compiled with compatible compiler settings), and which exports an initialization function.

To be importable by default (that is, by `importlib.machinery.ExtensionFileLoader`), the shared library must be available on `sys.path`, and must be named after the module name plus an extension listed in `importlib.machinery.EXTENSION_SUFFIXES`.

Note

Building, packaging and distributing extension modules is best done with third-party tools, and is out of scope of this document. One suitable tool is Setuptools, whose documentation can be found at https://setuptools.pypa.io/en/latest/setuptools.html.

Normally, the initialization function returns a module definition initialized using `PyModuleDef_Init()`. This allows splitting the creation process into several phases:

- Before any substantial code is executed, Python can determine which capabilities the module supports, and it can adjust the environment or refuse loading an incompatible extension.

- By default, Python itself creates the module object – that is, it does the equivalent of `object.__new__()` for classes. It also sets initial attributes like `__package__` and `__loader__`.
- Afterwards, the module object is initialized using extension-specific code – the equivalent of `__init__()` on classes.

This is called *multi-phase initialization* to distinguish it from the legacy (but still supported) *single-phase initialization* scheme, where the initialization function returns a fully constructed module. See the single-phase-initialization section below for details.

Changed in version 3.5: Added support for multi-phase initialization (**PEP 489** [https://peps.python.org/pep-0489/]).

Multiple module instances

By default, extension modules are not singletons. For example, if the `sys.modules` entry is removed and the module is re-imported, a new module object is created, and typically populated with fresh method and type objects. The old module is subject to normal garbage collection. This mirrors the behavior of pure-Python modules.

Additional module instances may be created in sub-interpreters or after Python runtime reinitialization (`Py_Finalize()` and `Py_Initialize()`). In these cases, sharing Python objects between module instances would likely cause crashes or undefined behavior.

To avoid such issues, each instance of an extension module should be *isolated*: changes to one instance should not implicitly affect the others, and all state owned by the module, including references to Python objects, should be specific to a particular module instance. See Isolating Extension Modules for more details and a practical guide.

A simpler way to avoid these issues is raising an error on repeated initialization.

All modules are expected to support sub-interpreters, or otherwise explicitly signal a lack of support. This is usually achieved by isolation or blocking repeated initialization, as above. A module may also be limited to the main interpreter using the **`Py_mod_multiple_interpreters`** slot.

Initialization function

The initialization function defined by an extension module has the following signature:

PyObject *PyInit_modulename(void)

Its name should be `PyInit_<name>`, with `<name>` replaced by the name of the module.

For modules with ASCII-only names, the function must instead be named `PyInit_<name>`, with `<name>` replaced by the name of the module. When using Multi-phase initialization, non-ASCII module names are allowed. In this case, the initialization function name is `PyInitU_<name>`, with `<name>` encoded using Python’s *punycode* encoding with hyphens replaced by underscores. In Python:

```
def initfunc_name(name):
    try:
        suffix = b'_' + name.encode('ascii')
    except UnicodeEncodeError:
        suffix = b'U_' + name.encode('punycode').replace(b'-',
b'_')
    return b'PyInit' + suffix
```

It is recommended to define the initialization function using a helper macro:

PyMODINIT_FUNC

Declare an extension module initialization function. This macro:

- specifies the PyObject* return type,
- adds any special linkage declarations required by the platform, and
- for C++, declares the function as `extern "C"`.

For example, a module called `spam` would be defined like this:

```
static struct PyModuleDef spam_module = {
    .m_base = PyModuleDef_HEAD_INIT,
    .m_name = "spam",
    ...
};

PyMODINIT_FUNC
PyInit_spam(void)
{
    return PyModuleDef_Init(&spam_module);
}
```

It is possible to export multiple modules from a single shared library by defining multiple initialization functions. However, importing them requires using symbolic links or a custom importer, because by default only the function corresponding to the filename is found. See the Multiple modules in one library [https://peps.python.org/pep-0489/#multiple-modules-in-one-library] section in **PEP 489** [https://peps.python.org/pep-0489/] for details.

The initialization function is typically the only non-`static` item defined in the module’s C source.

Multi-phase initialization

Normally, the initialization function (`PyInit_modulename`) returns a **`PyModuleDef`** instance with non-`NULL` **`m_slots`**. Before it is returned, the `PyModuleDef` instance must be initialized using the following function:

PyObject *PyModuleDef_Init(PyModuleDef *def)

Part of the Stable ABI since version 3.5.

Ensure a module definition is a properly initialized Python object that correctly reports its type and a reference count.

Return *def* cast to `PyObject*`, or `NULL` if an error occurred.

Calling this function is required for Multi-phase initialization. It should not be used in other contexts.

Note that Python assumes that `PyModuleDef` structures are statically allocated. This function may return either a new reference or a borrowed one; this reference must not be released.

Added in version 3.5.

Legacy single-phase initialization

Attention

Single-phase initialization is a legacy mechanism to initialize extension modules, with known drawbacks and design flaws. Extension module authors are encouraged to use multi-phase initialization instead.

In single-phase initialization, the initialization function (`PyInit_modulename`) should create, populate and return a module object. This is typically done using **`PyModule_Create()`** and functions like **`PyModule_AddObjectRef()`**.

Single-phase initialization differs from the default in the following ways:

- Single-phase modules are, or rather *contain*, “singletons”.

  When the module is first initialized, Python saves the contents of the module’s `__dict__` (that is, typically, the module’s functions and types).

  For subsequent imports, Python does not call the initialization function again. Instead, it creates a new module object with a new `__dict__`, and copies the saved contents to it. For example, given a single-phase module `_testsinglephase` [[1]] that defines a function `sum` and an exception class `error`:

  ```
  >>> import sys
  >>> import _testsinglephase as one
  >>> del sys.modules['_testsinglephase']
  >>> import _testsinglephase as two
  >>> one is two
  False
  >>> one.__dict__ is two.__dict__
  False
  >>> one.sum is two.sum
  True
  >>> one.error is two.error
  True
  ```

  The exact behavior should be considered a CPython implementation detail.

- To work around the fact that `PyInit_modulename` does not take a *spec* argument, some state of the import machinery is saved and applied to the first suitable module created during the `PyInit_modulename` call. Specifically, when a sub-module is imported, this mechanism prepends the parent package name to the name of the module.

  A single-phase `PyInit_modulename` function should create "its" module object as soon as possible, before any other module objects can be created.

- Non-ASCII module names (`PyInitU_modulename`) are not supported.

- Single-phase modules support module lookup functions like **`PyState_FindModule()`**.

[1]

`_testsinglephase` is an internal module used in CPython's self-test suite; your installation may or may not include it.

Utilities

The functions in this chapter perform various utility tasks, ranging from helping C code be more portable across platforms, using Python modules from C, and parsing function arguments and constructing Python values from C values.

- Operating System Utilities
- System Functions
- Process Control
- Importing Modules
- Data marshalling support
- Parsing arguments and building values
  - Parsing arguments
    - Strings and buffers
    - Numbers
    - Other objects
    - API Functions
  - Building values
- String conversion and formatting
- Character classification and conversion
- PyHash API
- Reflection
- Codec registry and support functions
  - Codec lookup API
  - Registry API for Unicode encoding error handlers
  - Codec utility variables
- PyTime C API
  - Types
  - Clock Functions
  - Raw Clock Functions
  - Conversion functions

- Support for Perf Maps

Operating System Utilities

PyObject *PyOS_FSPath(PyObject *path)

Return value: New reference. Part of the Stable ABI since version 3.6.

Return the file system representation for *path*. If the object is a **`str`** or **`bytes`** object, then a new strong reference is returned. If the object implements the **`os.PathLike`** interface, then **`__fspath__()`** is returned as long as it is a **`str`** or **`bytes`** object. Otherwise **`TypeError`** is raised and `NULL` is returned.

Added in version 3.6.

int Py_FdIsInteractive(FILE *fp, const char *filename)

Return true (nonzero) if the standard I/O file *fp* with name *filename* is deemed interactive. This is the case for files for which `isatty(fileno(fp))` is true. If the **`PyConfig.interactive`** is non-zero, this function also returns true if the *filename* pointer is `NULL` or if the name is equal to one of the strings `'<stdin>'` or `'???'`.

This function must not be called before Python is initialized.

void PyOS_BeforeFork()

Part of the Stable ABI on platforms with fork() since version 3.7.

Function to prepare some internal state before a process fork. This should be called before calling **`fork()`** or any similar function that clones the current process. Only available on systems where **`fork()`** is defined.

Warning

The C **`fork()`** call should only be made from the “main” thread (of the “main” interpreter). The same is true for `PyOS_BeforeFork()`.

Added in version 3.7.

void PyOS_AfterFork_Parent()

Part of the Stable ABI on platforms with fork() since version 3.7.

Function to update some internal state after a process fork. This should be called from the parent process after calling **`fork()`** or any similar function that clones the current process, regardless of whether process cloning was successful. Only available on systems where **`fork()`** is defined.

Warning

The C **`fork()`** call should only be made from the “main” thread (of the “main” interpreter). The same is true for `PyOS_AfterFork_Parent()`.

Added in version 3.7.

void PyOS_AfterFork_Child()

Part of the Stable ABI on platforms with fork() since version 3.7.

Function to update internal interpreter state after a process fork. This must be called from the child process after calling **`fork()`**, or any similar function that clones the current process, if there is any chance the process will call back into the Python interpreter. Only available on systems where **`fork()`** is defined.

Warning

The C **`fork()`** call should only be made from the “main” thread (of the “main” interpreter). The same is true for `PyOS_AfterFork_Child()`.

Added in version 3.7.

See also

`os.register_at_fork()` allows registering custom Python functions to be called by **`PyOS_BeforeFork()`**, **`PyOS_AfterFork_Parent()`** and **`PyOS_AfterFork_Child()`**.

void PyOS_AfterFork()

Part of the Stable ABI on platforms with fork().
Function to update some internal state after a process fork; this should be called in the new process if the Python interpreter will continue to be used. If a new executable is loaded into the new process, this function does not need to be called.

Deprecated since version 3.7: This function is superseded by **`PyOS_AfterFork_Child()`**.

int PyOS_CheckStack()

Part of the Stable ABI on platforms with USE_STACKCHECK since version 3.7.
Return true when the interpreter runs out of stack space. This is a reliable check, but is only available when **`USE_STACKCHECK`** is defined (currently on certain versions of Windows using the Microsoft Visual C++ compiler). **`USE_STACKCHECK`** will be defined automatically; you should never change the definition in your own code.

typedef void (*PyOS_sighandler_t)(int)

Part of the Stable ABI.

PyOS_sighandler_t PyOS_getsig(int i)

Part of the Stable ABI.

Return the current signal handler for signal *i*. This is a thin wrapper around either **`sigaction()`** or **`signal()`**. Do not call those functions directly!

PyOS_sighandler_t PyOS_setsig(int i, PyOS_sighandler_t h)

Part of the Stable ABI.

Set the signal handler for signal *i* to be *h*; return the old signal handler. This is a thin wrapper around either **`sigaction()`** or **`signal()`**. Do not call those functions directly!

int PyOS_InterruptOccurred(void)

Part of the Stable ABI.

Check if a **`SIGINT`** signal has been received.

Returns `1` if a **`SIGINT`** has occurred and clears the signal flag, or `0` otherwise.

In most cases, you should prefer **`PyErr_CheckSignals()`** over this function. **`PyErr_CheckSignals()`** invokes the appropriate signal handlers for all pending signals, allowing Python code to handle the signal properly. This function only detects **`SIGINT`** and does not invoke any Python signal handlers.

This function is async-signal-safe and this function cannot fail. The caller must hold an attached thread state.

wchar_t *Py_DecodeLocale(const char *arg, size_t *size)

Part of the Stable ABI since version 3.7.

Warning

This function should not be called directly: use the `PyConfig` API with the `PyConfig_SetBytesString()` function which ensures that Python is preinitialized.

This function must not be called before Python is preinitialized and so that the LC_CTYPE locale is properly configured: see the `Py_PreInitialize()` function.

Decode a byte string from the filesystem encoding and error handler. If the error handler is surrogateescape error handler, undecodable bytes are decoded as characters in range U+DC80..U+DCFF; and if a byte sequence can be decoded as a surrogate character, the bytes are escaped using the surrogateescape error handler instead of decoding them.

Return a pointer to a newly allocated wide character string, use `PyMem_RawFree()` to free the memory. If size is not `NULL`, write the number of wide characters excluding the null character into `*size`

Return `NULL` on decoding error or memory allocation error. If *size* is not `NULL`, `*size` is set to `(size_t)-1` on memory error or set to `(size_t)-2` on decoding error.

The filesystem encoding and error handler are selected by `PyConfig_Read()`: see `filesystem_encoding` and `filesystem_errors` members of `PyConfig`.

Decoding errors should never happen, unless there is a bug in the C library.

Use the `Py_EncodeLocale()` function to encode the character string back to a byte string.

See also

The `PyUnicode_DecodeFSDefaultAndSize()` and `PyUnicode_DecodeLocaleAndSize()` functions.

Added in version 3.5.

Changed in version 3.7: The function now uses the UTF-8 encoding in the Python UTF-8 Mode.

Changed in version 3.8: The function now uses the UTF-8 encoding on Windows if `PyPreConfig.legacy_windows_fs_encoding` is zero;

char *Py_EncodeLocale(const wchar_t *text, size_t *error_pos)

Part of the Stable ABI since version 3.7.

Encode a wide character string to the filesystem encoding and error handler. If the error handler is surrogateescape error handler, surrogate characters in the range U+DC80..U+DCFF are converted to bytes 0x80..0xFF.

Return a pointer to a newly allocated byte string, use `PyMem_Free()` to free the memory. Return `NULL` on encoding error or memory allocation error.

If error_pos is not `NULL`, `*error_pos` is set to `(size_t)-1` on success, or set to the index of the invalid character on encoding error.

The filesystem encoding and error handler are selected by `PyConfig_Read()`: see `filesystem_encoding` and `filesystem_errors` members of `PyConfig`.

Use the `Py_DecodeLocale()` function to decode the bytes string back to a wide character string.

Warning

This function must not be called before Python is preinitialized and so that the LC_CTYPE locale is properly configured: see the `Py_PreInitialize()` function.

See also

The `PyUnicode_EncodeFSDefault()` and `PyUnicode_EncodeLocale()` functions.

Added in version 3.5.

Changed in version 3.7: The function now uses the UTF-8 encoding in the Python UTF-8 Mode.

Changed in version 3.8: The function now uses the UTF-8 encoding on Windows if `PyPreConfig.legacy_windows_fs_encoding` is zero.

FILE *Py_fopen(PyObject *path, const char *mode)

Similar to `fopen()`, but *path* is a Python object and an exception is set on error.

path must be a `str` object, a `bytes` object, or a path-like object.

On success, return the new file pointer. On error, set an exception and return `NULL`.

The file must be closed by `Py_fclose()` rather than calling directly `fclose()`.

The file descriptor is created non-inheritable (**PEP 446** [https://peps.python.org/pep-0446/]).

The caller must have an attached thread state.

Added in version 3.14.

int Py_fclose(FILE *file)

Close a file that was opened by **`Py_fopen()`**.

On success, return `0`. On error, return `EOF` and `errno` is set to indicate the error. In either case, any further access (including another call to **`Py_fclose()`**) to the stream results in undefined behavior.

Added in version 3.14.

System Functions

These are utility functions that make functionality from the **`sys`** module accessible to C code. They all work with the current interpreter thread's **`sys`** module's dict, which is contained in the internal thread state structure.

PyObject *PySys_GetObject(const char *name)

Return value: Borrowed reference. Part of the Stable ABI.
Return the object *name* from the **`sys`** module or `NULL` if it does not exist, without setting an exception.

int PySys_SetObject(const char *name, PyObject *v)

Part of the Stable ABI.
Set *name* in the **`sys`** module to *v* unless *v* is `NULL`, in which case *name* is deleted from the sys module. Returns `0` on success, `-1` on error.

void PySys_ResetWarnOptions()

Part of the Stable ABI.

Reset `sys.warnoptions` to an empty list. This function may be called prior to `Py_Initialize()`.

Deprecated since version 3.13, will be removed in version 3.15: Clear `sys.warnoptions` and **`warnings.filters`** instead.

void PySys_WriteStdout(const char *format, ...)

Part of the Stable ABI.

Write the output string described by *format* to `sys.stdout`. No exceptions are raised, even if truncation occurs (see below).

format should limit the total size of the formatted output string to 1000 bytes or less – after 1000 bytes, the output string is truncated. In particular, this means that no unrestricted “%s” formats should occur; these should be limited using “%.<N>s” where <N> is a decimal number calculated so that <N> plus the maximum size of other formatted text does not exceed 1000 bytes. Also watch out for “%f”, which can print hundreds of digits for very large numbers.

If a problem occurs, or `sys.stdout` is unset, the formatted message is written to the real (C level) *stdout*.

void PySys_WriteStderr(const char *format, ...)

Part of the Stable ABI.

As `PySys_WriteStdout()`, but write to `sys.stderr` or *stderr* instead.

void PySys_FormatStdout(const char *format, ...)

Part of the Stable ABI.

Function similar to PySys_WriteStdout() but format the message using `PyUnicode_FromFormatV()` and don’t truncate the message to an arbitrary length.

Added in version 3.2.

void PySys_FormatStderr(const char *format, ...)

Part of the Stable ABI.

As `PySys_FormatStdout()`, but write to `sys.stderr` or *stderr* instead.

Added in version 3.2.

PyObject *PySys_GetXOptions()

Return value: Borrowed reference. Part of the Stable ABI since version 3.7.

Return the current dictionary of `-X` options, similarly to `sys._xoptions`. On error, `NULL` is returned and an exception is set.

Added in version 3.2.

int PySys_Audit(const char *event, const char *format, ...)

Part of the Stable ABI since version 3.13.

Raise an auditing event with any active hooks. Return zero for success and non-zero with an exception set on failure.

The *event* string argument must not be *NULL*.

If any hooks have been added, *format* and other arguments will be used to construct a tuple to pass. Apart from `N`, the same format characters as used in `Py_BuildValue()` are available. If the built value is not a tuple, it will be added into a single-element tuple.

The `N` format option must not be used. It consumes a reference, but since there is no way to know whether arguments to this function will be consumed, using it may cause reference leaks.

Note that `#` format characters should always be treated as **`Py_ssize_t`**, regardless of whether `PY_SSIZE_T_CLEAN` was defined.

`sys.audit()` performs the same function from Python code.

See also **`PySys_AuditTuple()`**.

Added in version 3.8.

Changed in version 3.8.2: Require **`Py_ssize_t`** for `#` format characters. Previously, an unavoidable deprecation warning was raised.

int PySys_AuditTuple(const char *event, PyObject *args)

Part of the Stable ABI since version 3.13.
Similar to **`PySys_Audit()`**, but pass arguments as a Python object. *args* must be a **`tuple`**. To pass no arguments, *args* can be *NULL*.

Added in version 3.13.

int PySys_AddAuditHook(Py_AuditHookFunction hook, void *userData)

Append the callable *hook* to the list of active auditing hooks. Return zero on success and non-zero on failure. If the runtime has been initialized, also set an error on failure. Hooks added through this API are called for all interpreters created by the runtime.

The *userData* pointer is passed into the hook function. Since hook functions may be called from different runtimes, this pointer should not refer directly to Python state.

This function is safe to call before **`Py_Initialize()`**. When called after runtime initialization, existing audit hooks are notified and may silently abort the operation by raising an error subclassed from **`Exception`** (other errors will not be silenced).

The hook function is always called with an attached thread state by the Python interpreter that raised the event.

See **PEP 578** [https://peps.python.org/pep-0578/] for a detailed description of auditing. Functions in the runtime and standard library that raise events are listed in the audit events table. Details are in each function's documentation.

If the interpreter is initialized, this function raises an auditing event `sys.addaudithook` with no arguments. If any existing hooks raise an exception derived from **`Exception`**, the new hook will not be added and the exception is cleared. As a result, callers cannot assume that their hook has been added unless they control all existing hooks.

typedef int (*Py_AuditHookFunction)(const char *event, PyObject *args, void *userData)

> The type of the hook function. *event* is the C string event argument passed to **`PySys_Audit()`** or **`PySys_AuditTuple()`**. *args* is guaranteed to be a **`PyTupleObject`**. *userData* is the argument passed to PySys_AddAuditHook().

Added in version 3.8.

Process Control

void Py_FatalError(const char *message)

Part of the Stable ABI.

Print a fatal error message and kill the process. No cleanup is performed. This function should only be invoked when a condition is detected that would make it dangerous to continue using the Python interpreter; e.g., when the object administration appears to be corrupted. On Unix, the standard C library function **`abort()`** is called which will attempt to produce a `core` file.

The `Py_FatalError()` function is replaced with a macro which logs automatically the name of the current function, unless the `Py_LIMITED_API` macro is defined.

Changed in version 3.9: Log the function name automatically.

void Py_Exit(int status)

Part of the Stable ABI.

Exit the current process. This calls **`Py_FinalizeEx()`** and then calls the standard C library function `exit(status)`. If **`Py_FinalizeEx()`** indicates an error, the exit status is set to 120.

Changed in version 3.6: Errors from finalization no longer ignored.

int Py_AtExit(void (*func)())

Part of the Stable ABI.

Register a cleanup function to be called by `Py_FinalizeEx()`. The cleanup function will be called with no arguments and should return no value. At most 32 cleanup functions can be registered. When the registration is successful, `Py_AtExit()` returns `0`; on failure, it returns `-1`. The cleanup function registered last is called first. Each cleanup function will be called at most once. Since Python’s internal finalization will have completed before the cleanup function, no Python APIs should be called by *func*.

See also

`PyUnstable_AtExit()` for passing a `void *data` argument.

Importing Modules

PyObject *PyImport_ImportModule(const char *name)

Return value: New reference. Part of the Stable ABI.
This is a wrapper around `PyImport_Import()` which takes a const char* as an argument instead of a PyObject*.

PyObject *PyImport_ImportModuleNoBlock(const char *name)

Return value: New reference. Part of the Stable ABI.
This function is a deprecated alias of `PyImport_ImportModule()`.

Changed in version 3.3: This function used to fail immediately when the import lock was held by another thread. In Python 3.3 though, the locking scheme switched to per-module locks for most purposes, so this function's special behaviour isn't needed anymore.

Deprecated since version 3.13, will be removed in version 3.15: Use `PyImport_ImportModule()` instead.

PyObject *PyImport_ImportModuleEx(const char *name, PyObject *globals, PyObject *locals, PyObject *fromlist)

Return value: New reference.
Import a module. This is best described by referring to the built-in Python function `__import__()`.

The return value is a new reference to the imported module or top-level package, or `NULL` with an exception set on failure. Like for `__import__()`, the return value when a submodule of a package was requested is normally the top-level package, unless a non-empty *fromlist* was given.

Failing imports remove incomplete module objects, like with **`PyImport_ImportModule()`**.

PyObject *PyImport_ImportModuleLevelObject(PyObject *name, PyObject *globals, PyObject *locals, PyObject *fromlist, int level)

Return value: New reference. Part of the Stable ABI since version 3.7.
Import a module. This is best described by referring to the built-in Python function **`__import__()`**, as the standard **`__import__()`** function calls this function directly.

The return value is a new reference to the imported module or top-level package, or `NULL` with an exception set on failure. Like for **`__import__()`**, the return value when a submodule of a package was requested is normally the top-level package, unless a non-empty *fromlist* was given.

Added in version 3.3.

PyObject *PyImport_ImportModuleLevel(const char *name, PyObject *globals, PyObject *locals, PyObject *fromlist, int level)

Return value: New reference. Part of the Stable ABI.
Similar to **`PyImport_ImportModuleLevelObject()`**, but the name is a UTF-8 encoded string instead of a Unicode object.

Changed in version 3.3: Negative values for *level* are no longer accepted.

PyObject *PyImport_Import(PyObject *name)

Return value: New reference. Part of the Stable ABI.

This is a higher-level interface that calls the current “import hook function” (with an explicit *level* of 0, meaning absolute import). It invokes the `__import__()` function from the `__builtins__` of the current globals. This means that the import is done using whatever import hooks are installed in the current environment.

This function always uses absolute imports.

PyObject *PyImport_ReloadModule(PyObject *m)

Return value: New reference. Part of the Stable ABI.
Reload a module. Return a new reference to the reloaded module, or `NULL` with an exception set on failure (the module still exists in this case).

PyObject *PyImport_AddModuleRef(const char *name)

Return value: New reference. Part of the Stable ABI since version 3.13.
Return the module object corresponding to a module name.

The *name* argument may be of the form `package.module`. First check the modules dictionary if there’s one there, and if not, create a new one and insert it in the modules dictionary.

Return a strong reference to the module on success. Return `NULL` with an exception set on failure.

The module name *name* is decoded from UTF-8.

This function does not load or import the module; if the module wasn’t already loaded, you will get an empty module object. Use `PyImport_ImportModule()` or one of its variants to import a module. Package structures implied by a dotted name for *name* are not created if not already present.

Added in version 3.13.

PyObject *PyImport_AddModuleObject(PyObject *name)

Return value: Borrowed reference. Part of the Stable ABI since version 3.7.
Similar to **`PyImport_AddModuleRef()`**, but return a borrowed reference and *name* is a Python **`str`** object.

Added in version 3.3.

PyObject *PyImport_AddModule(const char *name)

Return value: Borrowed reference. Part of the Stable ABI.
Similar to **`PyImport_AddModuleRef()`**, but return a borrowed reference.

PyObject *PyImport_ExecCodeModule(const char *name, PyObject *co)

Return value: New reference. Part of the Stable ABI.
Given a module name (possibly of the form `package.module`) and a code object read from a Python bytecode file or obtained from the built-in function **`compile()`**, load the module. Return a new reference to the module object, or `NULL` with an exception set if an error occurred. *name* is removed from **`sys.modules`** in error cases, even if *name* was already in **`sys.modules`** on entry to **`PyImport_ExecCodeModule()`**. Leaving incompletely initialized modules in **`sys.modules`** is dangerous, as imports of such modules have no way to know that the module object is an unknown (and probably damaged with respect to the module author's intents) state.

The module's **`__spec__`** and **`__loader__`** will be set, if not set already, with the appropriate values. The spec's loader will be set to the module’s `__loader__` (if set) and to an instance of `SourceFileLoader` otherwise.

The module’s `__file__` attribute will be set to the code object’s `co_filename`. If applicable, `__cached__` will also be set.

This function will reload the module if it was already imported. See `PyImport_ReloadModule()` for the intended way to reload a module.

If *name* points to a dotted name of the form `package.module`, any package structures not already created will still not be created.

See also `PyImport_ExecCodeModuleEx()` and `PyImport_ExecCodeModuleWithPathnames()`.

Changed in version 3.12: The setting of `__cached__` and `__loader__` is deprecated. See `ModuleSpec` for alternatives.

PyObject *PyImport_ExecCodeModuleEx(const char *name, PyObject *co, const char *pathname)

Return value: New reference. Part of the Stable ABI.
Like `PyImport_ExecCodeModule()`, but the `__file__` attribute of the module object is set to *pathname* if it is non-`NULL`.

See also `PyImport_ExecCodeModuleWithPathnames()`.

PyObject *PyImport_ExecCodeModuleObject(PyObject *name, PyObject *co, PyObject *pathname, PyObject *cpathname)

Return value: New reference. Part of the Stable ABI since version 3.7.
Like `PyImport_ExecCodeModuleEx()`, but the `__cached__` attribute of the module object is set to *cpathname* if it is

non-`NULL`. Of the three functions, this is the preferred one to use.

Added in version 3.3.

Changed in version 3.12: Setting **`__cached__`** is deprecated. See **`ModuleSpec`** for alternatives.

PyObject *PyImport_ExecCodeModuleWithPathnames(const char *name, PyObject *co, const char *pathname, const char *cpathname)

Return value: New reference. Part of the Stable ABI.
Like **`PyImport_ExecCodeModuleObject()`**, but *name*, *pathname* and *cpathname* are UTF-8 encoded strings. Attempts are also made to figure out what the value for *pathname* should be from *cpathname* if the former is set to `NULL`.

Added in version 3.2.

Changed in version 3.3: Uses **`imp.source_from_cache()`** in calculating the source path if only the bytecode path is provided.

Changed in version 3.12: No longer uses the removed **`imp`** module.

long PyImport_GetMagicNumber()

Part of the Stable ABI.
Return the magic number for Python bytecode files (a.k.a. `.pyc` file). The magic number should be present in the first four bytes of the bytecode file, in little-endian byte order. Returns `-1` on error.

Changed in version 3.3: Return value of `-1` upon failure.

const char *PyImport_GetMagicTag()

Part of the Stable ABI.
Return the magic tag string for **PEP 3147** [https://peps.python.org/pep-3147/] format Python bytecode file names. Keep in mind that the value at `sys.implementation.cache_tag` is authoritative and should be used instead of this function.

Added in version 3.2.

PyObject *PyImport_GetModuleDict()

Return value: Borrowed reference. Part of the Stable ABI.
Return the dictionary used for the module administration (a.k.a. `sys.modules`). Note that this is a per-interpreter variable.

PyObject *PyImport_GetModule(PyObject *name)

Return value: New reference. Part of the Stable ABI since version 3.8.
Return the already imported module with the given name. If the module has not been imported yet then returns `NULL` but does not set an error. Returns `NULL` and sets an error if the lookup failed.

Added in version 3.7.

PyObject *PyImport_GetImporter(PyObject *path)

Return value: New reference. Part of the Stable ABI.
Return a finder object for a **`sys.path`**/**`pkg.__path__`** item *path*, possibly by fetching it from the **`sys.path_importer_cache`** dict. If it wasn’t yet cached, traverse **`sys.path_hooks`** until a hook is found that can handle the path item. Return `None` if no hook could; this tells our caller that the path based finder could not find a finder for this path item. Cache the result in **`sys.path_importer_cache`**. Return a new reference to the finder object.

int PyImport_ImportFrozenModuleObject(PyObject *name)

Part of the Stable ABI since version 3.7.

Load a frozen module named *name*. Return `1` for success, `0` if the module is not found, and `-1` with an exception set if the initialization failed. To access the imported module on a successful load, use **`PyImport_ImportModule()`**. (Note the misnomer — this function would reload the module if it was already imported.)

Added in version 3.3.

Changed in version 3.4: The `__file__` attribute is no longer set on the module.

int PyImport_ImportFrozenModule(const char *name)

Part of the Stable ABI.

Similar to **`PyImport_ImportFrozenModuleObject()`**, but the name is a UTF-8 encoded string instead of a Unicode object.

struct _frozen

This is the structure type definition for frozen module descriptors, as generated by the **freeze** utility (see `Tools/freeze/` in the Python source distribution). Its definition, found in `Include/import.h`, is:

```
struct _frozen {
    const char *name;
    const unsigned char *code;
    int size;
    bool is_package;
};
```

Changed in version 3.11: The new `is_package` field indicates whether the module is a package or not. This replaces setting the `size` field to a negative value.

const struct _frozen *PyImport_FrozenModules

This pointer is initialized to point to an array of `_frozen` records, terminated by one whose members are all `NULL` or zero. When a frozen module is imported, it is searched in this table. Third-party code could play tricks with this to provide a dynamically created collection of frozen modules.

int PyImport_AppendInittab(const char *name, PyObject *(*initfunc)(void))

Part of the Stable ABI.

Add a single module to the existing table of built-in modules. This is a convenience wrapper around `PyImport_ExtendInittab()`, returning `-1` if the table could not be extended. The new module can be imported by the name *name*, and uses the function *initfunc* as the initialization function called on the first attempted import. This should be called before `Py_Initialize()`.

struct _inittab

Structure describing a single entry in the list of built-in modules. Programs which embed Python may use an array of these structures in conjunction with `PyImport_ExtendInittab()` to provide additional built-in modules. The structure consists of two members:

const char *name

The module name, as an ASCII encoded string.

PyObject *(*initfunc)(void)

Initialization function for a module built into the interpreter.

int PyImport_ExtendInittab(struct _inittab *newtab)

Add a collection of modules to the table of built-in modules. The *newtab* array must end with a sentinel entry which contains `NULL` for the `name` field; failure to provide the sentinel value can result in a memory fault. Returns `0` on success or `-1` if insufficient memory could be allocated to extend the internal table. In the event of failure, no modules are added to the internal table. This must be called before `Py_Initialize()`.

If Python is initialized multiple times, `PyImport_AppendInittab()` or `PyImport_ExtendInittab()` must be called before each Python initialization.

struct _inittab *PyImport_Inittab

The table of built-in modules used by Python initialization. Do not use this directly; use `PyImport_AppendInittab()` and `PyImport_ExtendInittab()` instead.

PyObject *PyImport_ImportModuleAttr(PyObject *mod_name, PyObject *attr_name)

Return value: New reference.
Import the module *mod_name* and get its attribute *attr_name*.

Names must be Python `str` objects.

Helper function combining `PyImport_Import()` and `PyObject_GetAttr()`. For example, it can raise `ImportError` if the module is not found, and `AttributeError` if the attribute doesn't exist.

Added in version 3.14.

PyObject *PyImport_ImportModuleAttrString(const char *mod_name, const char *attr_name)

Return value: New reference.
Similar to `PyImport_ImportModuleAttr()`, but names are UTF-8 encoded strings instead of Python `str` objects.

Added in version 3.14.

Data marshalling support

These routines allow C code to work with serialized objects using the same data format as the `marshal` module. There are functions to write data into the serialization format, and additional functions that can be used to read the data back. Files used to store marshalled data must be opened in binary mode.

Numeric values are stored with the least significant byte first.

The module supports several versions of the data format; see the `Python module documentation` for details.

Py_MARSHAL_VERSION

The current format version. See `marshal.version`.

void PyMarshal_WriteLongToFile(long value, FILE *file, int version)

Marshal a long integer, *value*, to *file*. This will only write the least-significant 32 bits of *value*; regardless of the size of the native long type. *version* indicates the file format.

This function can fail, in which case it sets the error indicator. Use `PyErr_Occurred()` to check for that.

void PyMarshal_WriteObjectToFile(PyObject *value, FILE *file, int version)

Marshal a Python object, *value*, to *file*. *version* indicates the file format.

This function can fail, in which case it sets the error indicator. Use **`PyErr_Occurred()`** to check for that.

PyObject *PyMarshal_WriteObjectToString(PyObject *value, int version)

Return value: New reference.
Return a bytes object containing the marshalled representation of *value*. *version* indicates the file format.

The following functions allow marshalled values to be read back in.

long PyMarshal_ReadLongFromFile(FILE *file)

Return a C long from the data stream in a FILE* opened for reading. Only a 32-bit value can be read in using this function, regardless of the native size of long.

On error, sets the appropriate exception (**`EOFError`**) and returns `-1`.

int PyMarshal_ReadShortFromFile(FILE *file)

Return a C short from the data stream in a FILE* opened for reading. Only a 16-bit value can be read in using this function, regardless of the native size of short.

On error, sets the appropriate exception (**`EOFError`**) and returns `-1`.

PyObject *PyMarshal_ReadObjectFromFile(FILE *file)

Return value: New reference.
Return a Python object from the data stream in a FILE* opened for reading.

On error, sets the appropriate exception (**`EOFError`**, **`ValueError`** or **`TypeError`**) and returns `NULL`.

PyObject *PyMarshal_ReadLastObjectFromFile(FILE *file)

Return value: New reference.
Return a Python object from the data stream in a FILE* opened for reading. Unlike **`PyMarshal_ReadObjectFromFile()`**, this function assumes that no further objects will be read from the file, allowing it to aggressively load file data into memory so that the de-serialization can operate from data in memory rather than reading a byte at a time from the file. Only use this variant if you are certain that you won’t be reading anything else from the file.

On error, sets the appropriate exception (**`EOFError`**, **`ValueError`** or **`TypeError`**) and returns `NULL`.

PyObject *PyMarshal_ReadObjectFromString(const char *data, Py_ssize_t len)

Return value: New reference.
Return a Python object from the data stream in a byte buffer containing *len* bytes pointed to by *data*.

On error, sets the appropriate exception (**`EOFError`**, **`ValueError`** or **`TypeError`**) and returns `NULL`.

Parsing arguments and building values

These functions are useful when creating your own extension functions and methods. Additional information and examples are available in Extending and Embedding the Python Interpreter.

The first three of these functions described, `PyArg_ParseTuple()`, `PyArg_ParseTupleAndKeywords()`, and `PyArg_Parse()`, all use *format strings* which are used to tell the function about the expected arguments. The format strings use the same syntax for each of these functions.

Parsing arguments

A format string consists of zero or more “format units.” A format unit describes one Python object; it is usually a single character or a parenthesized sequence of format units. With a few exceptions, a format unit that is not a parenthesized sequence normally corresponds to a single address argument to these functions. In the following description, the quoted form is the format unit; the entry in (round) parentheses is the Python object type that matches the format unit; and the entry in [square] brackets is the type of the C variable(s) whose address should be passed.

Strings and buffers

Note

On Python 3.12 and older, the macro **`PY_SSIZE_T_CLEAN`** must be defined before including `Python.h` to use all `#` variants of formats (`s#`, `y#`, etc.) explained below. This is not necessary on Python 3.13 and later.

These formats allow accessing an object as a contiguous chunk of memory. You don't have to provide raw storage for the returned unicode or bytes area.

Unless otherwise stated, buffers are not NUL-terminated.

There are three ways strings and buffers can be converted to C:

- Formats such as `y*` and `s*` fill a `Py_buffer` structure. This locks the underlying buffer so that the caller can subsequently use the buffer even inside a `Py_BEGIN_ALLOW_THREADS` block without the risk of mutable data being resized or destroyed. As a result, **you have to call** `PyBuffer_Release()` after you have finished processing the data (or in any early abort case).

- The `es`, `es#`, `et` and `et#` formats allocate the result buffer. **You have to call** `PyMem_Free()` after you have finished processing the data (or in any early abort case).

- Other formats take a `str` or a read-only bytes-like object, such as `bytes`, and provide a `const char *` pointer to its buffer. In this case the buffer is "borrowed": it is managed by the corresponding Python object, and shares the lifetime of this object. You won't have to release any memory yourself.

  To ensure that the underlying buffer may be safely borrowed, the object's `PyBufferProcs.bf_releasebuffer` field must be `NULL`. This disallows common mutable objects such as `bytearray`, but also some read-only objects such as `memoryview` of `bytes`.

Besides this `bf_releasebuffer` requirement, there is no check to verify whether the input object is immutable (e.g. whether it would honor a request for a writable buffer, or whether another thread can mutate the data).

`s` (`str`) [const char *]

Convert a Unicode object to a C pointer to a character string. A pointer to an existing string is stored in the character pointer variable whose address you pass. The C string is NUL-terminated. The Python string must not contain embedded null code points; if it does, a `ValueError` exception is raised. Unicode objects are converted to C strings using `'utf-8'` encoding. If this conversion fails, a `UnicodeError` is raised.

Note

This format does not accept bytes-like objects. If you want to accept filesystem paths and convert them to C character strings, it is preferable to use the `O&` format with `PyUnicode_FSConverter()` as *converter*.

Changed in version 3.5: Previously, `TypeError` was raised when embedded null code points were encountered in the Python string.

`s*` (`str` or bytes-like object) [Py_buffer]

This format accepts Unicode objects as well as bytes-like objects. It fills a `Py_buffer` structure provided by the caller. In this case the resulting C string may contain embedded NUL bytes. Unicode objects are converted to C strings using `'utf-8'` encoding.

`s#` (**`str`**, read-only bytes-like object) [const char *, **`Py_ssize_t`**]

Like `s*`, except that it provides a borrowed buffer. The result is stored into two C variables, the first one a pointer to a C string, the second one its length. The string may contain embedded null bytes. Unicode objects are converted to C strings using `'utf-8'` encoding.

`z` (**`str`** or `None`) [const char *]

Like `s`, but the Python object may also be `None`, in which case the C pointer is set to `NULL`.

`z*` (**`str`**, bytes-like object or `None`) [Py_buffer]

Like `s*`, but the Python object may also be `None`, in which case the `buf` member of the **`Py_buffer`** structure is set to `NULL`.

`z#` (**`str`**, read-only bytes-like object or `None`) [const char *, **`Py_ssize_t`**]

Like `s#`, but the Python object may also be `None`, in which case the C pointer is set to `NULL`.

`y` (read-only bytes-like object) [const char *]

This format converts a bytes-like object to a C pointer to a borrowed character string; it does not accept Unicode objects. The bytes buffer must not contain embedded null bytes; if it does, a **`ValueError`** exception is raised.

Changed in version 3.5: Previously, **`TypeError`** was raised when embedded null bytes were encountered in the bytes buffer.

`y*` (bytes-like object) [Py_buffer]

This variant on `s*` doesn’t accept Unicode objects, only bytes-like objects. **This is the recommended way to accept binary data.**

`y#` (read-only bytes-like object) [const char *, `Py_ssize_t`]

This variant on `s#` doesn't accept Unicode objects, only bytes-like objects.

`S` (`bytes`) [PyBytesObject *]

Requires that the Python object is a `bytes` object, without attempting any conversion. Raises `TypeError` if the object is not a bytes object. The C variable may also be declared as PyObject*.

`Y` (`bytearray`) [PyByteArrayObject *]

Requires that the Python object is a `bytearray` object, without attempting any conversion. Raises `TypeError` if the object is not a `bytearray` object. The C variable may also be declared as PyObject*.

`U` (`str`) [PyObject *]

Requires that the Python object is a Unicode object, without attempting any conversion. Raises `TypeError` if the object is not a Unicode object. The C variable may also be declared as PyObject*.

`w*` (read-write bytes-like object) [Py_buffer]

This format accepts any object which implements the read-write buffer interface. It fills a `Py_buffer` structure provided by the caller. The buffer may contain embedded null bytes. The caller has to call `PyBuffer_Release()` when it is done with the buffer.

`es` (`str`) [const char *encoding, char **buffer]

This variant on `s` is used for encoding Unicode into a character buffer. It only works for encoded data without embedded NUL bytes.

This format requires two arguments. The first is only used as input, and must be a const char* which points to the name of an encoding as a NUL-terminated string, or `NULL`, in which case `'utf-8'` encoding is used. An exception is raised if the named encoding is not known to Python. The second argument must be a char**; the value of the pointer it references will be set to a buffer with the contents of the argument text. The text will be encoded in the encoding specified by the first argument.

`PyArg_ParseTuple()` will allocate a buffer of the needed size, copy the encoded data into this buffer and adjust **buffer* to reference the newly allocated storage. The caller is responsible for calling `PyMem_Free()` to free the allocated buffer after use.

`et` (`str`, `bytes` or `bytearray`) [const char *encoding, char **buffer]

Same as `es` except that byte string objects are passed through without recoding them. Instead, the implementation assumes that the byte string object uses the encoding passed in as parameter.

`es#` (`str`) [const char *encoding, char **buffer, `Py_ssize_t` *buffer_length]

This variant on `s#` is used for encoding Unicode into a character buffer. Unlike the `es` format, this variant allows input data which contains NUL characters.

It requires three arguments. The first is only used as input, and must be a const char* which points to the name of an encoding as a NUL-terminated string, or `NULL`, in which case `'utf-8'` encoding is used. An exception is raised if the named encoding is not known to Python. The second argument must be a char**; the value of the pointer it references will be set to a buffer with the contents of the argument text. The text will be encoded in the encoding specified by the first argument. The third argument must be a pointer to an integer; the referenced integer will be set to the number of bytes in the output buffer.

There are two modes of operation:

If **buffer* points a `NULL` pointer, the function will allocate a buffer of the needed size, copy the encoded data into this buffer and set **buffer* to reference the newly allocated storage. The caller is responsible for calling `PyMem_Free()` to free the allocated buffer after usage.

If **buffer* points to a non-`NULL` pointer (an already allocated buffer), `PyArg_ParseTuple()` will use this location as the buffer and interpret the initial value of **buffer_length* as the buffer size. It will then copy the encoded data into the buffer and NUL-terminate it. If the buffer is not large enough, a `ValueError` will be set.

In both cases, **buffer_length* is set to the length of the encoded data without the trailing NUL byte.

`et#` (`str`, `bytes` or `bytearray`) [const char *encoding, char **buffer, `Py_ssize_t` *buffer_length]

Same as `es#` except that byte string objects are passed through without recoding them. Instead, the implementation assumes that the byte string object uses the encoding passed in as parameter.

Changed in version 3.12: `u`, `u#`, `Z`, and `Z#` are removed because they used a legacy `Py_UNICODE*` representation.

Numbers

These formats allow representing Python numbers or single characters as C numbers. Formats that require `int`, `float` or `complex` can also use the corresponding special methods `__index__()`, `__float__()` or `__complex__()` to convert the Python object to the required type.

For signed integer formats, `OverflowError` is raised if the value is out of range for the C type. For unsigned integer formats, no range checking is done — the most significant bits are silently truncated when the receiving field is too small to receive the value.

`b` (`int`) [unsigned char]
: Convert a nonnegative Python integer to an unsigned tiny integer, stored in a C unsigned char.

`B` (`int`) [unsigned char]
: Convert a Python integer to a tiny integer without overflow checking, stored in a C unsigned char.

`h` (`int`) [short int]
: Convert a Python integer to a C short int.

`H` (`int`) [unsigned short int]
: Convert a Python integer to a C unsigned short int, without overflow checking.

`i` (`int`) [int]
: Convert a Python integer to a plain C int.

`I` (`int`) [unsigned int]
: Convert a Python integer to a C unsigned int, without overflow checking.

`l` (`int`) [long int]
: Convert a Python integer to a C long int.

`k` (`int`) [unsigned long]

Convert a Python integer to a C unsigned long without overflow checking.

Changed in version 3.14: Use `__index__()` if available.

`L` (`int`) [long long]
Convert a Python integer to a C long long.

`K` (`int`) [unsigned long long]
Convert a Python integer to a C unsigned long long without overflow checking.

Changed in version 3.14: Use `__index__()` if available.

`n` (`int`) [`Py_ssize_t`]
Convert a Python integer to a C `Py_ssize_t`.

`c` (`bytes` or `bytearray` of length 1) [char]
Convert a Python byte, represented as a `bytes` or `bytearray` object of length 1, to a C char.

Changed in version 3.3: Allow `bytearray` objects.

`C` (`str` of length 1) [int]
Convert a Python character, represented as a `str` object of length 1, to a C int.

`f` (`float`) [float]
Convert a Python floating-point number to a C float.

`d` (`float`) [double]
Convert a Python floating-point number to a C double.

`D` (`complex`) [Py_complex]
Convert a Python complex number to a C `Py_complex` structure.

Other objects

`O` (object) [PyObject *]

Store a Python object (without any conversion) in a C object pointer. The C program thus receives the actual object that was passed. A new strong reference to the object is not created (i.e. its reference count is not increased). The pointer stored is not `NULL`.

`O!` (object) [*typeobject*, PyObject *]

Store a Python object in a C object pointer. This is similar to `O`, but takes two C arguments: the first is the address of a Python type object, the second is the address of the C variable (of type PyObject*) into which the object pointer is stored. If the Python object does not have the required type, **`TypeError`** is raised.

`O&` (object) [*converter*, *address*]

Convert a Python object to a C variable through a *converter* function. This takes two arguments: the first is a function, the second is the address of a C variable (of arbitrary type), converted to void*. The *converter* function in turn is called as follows:

```
status = converter(object, address);
```

where *object* is the Python object to be converted and *address* is the void* argument that was passed to the `PyArg_Parse*` function. The returned *status* should be `1` for a successful conversion and `0` if the conversion has failed. When the conversion fails, the *converter* function should raise an exception and leave the content of *address* unmodified.

If the *converter* returns **`Py_CLEANUP_SUPPORTED`**, it may get called a second time if the argument parsing eventually fails, giving the converter a chance to release any memory that it had already allocated. In this second call, the *object* parameter will be `NULL`; *address* will have the same value as in the original call.

Examples of converters: **`PyUnicode_FSConverter()`** and **`PyUnicode_FSDecoder()`**.

Changed in version 3.1: **`Py_CLEANUP_SUPPORTED`** was added.

`p` (**`bool`**) [int]

Tests the value passed in for truth (a boolean **p**redicate) and converts the result to its equivalent C true/false integer value. Sets the int to `1` if the expression was true and `0` if it was false. This accepts any valid Python value. See Truth Value Testing for more information about how Python tests values for truth.

Added in version 3.3.

`(items)` (sequence) [*matching-items*]

The object must be a Python sequence (except **`str`**, **`bytes`** or **`bytearray`**) whose length is the number of format units in *items*. The C arguments must correspond to the individual format units in *items*. Format units for sequences may be nested.

If *items* contains format units which store a borrowed buffer (`s`, `s#`, `z`, `z#`, `y`, or `y#`) or a borrowed reference (`S`, `Y`, `U`, `O`, or `O!`), the object must be a Python tuple. The *converter* for the `O&` format unit in *items* must not store a borrowed buffer or a borrowed reference.

Changed in version 3.14: **`str`** and **`bytearray`** objects no longer accepted as a sequence.

Deprecated since version 3.14: Non-tuple sequences are deprecated if *items* contains format units which store a borrowed buffer or a borrowed reference.

A few other characters have a meaning in a format string. These may not occur inside nested parentheses. They are:

|

Indicates that the remaining arguments in the Python argument list are optional. The C variables corresponding to optional arguments should be initialized to their default value — when an optional argument is not specified, `PyArg_ParseTuple()` does not touch the contents of the corresponding C variable(s).

$

`PyArg_ParseTupleAndKeywords()` only: Indicates that the remaining arguments in the Python argument list are keyword-only. Currently, all keyword-only arguments must also be optional arguments, so `|` must always be specified before `$` in the format string.

Added in version 3.3.

:

The list of format units ends here; the string after the colon is used as the function name in error messages (the “associated value” of the exception that `PyArg_ParseTuple()` raises).

;

The list of format units ends here; the string after the semicolon is used as the error message *instead* of the default error message. `:` and `;` mutually exclude each other.

Note that any Python object references which are provided to the caller are *borrowed* references; do not release them (i.e. do not decrement their reference count)!

Additional arguments passed to these functions must be addresses of variables whose type is determined by the format string; these are used to store values from the input tuple. There are a few cases, as described in the list of format units above, where these parameters are used as input values; they should match what is specified for the corresponding format unit in that case.

For the conversion to succeed, the *arg* object must match the format and the format must be exhausted. On success, the `PyArg_Parse*` functions return true, otherwise they return false and raise an appropriate exception. When the `PyArg_Parse*` functions fail due to conversion failure in one of the format units, the variables at the addresses corresponding to that and the following format units are left untouched.

API Functions

int PyArg_ParseTuple(PyObject *args, const char *format, ...)

Part of the Stable ABI.

Parse the parameters of a function that takes only positional parameters into local variables. Returns true on success; on failure, it returns false and raises the appropriate exception.

int PyArg_VaParse(PyObject *args, const char *format, va_list vargs)

Part of the Stable ABI.

Identical to **`PyArg_ParseTuple()`**, except that it accepts a va_list rather than a variable number of arguments.

int PyArg_ParseTupleAndKeywords(PyObject *args, PyObject *kw, const char *format, char *const *keywords, ...)

Part of the Stable ABI.
Parse the parameters of a function that takes both positional and keyword parameters into local variables. The *keywords* argument is a `NULL`-terminated array of keyword parameter names specified as null-terminated ASCII or UTF-8 encoded C strings. Empty names denote positional-only parameters. Returns true on success; on failure, it returns false and raises the appropriate exception.

Note

The *keywords* parameter declaration is char *const* in C and const char *const* in C++. This can be overridden with the **`PY_CXX_CONST`** macro.

Changed in version 3.6: Added support for positional-only parameters.

Changed in version 3.13: The *keywords* parameter has now type char *const* in C and const char *const* in C++, instead of char**. Added support for non-ASCII keyword parameter names.

int PyArg_VaParseTupleAndKeywords(PyObject *args, PyObject *kw, const char *format, char *const *keywords, va_list vargs)

Part of the Stable ABI.
Identical to **`PyArg_ParseTupleAndKeywords()`**, except that it accepts a va_list rather than a variable number of arguments.

int PyArg_ValidateKeywordArguments(PyObject*)

Part of the Stable ABI.
Ensure that the keys in the keywords argument dictionary are strings. This is only needed if **`PyArg_ParseTupleAndKeywords()`** is not used, since the latter already does this check.

Added in version 3.2.

int PyArg_Parse(PyObject *args, const char *format, ...)

Part of the Stable ABI.
Parse the parameter of a function that takes a single positional parameter into a local variable. Returns true on success; on failure, it returns false and raises the appropriate exception.

Example:

```
// Function using METH_O calling convention
static PyObject*
my_function(PyObject *module, PyObject *arg)
{
    int value;
    if (!PyArg_Parse(arg, "i:my_function", &value)) {
        return NULL;
    }
    // ... use value ...
}
```

int PyArg_UnpackTuple(PyObject *args, const char *name, Py_ssize_t min, Py_ssize_t max, ...)

Part of the Stable ABI.
A simpler form of parameter retrieval which does not use a format string to specify the types of the arguments. Functions which use this method to retrieve their parameters should be declared as **`METH_VARARGS`** in function or method tables. The tuple containing the actual parameters should be passed as *args*; it must actually be

a tuple. The length of the tuple must be at least *min* and no more than *max*; *min* and *max* may be equal. Additional arguments must be passed to the function, each of which should be a pointer to a PyObject* variable; these will be filled in with the values from *args*; they will contain borrowed references. The variables which correspond to optional parameters not given by *args* will not be filled in; these should be initialized by the caller. This function returns true on success and false if *args* is not a tuple or contains the wrong number of elements; an exception will be set if there was a failure.

This is an example of the use of this function, taken from the sources for the **`_weakref`** helper module for weak references:

```
static PyObject *
weakref_ref(PyObject *self, PyObject *args)
{
    PyObject *object;
    PyObject *callback = NULL;
    PyObject *result = NULL;

    if (PyArg_UnpackTuple(args, "ref", 1, 2, &object,
&callback)) {
        result = PyWeakref_NewRef(object, callback);
    }
    return result;
}
```

The call to **`PyArg_UnpackTuple()`** in this example is entirely equivalent to this call to **`PyArg_ParseTuple()`**:

```
PyArg_ParseTuple(args, "O|O:ref", &object, &callback)
```

PY_CXX_CONST

The value to be inserted, if any, before char *const* in the *keywords* parameter declaration of **`PyArg_ParseTupleAndKeywords()`** and

`PyArg_VaParseTupleAndKeywords()`. Default empty for C and `const` for C++ (const char *const*). To override, define it to the desired value before including `Python.h`.

Added in version 3.13.

Building values

PyObject *Py_BuildValue(const char *format, ...)

Return value: New reference. Part of the Stable ABI. Create a new value based on a format string similar to those accepted by the `PyArg_Parse*` family of functions and a sequence of values. Returns the value or `NULL` in the case of an error; an exception will be raised if `NULL` is returned.

`Py_BuildValue()` does not always build a tuple. It builds a tuple only if its format string contains two or more format units. If the format string is empty, it returns `None`; if it contains exactly one format unit, it returns whatever object is described by that format unit. To force it to return a tuple of size 0 or one, parenthesize the format string.

When memory buffers are passed as parameters to supply data to build objects, as for the `s` and `s#` formats, the required data is copied. Buffers provided by the caller are never referenced by the objects created by **`Py_BuildValue()`**. In other words, if your code invokes **`malloc()`** and passes the allocated memory to **`Py_BuildValue()`**, your code is responsible for calling **`free()`** for that memory once **`Py_BuildValue()`** returns.

In the following description, the quoted form is the format unit; the entry in (round) parentheses is the Python object type that the format unit will return; and the entry in [square] brackets is the type of the C value(s) to be passed.

The characters space, tab, colon and comma are ignored in format strings (but not within format units such as `s#`). This can be used to make long format strings a tad more readable.

`s` (**`str`** or `None`) [const char *]
: Convert a null-terminated C string to a Python **`str`** object using `'utf-8'` encoding. If the C string pointer is `NULL`, `None` is used.

`s#` (**`str`** or `None`) [const char *, **`Py_ssize_t`**]
: Convert a C string and its length to a Python **`str`** object using `'utf-8'` encoding. If the C string pointer is `NULL`, the length is ignored and `None` is returned.

`y` (**`bytes`**) [const char *]
: This converts a C string to a Python **`bytes`** object. If the C string pointer is `NULL`, `None` is returned.

`y#` (**`bytes`**) [const char *, **`Py_ssize_t`**]
: This converts a C string and its lengths to a Python object. If the C string pointer is `NULL`, `None` is returned.

`z` (**`str`** or `None`) [const char *]
: Same as `s`.

`z#` (**`str`** or `None`) [const char *, **`Py_ssize_t`**]
: Same as `s#`.

`u` (**`str`**) [const wchar_t *]
: Convert a null-terminated **`wchar_t`** buffer of Unicode (UTF-16 or UCS-4) data to a Python Unicode object. If the Unicode buffer pointer is `NULL`, `None` is returned.

`u#` (str) [const wchar_t *, Py_ssize_t]
Convert a Unicode (UTF-16 or UCS-4) data buffer and its length to a Python Unicode object. If the Unicode buffer pointer is `NULL`, the length is ignored and `None` is returned.

`U` (str or `None`) [const char *]
Same as `s`.

`U#` (str or `None`) [const char *, Py_ssize_t]
Same as `s#`.

`i` (int) [int]
Convert a plain C int to a Python integer object.

`b` (int) [char]
Convert a plain C char to a Python integer object.

`h` (int) [short int]
Convert a plain C short int to a Python integer object.

`l` (int) [long int]
Convert a C long int to a Python integer object.

`B` (int) [unsigned char]
Convert a C unsigned char to a Python integer object.

`H` (int) [unsigned short int]
Convert a C unsigned short int to a Python integer object.

`I` (int) [unsigned int]
Convert a C unsigned int to a Python integer object.

`k` (int) [unsigned long]
Convert a C unsigned long to a Python integer object.

`L` (**int**) [long long]
: Convert a C long long to a Python integer object.

`K` (**int**) [unsigned long long]
: Convert a C unsigned long long to a Python integer object.

`n` (**int**) [**Py_ssize_t**]
: Convert a C **Py_ssize_t** to a Python integer.

`p` (**bool**) [int]
: Convert a C int to a Python **bool** object.

Be aware that this format requires an `int` argument. Unlike most other contexts in C, variadic arguments are not coerced to a suitable type automatically. You can convert another type (for example, a pointer or a float) to a suitable `int` value using `(x) ? 1 : 0` or `!!x`.

Added in version 3.14.

`c` (**bytes** of length 1) [char]
: Convert a C int representing a byte to a Python **bytes** object of length 1.

`C` (**str** of length 1) [int]
: Convert a C int representing a character to Python **str** object of length 1.

`d` (**float**) [double]
: Convert a C double to a Python floating-point number.

`f` (**float**) [float]
: Convert a C float to a Python floating-point number.

`D` (**complex**) [Py_complex *]

Convert a C **`Py_complex`** structure to a Python complex number.

`O` (object) [PyObject *]
: Pass a Python object untouched but create a new strong reference to it (i.e. its reference count is incremented by one). If the object passed in is a `NULL` pointer, it is assumed that this was caused because the call producing the argument found an error and set an exception. Therefore, **`Py_BuildValue()`** will return `NULL` but won't raise an exception. If no exception has been raised yet, **`SystemError`** is set.

`S` (object) [PyObject *]
: Same as `O`.

`N` (object) [PyObject *]
: Same as `O`, except it doesn't create a new strong reference. Useful when the object is created by a call to an object constructor in the argument list.

`O&` (object) [*converter*, *anything*]
: Convert *anything* to a Python object through a *converter* function. The function is called with *anything* (which should be compatible with void*) as its argument and should return a "new" Python object, or `NULL` if an error occurred.

`(items)` (**`tuple`**) [*matching-items*]
: Convert a sequence of C values to a Python tuple with the same number of items.

`[items]` (**`list`**) [*matching-items*]
: Convert a sequence of C values to a Python list with the same number of items.

`{items}` (`dict`) [*matching-items*]

Convert a sequence of C values to a Python dictionary. Each pair of consecutive C values adds one item to the dictionary, serving as key and value, respectively.

If there is an error in the format string, the `SystemError` exception is set and `NULL` returned.

PyObject *Py_VaBuildValue(const char *format, va_list vargs)

Return value: New reference. Part of the Stable ABI. Identical to `Py_BuildValue()`, except that it accepts a va_list rather than a variable number of arguments.

String conversion and formatting

Functions for number conversion and formatted string output.

int PyOS_snprintf(char *str, size_t size, const char *format, ...)

Part of the Stable ABI.
Output not more than *size* bytes to *str* according to the format string *format* and the extra arguments. See the Unix man page *snprintf(3)* *[https://manpages.debian.org/snprintf(3)]*.

int PyOS_vsnprintf(char *str, size_t size, const char *format, va_list va)

Part of the Stable ABI.
Output not more than *size* bytes to *str* according to the format string *format* and the variable argument list *va*. Unix man page *vsnprintf(3)* *[https://manpages.debian.org/vsnprintf(3)]*.

`PyOS_snprintf()` and **`PyOS_vsnprintf()`** wrap the Standard C library functions **`snprintf()`** and **`vsnprintf()`**. Their purpose is to guarantee consistent behavior in corner cases, which the Standard C functions do not.

The wrappers ensure that `str[size-1]` is always `'\0'` upon return. They never write more than *size* bytes (including the trailing `'\0'`) into str. Both functions require that `str != NULL`, `size > 0`, `format != NULL` and `size < INT_MAX`. Note that this means there is no equivalent to the C99 `n = snprintf(NULL, 0, ...)` which would determine the necessary buffer size.

The return value (*rv*) for these functions should be interpreted as follows:

- When `0 <= rv < size`, the output conversion was successful and *rv* characters were written to *str* (excluding the trailing `'\0'` byte at `str[rv]`).
- When `rv >= size`, the output conversion was truncated and a buffer with `rv + 1` bytes would have been needed to succeed. `str[size-1]` is `'\0'` in this case.
- When `rv < 0`, the output conversion failed and `str[size-1]` is `'\0'` in this case too, but the rest of *str* is undefined. The exact cause of the error depends on the underlying platform.

The following functions provide locale-independent string to number conversions.

unsigned long PyOS_strtoul(const char *str, char **ptr, int base)

Part of the Stable ABI.
Convert the initial part of the string in `str` to an unsigned long value according to the given `base`, which must be between `2` and `36` inclusive, or be the special value `0`.

Leading white space and case of characters are ignored. If `base` is zero it looks for a leading `0b`, `0o` or `0x` to tell which base. If these are absent it defaults to `10`. Base must be 0 or between 2 and 36 (inclusive). If `ptr` is non-`NULL` it will contain a pointer to the end of the scan.

If the converted value falls out of range of corresponding return type, range error occurs (**`errno`** is set to **`ERANGE`**) and

`ULONG_MAX` is returned. If no conversion can be performed, `0` is returned.

See also the Unix man page *strtoul(3)* *[https://manpages.debian.org/strtoul(3)]*.

Added in version 3.2.

long PyOS_strtol(const char *str, char **ptr, int base)

Part of the Stable ABI.
Convert the initial part of the string in `str` to an long value according to the given `base`, which must be between `2` and `36` inclusive, or be the special value `0`.

Same as **`PyOS_strtoul()`**, but return a long value instead and **`LONG_MAX`** on overflows.

See also the Unix man page *strtol(3)* *[https://manpages.debian.org/strtol(3)]*.

Added in version 3.2.

double PyOS_string_to_double(const char *s, char **endptr, PyObject *overflow_exception)

Part of the Stable ABI.
Convert a string `s` to a double, raising a Python exception on failure. The set of accepted strings corresponds to the set of strings accepted by Python's **`float()`** constructor, except that `s` must not have leading or trailing whitespace. The conversion is independent of the current locale.

If `endptr` is `NULL`, convert the whole string. Raise **`ValueError`** and return `-1.0` if the string is not a valid representation of a floating-point number.

If endptr is not `NULL`, convert as much of the string as possible and set `*endptr` to point to the first unconverted character. If no initial segment of the string is the valid representation of a floating-point number, set `*endptr` to point to the beginning of the string, raise ValueError, and return `-1.0`.

If `s` represents a value that is too large to store in a float (for example, `"1e500"` is such a string on many platforms) then if `overflow_exception` is `NULL` return `Py_INFINITY` (with an appropriate sign) and don’t set any exception. Otherwise, `overflow_exception` must point to a Python exception object; raise that exception and return `-1.0`. In both cases, set `*endptr` to point to the first character after the converted value.

If any other error occurs during the conversion (for example an out-of-memory error), set the appropriate Python exception and return `-1.0`.

Added in version 3.1.

char *PyOS_double_to_string(double val, char format_code, int precision, int flags, int *ptype)

Part of the Stable ABI.
Convert a double *val* to a string using supplied *format_code*, *precision*, and *flags*.

format_code must be one of `'e'`, `'E'`, `'f'`, `'F'`, `'g'`, `'G'` or `'r'`. For `'r'`, the supplied *precision* must be 0 and is ignored. The `'r'` format code specifies the standard **`repr()`** format.

flags can be zero or more of the following values or-ed together:

Py_DTSF_SIGN

Always precede the returned string with a sign character, even if *val* is non-negative.

Py_DTSF_ADD_DOT_0

Ensure that the returned string will not look like an integer.

Py_DTSF_ALT

Apply “alternate” formatting rules. See the documentation for the **`PyOS_snprintf()`** `'#'` specifier for details.

Py_DTSF_NO_NEG_0

Negative zero is converted to positive zero.

Added in version 3.11.

If *ptype* is non-`NULL`, then the value it points to will be set to one of `Py_DTST_FINITE`, `Py_DTST_INFINITE`, or `Py_DTST_NAN`, signifying that *val* is a finite number, an infinite number, or not a number, respectively.

The return value is a pointer to *buffer* with the converted string or `NULL` if the conversion failed. The caller is responsible for freeing the returned string by calling **`PyMem_Free()`**.

Added in version 3.1.

int PyOS_mystricmp(const char *str1, const char *str2)
int PyOS_mystrnicmp(const char *str1, const char *str2, Py_ssize_t size)

Part of the Stable ABI.
Case insensitive comparison of strings. These functions work almost identically to **`strcmp()`** and **`strncmp()`**

(respectively), except that they ignore the case of ASCII characters.

Return `0` if the strings are equal, a negative value if *str1* sorts lexicographically before *str2*, or a positive value if it sorts after.

In the *str1* or *str2* arguments, a NUL byte marks the end of the string. For **`PyOS_mystrnicmp()`**, the *size* argument gives the maximum size of the string, as if NUL was present at the index given by *size*.

These functions do not use the locale.

int PyOS_stricmp(const char *str1, const char *str2)
int PyOS_strnicmp(const char *str1, const char *str2, Py_ssize_t size)

Case insensitive comparison of strings.

On Windows, these are aliases of **`stricmp()`** and **`strnicmp()`**, respectively.

On other platforms, they are aliases of **`PyOS_mystricmp()`** and **`PyOS_mystrnicmp()`**, respectively.

Character classification and conversion

The following macros provide locale-independent (unlike the C standard library `ctype.h`) character classification and conversion. The argument must be a signed or unsigned char.

Py_ISALNUM(c)

Return true if the character *c* is an alphanumeric character.

Py_ISALPHA(c)

Return true if the character *c* is an alphabetic character (`a-z` and `A-Z`).

Py_ISDIGIT(c)

Return true if the character *c* is a decimal digit (`0-9`).

Py_ISLOWER(c)

Return true if the character *c* is a lowercase ASCII letter (`a-z`).

Py_ISUPPER(c)

Return true if the character *c* is an uppercase ASCII letter (`A-Z`).

Py_ISSPACE(c)

Return true if the character *c* is a whitespace character (space, tab, carriage return, newline, vertical tab, or form feed).

Py_ISXDIGIT(c)

Return true if the character *c* is a hexadecimal digit (`0-9`, `a-f`, and `A-F`).

Py_TOLOWER(c)

Return the lowercase equivalent of the character *c*.

Py_TOUPPER(c)

Return the uppercase equivalent of the character *c*.

PyHash API

See also the `PyTypeObject.tp_hash` member and Hashing of numeric types.

type Py_hash_t

Hash value type: signed integer.

Added in version 3.2.

type Py_uhash_t

Hash value type: unsigned integer.

Added in version 3.2.

Py_HASH_ALGORITHM

A numerical value indicating the algorithm for hashing of `str`, `bytes`, and `memoryview`.

The algorithm name is exposed by `sys.hash_info.algorithm`.

Added in version 3.4.

Py_HASH_FNV
Py_HASH_SIPHASH24
Py_HASH_SIPHASH13

Numerical values to compare to `Py_HASH_ALGORITHM` to determine which algorithm is used for hashing. The hash algorithm can be configured via the configure `--with-hash-algorithm` option.

Added in version 3.4: Add **`Py_HASH_FNV`** and **`Py_HASH_SIPHASH24`**.

Added in version 3.11: Add **`Py_HASH_SIPHASH13`**.

Py_HASH_CUTOFF

Buffers of length in range `[1, Py_HASH_CUTOFF)` are hashed using DJBX33A instead of the algorithm described by **`Py_HASH_ALGORITHM`**.

- A **`Py_HASH_CUTOFF`** of 0 disables the optimization.
- **`Py_HASH_CUTOFF`** must be non-negative and less or equal than 7.

32-bit platforms should use a cutoff smaller than 64-bit platforms because it is easier to create colliding strings. A cutoff of 7 on 64-bit platforms and 5 on 32-bit platforms should provide a decent safety margin.

This corresponds to the **`sys.hash_info.cutoff`** constant.

Added in version 3.4.

PyHASH_MODULUS

The Mersenne prime [https://en.wikipedia.org/wiki/Mersenne_prime] `P = 2**n -1`, used for numeric hash scheme.

This corresponds to the **`sys.hash_info.modulus`** constant.

Added in version 3.13.

PyHASH_BITS

The exponent `n` of `P` in **`PyHASH_MODULUS`**.

Added in version 3.13.

PyHASH_MULTIPLIER

Prime multiplier used in string and various other hashes.

Added in version 3.13.

PyHASH_INF

The hash value returned for a positive infinity.

This corresponds to the `sys.hash_info.inf` constant.

Added in version 3.13.

PyHASH_IMAG

The multiplier used for the imaginary part of a complex number.

This corresponds to the `sys.hash_info.imag` constant.

Added in version 3.13.

type PyHash_FuncDef

Hash function definition used by `PyHash_GetFuncDef()`.

Py_hash_t (*const hash)(const void*, Py_ssize_t)

Hash function.

const char *name

Hash function name (UTF-8 encoded string).

This corresponds to the `sys.hash_info.algorithm` constant.

const int hash_bits

Internal size of the hash value in bits.

This corresponds to the `sys.hash_info.hash_bits` constant.

const int seed_bits

Size of seed input in bits.

This corresponds to the `sys.hash_info.seed_bits` constant.

Added in version 3.4.

PyHash_FuncDef *PyHash_GetFuncDef(void)

Get the hash function definition.

See also

PEP 456 [https://peps.python.org/pep-0456/] “Secure and interchangeable hash algorithm”.

Added in version 3.4.

Py_hash_t Py_HashPointer(const void *ptr)

Hash a pointer value: process the pointer value as an integer (cast it to `uintptr_t` internally). The pointer is not dereferenced.

The function cannot fail: it cannot return `-1`.

Added in version 3.13.

Py_hash_t Py_HashBuffer(const void *ptr, Py_ssize_t len)

Compute and return the hash value of a buffer of *len* bytes starting at address *ptr*. The hash is guaranteed to match that of `bytes`, `memoryview`, and other built-in objects that implement the buffer protocol.

Use this function to implement hashing for immutable objects whose `tp_richcompare` function compares to another object’s buffer.

len must be greater than or equal to `0`.

This function always succeeds.

Added in version 3.14.

Py_hash_t PyObject_GenericHash(PyObject *obj)

Generic hashing function that is meant to be put into a type object's `tp_hash` slot. Its result only depends on the object's identity.

CPython implementation detail: In CPython, it is equivalent to **`Py_HashPointer()`**.

Added in version 3.13.

Reflection

PyObject *PyEval_GetBuiltins(void)

Return value: Borrowed reference. Part of the Stable ABI.
Deprecated since version 3.13: Use `PyEval_GetFrameBuiltins()` instead.

Return a dictionary of the builtins in the current execution frame, or the interpreter of the thread state if no frame is currently executing.

PyObject *PyEval_GetLocals(void)

Return value: Borrowed reference. Part of the Stable ABI.
Deprecated since version 3.13: Use either `PyEval_GetFrameLocals()` to obtain the same behaviour as calling `locals()` in Python code, or else call `PyFrame_GetLocals()` on the result of `PyEval_GetFrame()` to access the `f_locals` attribute of the currently executing frame.

Return a mapping providing access to the local variables in the current execution frame, or `NULL` if no frame is currently executing.

Refer to `locals()` for details of the mapping returned at different scopes.

As this function returns a borrowed reference, the dictionary returned for optimized scopes is cached on the frame object and will remain alive as long as the frame object does. Unlike `PyEval_GetFrameLocals()` and `locals()`, subsequent calls to this function in the same frame will update the contents of the cached dictionary to reflect changes in the state of the local variables rather than returning a new snapshot.

Changed in version 3.13: As part of **PEP 667** [https://peps.python.org/pep-0667/], **`PyFrame_GetLocals()`**, **`locals()`**, and **`FrameType.f_locals`** no longer make use of the shared cache dictionary. Refer to the What's New entry for additional details.

PyObject *PyEval_GetGlobals(void)

Return value: Borrowed reference. Part of the Stable ABI.
Deprecated since version 3.13: Use **`PyEval_GetFrameGlobals()`** instead.

Return a dictionary of the global variables in the current execution frame, or `NULL` if no frame is currently executing.

PyFrameObject *PyEval_GetFrame(void)

Return value: Borrowed reference. Part of the Stable ABI.
Return the attached thread state's frame, which is `NULL` if no frame is currently executing.

See also **`PyThreadState_GetFrame()`**.

PyObject *PyEval_GetFrameBuiltins(void)

Return value: New reference. Part of the Stable ABI since version 3.13.
Return a dictionary of the builtins in the current execution frame, or the interpreter of the thread state if no frame is currently executing.

Added in version 3.13.

PyObject *PyEval_GetFrameLocals(void)

Return value: New reference. Part of the Stable ABI since version 3.13.
Return a dictionary of the local variables in the current execution frame, or `NULL` if no frame is currently executing. Equivalent to calling **`locals()`** in Python code.

To access **`f_locals`** on the current frame without making an independent snapshot in optimized scopes, call **`PyFrame_GetLocals()`** on the result of **`PyEval_GetFrame()`**.

Added in version 3.13.

PyObject *PyEval_GetFrameGlobals(void)

Return value: New reference. Part of the Stable ABI since version 3.13.
Return a dictionary of the global variables in the current execution frame, or `NULL` if no frame is currently executing. Equivalent to calling **`globals()`** in Python code.

Added in version 3.13.

const char *PyEval_GetFuncName(PyObject *func)

Part of the Stable ABI.
Return the name of *func* if it is a function, class or instance object, else the name of *func*s type.

const char *PyEval_GetFuncDesc(PyObject *func)

Part of the Stable ABI.
Return a description string, depending on the type of *func*. Return values include “()” for functions and methods, “ constructor”, “ instance”, and “ object”. Concatenated with the result of **`PyEval_GetFuncName()`**, the result will be a description of *func*.

Codec registry and support functions

int PyCodec_Register(PyObject *search_function)

Part of the Stable ABI.

Register a new codec search function.

As a side effect, this tries to load the `encodings` package, if not yet done, to make sure that it is always first in the list of search functions.

int PyCodec_Unregister(PyObject *search_function)

Part of the Stable ABI since version 3.10.

Unregister a codec search function and clear the registry’s cache. If the search function is not registered, do nothing. Return 0 on success. Raise an exception and return -1 on error.

Added in version 3.10.

int PyCodec_KnownEncoding(const char *encoding)

Part of the Stable ABI.

Return `1` or `0` depending on whether there is a registered codec for the given *encoding*. This function always succeeds.

PyObject *PyCodec_Encode(PyObject *object, const char *encoding, const char *errors)

Return value: New reference. Part of the Stable ABI.

Generic codec based encoding API.

object is passed through the encoder function found for the given *encoding* using the error handling method defined by *errors*. *errors* may be `NULL` to use the default method defined for the codec. Raises a **`LookupError`** if no encoder can be found.

PyObject *PyCodec_Decode(PyObject *object, const char *encoding, const char *errors)

Return value: New reference. Part of the Stable ABI.
Generic codec based decoding API.

object is passed through the decoder function found for the given *encoding* using the error handling method defined by *errors*. *errors* may be `NULL` to use the default method defined for the codec. Raises a **`LookupError`** if no decoder can be found.

Codec lookup API

In the following functions, the *encoding* string is looked up converted to all lower-case characters, which makes encodings looked up through this mechanism effectively case-insensitive. If no codec is found, a **`KeyError`** is set and `NULL` returned.

PyObject *PyCodec_Encoder(const char *encoding)

Return value: New reference. Part of the Stable ABI.
Get an encoder function for the given *encoding*.

PyObject *PyCodec_Decoder(const char *encoding)

Return value: New reference. Part of the Stable ABI.
Get a decoder function for the given *encoding*.

PyObject *PyCodec_IncrementalEncoder(const char *encoding, const char *errors)

Return value: New reference. Part of the Stable ABI.
Get an `IncrementalEncoder` object for the given *encoding*.

PyObject *PyCodec_IncrementalDecoder(const char *encoding, const char *errors)

Return value: New reference. Part of the Stable ABI.
Get an `IncrementalDecoder` object for the given *encoding*.

PyObject *PyCodec_StreamReader(const char *encoding, PyObject *stream, const char *errors)

Return value: New reference. Part of the Stable ABI.
Get a `StreamReader` factory function for the given *encoding*.

PyObject *PyCodec_StreamWriter(const char *encoding, PyObject *stream, const char *errors)

Return value: New reference. Part of the Stable ABI.
Get a `StreamWriter` factory function for the given *encoding*.

Registry API for Unicode encoding error handlers

int PyCodec_RegisterError(const char *name, PyObject *error)

Part of the Stable ABI.
Register the error handling callback function *error* under the given *name*. This callback function will be called by a codec when it encounters unencodable characters/undecodable bytes and *name* is specified as the error parameter in the call to the encode/decode function.

The callback gets a single argument, an instance of `UnicodeEncodeError`, `UnicodeDecodeError` or `UnicodeTranslateError` that holds information about the problematic sequence of characters or bytes and their offset in the original string (see Unicode Exception Objects for functions to extract this information). The callback must either raise the given exception, or return a two-item tuple containing the replacement for the problematic sequence, and an integer giving the offset in the original string at which encoding/decoding should be resumed.

Return `0` on success, `-1` on error.

PyObject *PyCodec_LookupError(const char *name)

Return value: New reference. Part of the Stable ABI.
Lookup the error handling callback function registered under *name*. As a special case `NULL` can be passed, in which case the error handling callback for “strict” will be returned.

PyObject *PyCodec_StrictErrors(PyObject *exc)

Return value: Always NULL. Part of the Stable ABI.
Raise *exc* as an exception.

PyObject *PyCodec_IgnoreErrors(PyObject *exc)

Return value: New reference. Part of the Stable ABI.
Ignore the unicode error, skipping the faulty input.

PyObject *PyCodec_ReplaceErrors(PyObject *exc)

Return value: New reference. Part of the Stable ABI.
Replace the unicode encode error with `?` or `U+FFFD`.

PyObject *PyCodec_XMLCharRefReplaceErrors(PyObject *exc)

Return value: New reference. Part of the Stable ABI.
Replace the unicode encode error with XML character references.

PyObject *PyCodec_BackslashReplaceErrors(PyObject *exc)

Return value: New reference. Part of the Stable ABI.

Replace the unicode encode error with backslash escapes (`\x`, `\u` and `\U`).

PyObject *PyCodec_NameReplaceErrors(PyObject *exc)

Return value: New reference. Part of the Stable ABI since version 3.7.

Replace the unicode encode error with `\N{...}` escapes.

Added in version 3.5.

Codec utility variables

const char *Py_hexdigits

A string constant containing the lowercase hexadecimal digits: `"0123456789abcdef"`.

Added in version 3.3.

PyTime C API

Added in version 3.13.

The clock C API provides access to system clocks. It is similar to the Python **`time`** module.

For C API related to the **`datetime`** module, see DateTime Objects.

Types

type PyTime_t

A timestamp or duration in nanoseconds, represented as a signed 64-bit integer.

The reference point for timestamps depends on the clock used. For example, **`PyTime_Time()`** returns timestamps relative to the UNIX epoch.

The supported range is around [-292.3 years; +292.3 years]. Using the Unix epoch (January 1st, 1970) as reference, the supported date range is around [1677-09-21; 2262-04-11]. The exact limits are exposed as constants:

PyTime_t PyTime_MIN

Minimum value of **`PyTime_t`**.

PyTime_t PyTime_MAX

Maximum value of **`PyTime_t`**.

Clock Functions

The following functions take a pointer to a PyTime_t that they set to the value of a particular clock. Details of each clock are given in the documentation of the corresponding Python function.

The functions return `0` on success, or `-1` (with an exception set) on failure.

On integer overflow, they set the **`PyExc_OverflowError`** exception and set `*result` to the value clamped to the `[PyTime_MIN; PyTime_MAX]` range. (On current systems, integer overflows are likely caused by misconfigured system time.)

As any other C API (unless otherwise specified), the functions must be called with an attached thread state.

int PyTime_Monotonic(PyTime_t *result)

Read the monotonic clock. See **`time.monotonic()`** for important details on this clock.

int PyTime_PerfCounter(PyTime_t *result)

Read the performance counter. See **`time.perf_counter()`** for important details on this clock.

int PyTime_Time(PyTime_t *result)

Read the “wall clock” time. See **`time.time()`** for details important on this clock.

Raw Clock Functions

Similar to clock functions, but don’t set an exception on error and don’t require the caller to have an attached thread state.

On success, the functions return `0`.

On failure, they set `*result` to `0` and return `-1`, *without* setting an exception. To get the cause of the error, attach a thread state, and call the regular (non-`Raw`) function. Note that the regular function may succeed after the `Raw` one failed.

int PyTime_MonotonicRaw(PyTime_t *result)

Similar to **`PyTime_Monotonic()`**, but don't set an exception on error and don't require an attached thread state.

int PyTime_PerfCounterRaw(PyTime_t *result)

Similar to **`PyTime_PerfCounter()`**, but don't set an exception on error and don't require an attached thread state.

int PyTime_TimeRaw(PyTime_t *result)

Similar to **`PyTime_Time()`**, but don't set an exception on error and don't require an attached thread state.

Conversion functions

double PyTime_AsSecondsDouble(PyTime_t t)

Convert a timestamp to a number of seconds as a C double.

The function cannot fail, but note that double has limited accuracy for large values.

Support for Perf Maps

On supported platforms (as of this writing, only Linux), the runtime can take advantage of *perf map files* to make Python functions visible to an external profiling tool (such as perf [https://perf.wiki.kernel.org/index.php/Main_Page]). A running process may create a file in the `/tmp` directory, which contains entries that can map a section of executable code to a name. This interface is described in the documentation of the Linux Perf tool [https://git.kernel.org/pub/scm/linux/kernel/git/torvalds/linux.git/tree/tools/perf/Documentation/jit-interface.txt].

In Python, these helper APIs can be used by libraries and features that rely on generating machine code on the fly.

Note that holding an attached thread state is not required for these APIs.

int PyUnstable_PerfMapState_Init(void)

> *This is Unstable API. It may change without warning in minor releases.*

Open the `/tmp/perf-$pid.map` file, unless it's already opened, and create a lock to ensure thread-safe writes to the file (provided the writes are done through **`PyUnstable_WritePerfMapEntry()`**). Normally, there's no need to call this explicitly; just use **`PyUnstable_WritePerfMapEntry()`** and it will initialize the state on first call.

Returns `0` on success, `-1` on failure to create/open the perf map file, or `-2` on failure to create a lock. Check `errno` for more information about the cause of a failure.

int PyUnstable_WritePerfMapEntry(const void *code_addr, unsigned int code_size, const char *entry_name)

This is Unstable API. It may change without warning in minor releases.

Write one single entry to the `/tmp/perf-$pid.map` file. This function is thread safe. Here is what an example entry looks like:

```
# address      size  name
7f3529fcf759 b     py::bar:/run/t.py
```

Will call `PyUnstable_PerfMapState_Init()` before writing the entry, if the perf map file is not already opened. Returns `0` on success, or the same error codes as `PyUnstable_PerfMapState_Init()` on failure.

void PyUnstable_PerfMapState_Fini(void)

This is Unstable API. It may change without warning in minor releases.

Close the perf map file opened by `PyUnstable_PerfMapState_Init()`. This is called by the runtime itself during interpreter shut-down. In general, there shouldn't be a reason to explicitly call this, except to handle specific scenarios such as forking.

Abstract Objects Layer

The functions in this chapter interact with Python objects regardless of their type, or with wide classes of object types (e.g. all numerical types, or all sequence types). When used on object types for which they do not apply, they will raise a Python exception.

It is not possible to use these functions on objects that are not properly initialized, such as a list object that has been created by `PyList_New()`, but whose items have not been set to some non-`NULL` value yet.

Object Protocol

PyObject *Py_GetConstant(unsigned int constant_id)

Part of the Stable ABI since version 3.13.
Get a strong reference to a constant.

Set an exception and return `NULL` if *constant_id* is invalid.

constant_id must be one of these constant identifiers:

Constant Identifier	Value	Returned object
Py_CONSTANT_NONE	`0`	`None`
Py_CONSTANT_FALSE	`1`	`False`
Py_CONSTANT_TRUE	`2`	`True`
Py_CONSTANT_ELLIPSIS	`3`	`Ellipsis`
Py_CONSTANT_NOT_IMPLEMENTED	`4`	`NotImplemented`
Py_CONSTANT_ZERO	`5`	`0`
Py_CONSTANT_ONE	`6`	`1`
Py_CONSTANT_EMPTY_STR	`7`	`''`
Py_CONSTANT_EMPTY_BYTES	`8`	`b''`
Py_CONSTANT_EMPTY_TUPLE	`9`	`()`

Numeric values are only given for projects which cannot use the constant identifiers.

Added in version 3.13.

CPython implementation detail: In CPython, all of these constants are immortal.

PyObject *Py_GetConstantBorrowed(unsigned int constant_id)

Part of the Stable ABI since version 3.13.
Similar to `Py_GetConstant()`, but return a borrowed reference.

This function is primarily intended for backwards compatibility: using `Py_GetConstant()` is recommended for new code.

The reference is borrowed from the interpreter, and is valid until the interpreter finalization.

Added in version 3.13.

PyObject *Py_NotImplemented

The `NotImplemented` singleton, used to signal that an operation is not implemented for the given type combination.

Py_RETURN_NOTIMPLEMENTED

Properly handle returning `Py_NotImplemented` from within a C function (that is, create a new strong reference to `NotImplemented` and return it).

Py_PRINT_RAW

Flag to be used with multiple functions that print the object (like `PyObject_Print()` and `PyFile_WriteObject()`). If passed, these functions use the `str()` of the object instead of the `repr()`.

int PyObject_Print(PyObject *o, FILE *fp, int flags)

Print an object *o*, on file *fp*. Returns `-1` on error. The flags argument is used to enable certain printing options. The only option currently supported is `Py_PRINT_RAW`; if given, the `str()` of the object is written instead of the `repr()`.

int PyObject_HasAttrWithError(PyObject *o, PyObject *attr_name)

Part of the Stable ABI since version 3.13.
Returns `1` if *o* has the attribute *attr_name*, and `0` otherwise. This is equivalent to the Python expression `hasattr(o, attr_name)`. On failure, return `-1`.

Added in version 3.13.

int PyObject_HasAttrStringWithError(PyObject *o, const char *attr_name)

Part of the Stable ABI since version 3.13.
This is the same as `PyObject_HasAttrWithError()`, but *attr_name* is specified as a const char* UTF-8 encoded bytes string, rather than a PyObject*.

Added in version 3.13.

int PyObject_HasAttr(PyObject *o, PyObject *attr_name)

Part of the Stable ABI.
Returns `1` if *o* has the attribute *attr_name*, and `0` otherwise. This function always succeeds.

Note

Exceptions that occur when this calls `__getattr__()` and `__getattribute__()` methods aren’t propagated, but instead given to `sys.unraisablehook()`. For proper error handling, use `PyObject_HasAttrWithError()`, `PyObject_GetOptionalAttr()` or `PyObject_GetAttr()` instead.

int PyObject_HasAttrString(PyObject *o, const char *attr_name)

Part of the Stable ABI.

This is the same as `PyObject_HasAttr()`, but *attr_name* is specified as a const char* UTF-8 encoded bytes string, rather than a PyObject*.

Note

Exceptions that occur when this calls `__getattr__()` and `__getattribute__()` methods or while creating the temporary `str` object are silently ignored. For proper error handling, use `PyObject_HasAttrStringWithError()`, `PyObject_GetOptionalAttrString()` or `PyObject_GetAttrString()` instead.

PyObject *PyObject_GetAttr(PyObject *o, PyObject *attr_name)

Return value: New reference. Part of the Stable ABI.

Retrieve an attribute named *attr_name* from object *o*. Returns the attribute value on success, or `NULL` on failure. This is the equivalent of the Python expression `o.attr_name`.

If the missing attribute should not be treated as a failure, you can use `PyObject_GetOptionalAttr()` instead.

PyObject *PyObject_GetAttrString(PyObject *o, const char *attr_name)

Return value: New reference. Part of the Stable ABI.
This is the same as **`PyObject_GetAttr()`**, but *attr_name* is specified as a const char* UTF-8 encoded bytes string, rather than a PyObject*.

If the missing attribute should not be treated as a failure, you can use **`PyObject_GetOptionalAttrString()`** instead.

int PyObject_GetOptionalAttr(PyObject *obj, PyObject *attr_name, PyObject **result);

Part of the Stable ABI since version 3.13.
Variant of **`PyObject_GetAttr()`** which doesn't raise **`AttributeError`** if the attribute is not found.

If the attribute is found, return `1` and set **result* to a new strong reference to the attribute. If the attribute is not found, return `0` and set **result* to `NULL`; the **`AttributeError`** is silenced. If an error other than **`AttributeError`** is raised, return `-1` and set **result* to `NULL`.

Added in version 3.13.

int PyObject_GetOptionalAttrString(PyObject *obj, const char *attr_name, PyObject **result);

Part of the Stable ABI since version 3.13.
This is the same as **`PyObject_GetOptionalAttr()`**, but *attr_name* is specified as a const char* UTF-8 encoded bytes string, rather than a PyObject*.

Added in version 3.13.

PyObject *PyObject_GenericGetAttr(PyObject *o, PyObject *name)

Return value: New reference. Part of the Stable ABI.
Generic attribute getter function that is meant to be put into a type object's `tp_getattro` slot. It looks for a

descriptor in the dictionary of classes in the object's MRO as well as an attribute in the object's `__dict__` (if present). As outlined in Implementing Descriptors, data descriptors take preference over instance attributes, while non-data descriptors don't. Otherwise, an `AttributeError` is raised.

int PyObject_SetAttr(PyObject *o, PyObject *attr_name, PyObject *v)

Part of the Stable ABI.
Set the value of the attribute named *attr_name*, for object *o*, to the value *v*. Raise an exception and return `-1` on failure; return `0` on success. This is the equivalent of the Python statement `o.attr_name = v`.

If *v* is `NULL`, the attribute is deleted. This behaviour is deprecated in favour of using `PyObject_DelAttr()`, but there are currently no plans to remove it.

int PyObject_SetAttrString(PyObject *o, const char *attr_name, PyObject *v)

Part of the Stable ABI.
This is the same as `PyObject_SetAttr()`, but *attr_name* is specified as a const char* UTF-8 encoded bytes string, rather than a PyObject*.

If *v* is `NULL`, the attribute is deleted, but this feature is deprecated in favour of using `PyObject_DelAttrString()`.

The number of different attribute names passed to this function should be kept small, usually by using a statically allocated string as *attr_name*. For attribute names that aren't known at compile time, prefer calling `PyUnicode_FromString()` and `PyObject_SetAttr()` directly. For more details, see `PyUnicode_InternFromString()`, which may be used internally to create a key object.

int PyObject_GenericSetAttr(PyObject *o, PyObject *name, PyObject *value)

Part of the Stable ABI.

Generic attribute setter and deleter function that is meant to be put into a type object's **`tp_setattro`** slot. It looks for a data descriptor in the dictionary of classes in the object's MRO, and if found it takes preference over setting or deleting the attribute in the instance dictionary. Otherwise, the attribute is set or deleted in the object's **`__dict__`** (if present). On success, `0` is returned, otherwise an **`AttributeError`** is raised and `-1` is returned.

int PyObject_DelAttr(PyObject *o, PyObject *attr_name)

Part of the Stable ABI since version 3.13.

Delete attribute named *attr_name*, for object *o*. Returns `-1` on failure. This is the equivalent of the Python statement `del o.attr_name`.

int PyObject_DelAttrString(PyObject *o, const char *attr_name)

Part of the Stable ABI since version 3.13.

This is the same as **`PyObject_DelAttr()`**, but *attr_name* is specified as a const char* UTF-8 encoded bytes string, rather than a PyObject*.

The number of different attribute names passed to this function should be kept small, usually by using a statically allocated string as *attr_name*. For attribute names that aren't known at compile time, prefer calling **`PyUnicode_FromString()`** and **`PyObject_DelAttr()`** directly. For more details, see **`PyUnicode_InternFromString()`**, which may be used internally to create a key object for lookup.

PyObject *PyObject_GenericGetDict(PyObject *o, void *context)

Return value: New reference. Part of the Stable ABI since version 3.10.

A generic implementation for the getter of a `__dict__` descriptor. It creates the dictionary if necessary.

This function may also be called to get the **`__dict__`** of the object *o*. Pass `NULL` for *context* when calling it. Since this function may need to allocate memory for the dictionary, it may be more efficient to call **`PyObject_GetAttr()`** when accessing an attribute on the object.

On failure, returns `NULL` with an exception set.

Added in version 3.3.

int PyObject_GenericSetDict(PyObject *o, PyObject *value, void *context)

Part of the Stable ABI since version 3.7.

A generic implementation for the setter of a `__dict__` descriptor. This implementation does not allow the dictionary to be deleted.

Added in version 3.3.

PyObject **_PyObject_GetDictPtr(PyObject *obj)

Return a pointer to **`__dict__`** of the object *obj*. If there is no `__dict__`, return `NULL` without setting an exception.

This function may need to allocate memory for the dictionary, so it may be more efficient to call **`PyObject_GetAttr()`** when accessing an attribute on the object.

PyObject *PyObject_RichCompare(PyObject *o1, PyObject *o2, int opid)

Return value: New reference. Part of the Stable ABI.

Compare the values of *o1* and *o2* using the operation specified by *opid*, which must be one of **`Py_LT`**, **`Py_LE`**, **`Py_EQ`**, **`Py_NE`**, **`Py_GT`**, or **`Py_GE`**, corresponding to `<`, `<=`, `==`, `!=`, `>`, or `>=` respectively. This is the equivalent of the Python expression `o1 op o2`, where `op` is the operator corresponding to *opid*. Returns the value of the comparison on success, or `NULL` on failure.

int PyObject_RichCompareBool(PyObject *o1, PyObject *o2, int opid)

Part of the Stable ABI.

Compare the values of *o1* and *o2* using the operation specified by *opid*, like **`PyObject_RichCompare()`**, but returns `-1` on error, `0` if the result is false, `1` otherwise.

Note

If *o1* and *o2* are the same object, **`PyObject_RichCompareBool()`** will always return `1` for **`Py_EQ`** and `0` for **`Py_NE`**.

PyObject *PyObject_Format(PyObject *obj, PyObject *format_spec)

Part of the Stable ABI.

Format *obj* using *format_spec*. This is equivalent to the Python expression `format(obj, format_spec)`.

format_spec may be `NULL`. In this case the call is equivalent to `format(obj)`. Returns the formatted string on success, `NULL` on failure.

PyObject *PyObject_Repr(PyObject *o)

Return value: New reference. Part of the Stable ABI. Compute a string representation of object *o*. Returns the string representation on success, `NULL` on failure. This is the equivalent of the Python expression `repr(o)`. Called by the **`repr()`** built-in function.

Changed in version 3.4: This function now includes a debug assertion to help ensure that it does not silently discard an active exception.

PyObject *PyObject_ASCII(PyObject *o)

Return value: New reference. Part of the Stable ABI. As **`PyObject_Repr()`**, compute a string representation of object *o*, but escape the non-ASCII characters in the string returned by **`PyObject_Repr()`** with `\x`, `\u` or `\U` escapes. This generates a string similar to that returned by **`PyObject_Repr()`** in Python 2. Called by the **`ascii()`** built-in function.

PyObject *PyObject_Str(PyObject *o)

Return value: New reference. Part of the Stable ABI. Compute a string representation of object *o*. Returns the string representation on success, `NULL` on failure. This is the equivalent of the Python expression `str(o)`. Called by the **`str()`** built-in function and, therefore, by the **`print()`** function.

Changed in version 3.4: This function now includes a debug assertion to help ensure that it does not silently discard an active exception.

PyObject *PyObject_Bytes(PyObject *o)

Return value: New reference. Part of the Stable ABI. Compute a bytes representation of object *o*. `NULL` is returned on failure and a bytes object on success. This is equivalent to the Python expression `bytes(o)`, when *o* is not an integer. Unlike `bytes(o)`, a TypeError is raised when *o* is an integer instead of a zero-initialized bytes object.

int PyObject_IsSubclass(PyObject *derived, PyObject *cls)

Part of the Stable ABI.

Return `1` if the class *derived* is identical to or derived from the class *cls*, otherwise return `0`. In case of an error, return `-1`.

If *cls* is a tuple, the check will be done against every entry in *cls*. The result will be `1` when at least one of the checks returns `1`, otherwise it will be `0`.

If *cls* has a **`__subclasscheck__()`** method, it will be called to determine the subclass status as described in **PEP 3119** [https://peps.python.org/pep-3119/]. Otherwise, *derived* is a subclass of *cls* if it is a direct or indirect subclass, i.e. contained in **`cls.__mro__`**.

Normally only class objects, i.e. instances of **`type`** or a derived class, are considered classes. However, objects can override this by having a **`__bases__`** attribute (which must be a tuple of base classes).

int PyObject_IsInstance(PyObject *inst, PyObject *cls)

Part of the Stable ABI.

Return `1` if *inst* is an instance of the class *cls* or a subclass of *cls*, or `0` if not. On error, returns `-1` and sets an exception.

If *cls* is a tuple, the check will be done against every entry in *cls*. The result will be `1` when at least one of the checks returns `1`, otherwise it will be `0`.

If *cls* has a **`__instancecheck__()`** method, it will be called to determine the subclass status as described in **PEP 3119** [https://peps.python.org/pep-3119/]. Otherwise, *inst* is an instance of *cls* if its class is a subclass of *cls*.

An instance *inst* can override what is considered its class by having a **`__class__`** attribute.

An object *cls* can override if it is considered a class, and what its base classes are, by having a **`__bases__`** attribute (which must be a tuple of base classes).

Py_hash_t PyObject_Hash(PyObject *o)

Part of the Stable ABI.
Compute and return the hash value of an object *o*. On failure, return `-1`. This is the equivalent of the Python expression `hash(o)`.

Changed in version 3.2: The return type is now Py_hash_t. This is a signed integer the same size as **`Py_ssize_t`**.

Py_hash_t PyObject_HashNotImplemented(PyObject *o)

Part of the Stable ABI.
Set a **`TypeError`** indicating that `type(o)` is not hashable and return `-1`. This function receives special treatment when stored in a `tp_hash` slot, allowing a type to explicitly indicate to the interpreter that it is not hashable.

int PyObject_IsTrue(PyObject *o)

Part of the Stable ABI.
Returns `1` if the object *o* is considered to be true, and `0` otherwise. This is equivalent to the Python expression `not not o`. On failure, return `-1`.

int PyObject_Not(PyObject *o)

Part of the Stable ABI.

Returns `0` if the object *o* is considered to be true, and `1` otherwise. This is equivalent to the Python expression `not o`. On failure, return `-1`.

PyObject *PyObject_Type(PyObject *o)

Return value: New reference. Part of the Stable ABI.
When *o* is non-`NULL`, returns a type object corresponding to the object type of object *o*. On failure, raises **`SystemError`** and returns `NULL`. This is equivalent to the Python expression `type(o)`. This function creates a new strong reference to the return value. There's really no reason to use this function instead of the **`Py_TYPE()`** function, which returns a pointer of type PyTypeObject*, except when a new strong reference is needed.

int PyObject_TypeCheck(PyObject *o, PyTypeObject *type)

Return non-zero if the object *o* is of type *type* or a subtype of *type*, and `0` otherwise. Both parameters must be non-`NULL`.

Py_ssize_t PyObject_Size(PyObject *o)
Py_ssize_t PyObject_Length(PyObject *o)

Part of the Stable ABI.
Return the length of object *o*. If the object *o* provides either the sequence and mapping protocols, the sequence length is returned. On error, `-1` is returned. This is the equivalent to the Python expression `len(o)`.

Py_ssize_t PyObject_LengthHint(PyObject *o, Py_ssize_t defaultvalue)

Return an estimated length for the object *o*. First try to return its actual length, then an estimate using **`__length_hint__()`**, and finally return the default value. On error return `-1`. This is the equivalent to the Python expression `operator.length_hint(o, defaultvalue)`.

Added in version 3.4.

PyObject *PyObject_GetItem(PyObject *o, PyObject *key)

Return value: New reference. Part of the Stable ABI.

Return element of *o* corresponding to the object *key* or `NULL` on failure. This is the equivalent of the Python expression `o[key]`.

int PyObject_SetItem(PyObject *o, PyObject *key, PyObject *v)

Part of the Stable ABI.

Map the object *key* to the value *v*. Raise an exception and return `-1` on failure; return `0` on success. This is the equivalent of the Python statement `o[key] = v`. This function *does not* steal a reference to *v*.

int PyObject_DelItem(PyObject *o, PyObject *key)

Part of the Stable ABI.

Remove the mapping for the object *key* from the object *o*. Return `-1` on failure. This is equivalent to the Python statement `del o[key]`.

int PyObject_DelItemString(PyObject *o, const char *key)

Part of the Stable ABI.

This is the same as **`PyObject_DelItem()`**, but *key* is specified as a const char* UTF-8 encoded bytes string, rather than a PyObject*.

PyObject *PyObject_Dir(PyObject *o)

Return value: New reference. Part of the Stable ABI.

This is equivalent to the Python expression `dir(o)`, returning a (possibly empty) list of strings appropriate for the object argument, or `NULL` if there was an error. If the argument is `NULL`, this is like the Python `dir()`, returning the names of the current locals; in this case, if no execution frame is active then `NULL` is returned but **`PyErr_Occurred()`** will return false.

PyObject *PyObject_GetIter(PyObject *o)

Return value: New reference. Part of the Stable ABI.
This is equivalent to the Python expression `iter(o)`. It returns a new iterator for the object argument, or the object itself if the object is already an iterator. Raises **`TypeError`** and returns `NULL` if the object cannot be iterated.

PyObject *PyObject_SelfIter(PyObject *obj)

Return value: New reference. Part of the Stable ABI.
This is equivalent to the Python `__iter__(self): return self` method. It is intended for iterator types, to be used in the **`PyTypeObject.tp_iter`** slot.

PyObject *PyObject_GetAIter(PyObject *o)

Return value: New reference. Part of the Stable ABI since version 3.10.
This is the equivalent to the Python expression `aiter(o)`. Takes an **`AsyncIterable`** object and returns an **`AsyncIterator`** for it. This is typically a new iterator but if the argument is an **`AsyncIterator`**, this returns itself. Raises **`TypeError`** and returns `NULL` if the object cannot be iterated.

Added in version 3.10.

void *PyObject_GetTypeData(PyObject *o, PyTypeObject *cls)

Part of the Stable ABI since version 3.12.
Get a pointer to subclass-specific data reserved for *cls*.

The object *o* must be an instance of *cls*, and *cls* must have been created using negative **`PyType_Spec.basicsize`**. Python does not check this.

On error, set an exception and return `NULL`.

Added in version 3.12.

Py_ssize_t PyType_GetTypeDataSize(PyTypeObject *cls)

Part of the Stable ABI since version 3.12.
Return the size of the instance memory space reserved for *cls*, i.e. the size of the memory **`PyObject_GetTypeData()`** returns.

This may be larger than requested using **`-PyType_Spec.basicsize`**; it is safe to use this larger size (e.g. with **`memset()`**).

The type *cls* **must** have been created using negative **`PyType_Spec.basicsize`**. Python does not check this.

On error, set an exception and return a negative value.

Added in version 3.12.

void *PyObject_GetItemData(PyObject *o)

Get a pointer to per-item data for a class with **`Py_TPFLAGS_ITEMS_AT_END`**.

On error, set an exception and return `NULL`. **`TypeError`** is raised if *o* does not have **`Py_TPFLAGS_ITEMS_AT_END`** set.

Added in version 3.12.

int PyObject_VisitManagedDict(PyObject *obj, visitproc visit, void *arg)

Visit the managed dictionary of *obj*.

This function must only be called in a traverse function of the type which has the **`Py_TPFLAGS_MANAGED_DICT`** flag set.

Added in version 3.13.

void PyObject_ClearManagedDict(PyObject *obj)

Clear the managed dictionary of *obj*.

This function must only be called in a clear function of the type which has the `Py_TPFLAGS_MANAGED_DICT` flag set.

Added in version 3.13.

int PyUnstable_Object_EnableDeferredRefcount(PyObject *obj)

This is Unstable API. It may change without warning in minor releases.

Enable deferred reference counting [https://peps.python.org/pep-0703/#deferred-reference-counting] on *obj*, if supported by the runtime. In the free-threaded build, this allows the interpreter to avoid reference count adjustments to *obj*, which may improve multi-threaded performance. The tradeoff is that *obj* will only be deallocated by the tracing garbage collector, and not when the interpreter no longer has any references to it.

This function returns `1` if deferred reference counting is enabled on *obj*, and `0` if deferred reference counting is not supported or if the hint was ignored by the interpreter, such as when deferred reference counting is already enabled on *obj*. This function is thread-safe, and cannot fail.

This function does nothing on builds with the GIL enabled, which do not support deferred reference counting. This also does nothing if *obj* is not an object tracked by the garbage collector (see `gc.is_tracked()` and `PyObject_GC_IsTracked()`).

This function is intended to be used soon after *obj* is created, by the code that creates it, such as in the object's **`tp_new`** slot.

Added in version 3.14.

int PyUnstable_Object_IsUniqueReferencedTemporary(PyObject *obj)

This is Unstable API. It may change without warning in minor releases.

Check if *obj* is a unique temporary object. Returns `1` if *obj* is known to be a unique temporary object, and `0` otherwise. This function cannot fail, but the check is conservative, and may return `0` in some cases even if *obj* is a unique temporary object.

If an object is a unique temporary, it is guaranteed that the current code has the only reference to the object. For arguments to C functions, this should be used instead of checking if the reference count is `1`. Starting with Python 3.14, the interpreter internally avoids some reference count modifications when loading objects onto the operands stack by borrowing references when possible, which means that a reference count of `1` by itself does not guarantee that a function argument uniquely referenced.

In the example below, `my_func` is called with a unique temporary object as its argument:

```
my_func([1, 2, 3])
```

In the example below, `my_func` is **not** called with a unique temporary object as its argument, even if its refcount is

```
1:

my_list = [1, 2, 3]
my_func(my_list)
```

See also the function `Py_REFCNT()`.

Added in version 3.14.

int PyUnstable_IsImmortal(PyObject *obj)

This is Unstable API. It may change without warning in minor releases.

This function returns non-zero if *obj* is immortal, and zero otherwise. This function cannot fail.

Note

Objects that are immortal in one CPython version are not guaranteed to be immortal in another.

Added in version 3.14.

int PyUnstable_TryIncRef(PyObject *obj)

This is Unstable API. It may change without warning in minor releases.

Increments the reference count of *obj* if it is not zero. Returns `1` if the object’s reference count was successfully incremented. Otherwise, this function returns `0`.

`PyUnstable_EnableTryIncRef()` must have been called earlier on *obj* or this function may spuriously return `0` in the free threading build.

This function is logically equivalent to the following C code, except that it behaves atomically in the free threading build:

```
if (Py_REFCNT(op) > 0) {
   Py_INCREF(op);
   return 1;
}
return 0;
```

This is intended as a building block for managing weak references without the overhead of a Python weak reference object.

Typically, correct use of this function requires support from *obj*’s deallocator (**`tp_dealloc`**). For example, the following sketch could be adapted to implement a “weakmap” that works like a **`WeakValueDictionary`** for a specific type:

```
PyMutex mutex;

PyObject *
add_entry(weakmap_key_type *key, PyObject *value)
{
    PyUnstable_EnableTryIncRef(value);
    weakmap_type weakmap = ...;
    PyMutex_Lock(&mutex);
    weakmap_add_entry(weakmap, key, value);
    PyMutex_Unlock(&mutex);
    Py_RETURN_NONE;
}

PyObject *
get_value(weakmap_key_type *key)
{
    weakmap_type weakmap = ...;
    PyMutex_Lock(&mutex);
    PyObject *result = weakmap_find(weakmap, key);
    if (PyUnstable_TryIncRef(result)) {
        // `result` is safe to use
        PyMutex_Unlock(&mutex);
        return result;
    }
    // if we get here, `result` is starting to be garbage-
collected,
    // but has not been removed from the weakmap yet
    PyMutex_Unlock(&mutex);
    return NULL;
}

// tp_dealloc function for weakmap values
void
value_dealloc(PyObject *value)
{
    weakmap_type weakmap = ...;
    PyMutex_Lock(&mutex);
    weakmap_remove_value(weakmap, value);

    ...
    PyMutex_Unlock(&mutex);
}
```

Added in version 3.14.

void PyUnstable_EnableTryIncRef(PyObject *obj)

This is Unstable API. It may change without warning in minor releases.

Enables subsequent uses of **`PyUnstable_TryIncRef()`** on *obj*. The caller must hold a strong reference to *obj* when calling this.

Added in version 3.14.

int PyUnstable_Object_IsUniquelyReferenced(PyObject *op)

This is Unstable API. It may change without warning in minor releases.

Determine if *op* only has one reference.

On GIL-enabled builds, this function is equivalent to Py_REFCNT(op) == 1.

On a free threaded build, this checks if *op*’s reference count is equal to one and additionally checks if *op* is only used by this thread. Py_REFCNT(op) == 1 is **not** thread-safe on free threaded builds; prefer this function.

The caller must hold an attached thread state, despite the fact that this function doesn’t call into the Python interpreter. This function cannot fail.

Added in version 3.14.

Call Protocol

CPython supports two different calling protocols: *tp_call* and vectorcall.

The *tp_call* Protocol

Instances of classes that set **`tp_call`** are callable. The signature of the slot is:

```
PyObject *tp_call(PyObject *callable, PyObject *args, PyObject
*kwargs);
```

A call is made using a tuple for the positional arguments and a dict for the keyword arguments, similarly to `callable(*args, **kwargs)` in Python code. *args* must be non-NULL (use an empty tuple if there are no arguments) but *kwargs* may be *NULL* if there are no keyword arguments.

This convention is not only used by *tp_call*: **`tp_new`** and **`tp_init`** also pass arguments this way.

To call an object, use **`PyObject_Call()`** or another call API.

The Vectorcall Protocol

Added in version 3.9.

The vectorcall protocol was introduced in **PEP 590** [https://peps.python.org/pep-0590/] as an additional protocol for making calls more efficient.

As rule of thumb, CPython will prefer the vectorcall for internal calls if the callable supports it. However, this is not a hard rule. Additionally, some third-party extensions use *tp_call* directly (rather than using `PyObject_Call()`). Therefore, a class supporting vectorcall must also implement `tp_call`. Moreover, the callable must behave the same regardless of which protocol is used. The recommended way to achieve this is by setting `tp_call` to `PyVectorcall_Call()`. This bears repeating:

Warning

A class supporting vectorcall **must** also implement `tp_call` with the same semantics.

Changed in version 3.12: The `Py_TPFLAGS_HAVE_VECTORCALL` flag is now removed from a class when the class's `__call__()` method is reassigned. (This internally sets `tp_call` only, and thus may make it behave differently than the vectorcall function.) In earlier Python versions, vectorcall should only be used with `immutable` or static types.

A class should not implement vectorcall if that would be slower than *tp_call*. For example, if the callee needs to convert the arguments to an args tuple and kwargs dict anyway, then there is no point in implementing vectorcall.

Classes can implement the vectorcall protocol by enabling the `Py_TPFLAGS_HAVE_VECTORCALL` flag and setting `tp_vectorcall_offset` to the offset inside the object structure where a *vectorcallfunc* appears. This is a pointer to a function with the following signature:

typedef PyObject *(*vectorcallfunc)(PyObject *callable, PyObject *const *args, size_t nargsf, PyObject *kwnames)

Part of the Stable ABI since version 3.12.

- *callable* is the object being called.
- *args* is a C array consisting of the positional arguments followed by the
  values of the keyword arguments. This can be *NULL* if there are no arguments.

- *nargsf* is the number of positional arguments plus possibly the
  `PY_VECTORCALL_ARGUMENTS_OFFSET` flag. To get the actual number of positional arguments from *nargsf*, use **`PyVectorcall_NARGS()`**.

- *kwnames* is a tuple containing the names of the keyword arguments;
  in other words, the keys of the kwargs dict. These names must be strings (instances of `str` or a subclass) and they must be unique. If there are no keyword arguments, then *kwnames* can instead be *NULL*.

PY_VECTORCALL_ARGUMENTS_OFFSET

Part of the Stable ABI since version 3.12.
If this flag is set in a vectorcall *nargsf* argument, the callee is allowed to temporarily change `args[-1]`. In other words, *args* points to argument 1 (not 0) in the allocated vector. The callee must restore the value of `args[-1]` before returning.

For **`PyObject_VectorcallMethod()`**, this flag means instead that `args[0]` may be changed.

Whenever they can do so cheaply (without additional allocation), callers are encouraged to use **`PY_VECTORCALL_ARGUMENTS_OFFSET`**. Doing so will allow callables such as bound methods to make their onward calls (which include a prepended *self* argument) very efficiently.

Added in version 3.8.

To call an object that implements vectorcall, use a call API function as with any other callable. `PyObject_Vectorcall()` will usually be most efficient.

Recursion Control

When using *tp_call*, callees do not need to worry about recursion: CPython uses `Py_EnterRecursiveCall()` and `Py_LeaveRecursiveCall()` for calls made using *tp_call*.

For efficiency, this is not the case for calls done using vectorcall: the callee should use *Py_EnterRecursiveCall* and *Py_LeaveRecursiveCall* if needed.

Vectorcall Support API

Py_ssize_t PyVectorcall_NARGS(size_t nargsf)

Part of the Stable ABI since version 3.12.
Given a vectorcall *nargsf* argument, return the actual number of arguments. Currently equivalent to:

```
(Py_ssize_t)(nargsf & ~PY_VECTORCALL_ARGUMENTS_OFFSET)
```

However, the function `PyVectorcall_NARGS` should be used to allow for future extensions.

Added in version 3.8.

vectorcallfunc PyVectorcall_Function(PyObject *op)

If *op* does not support the vectorcall protocol (either because the type does not or because the specific instance does not), return *NULL*. Otherwise, return the vectorcall function pointer stored in *op*. This function never raises an exception.

This is mostly useful to check whether or not *op* supports vectorcall, which can be done by checking

`PyVectorcall_Function(op) != NULL`.

Added in version 3.9.

PyObject *PyVectorcall_Call(PyObject *callable, PyObject *tuple, PyObject *dict)

Part of the Stable ABI since version 3.12.
Call *callable*'s **`vectorcallfunc`** with positional and keyword arguments given in a tuple and dict, respectively.

This is a specialized function, intended to be put in the **`tp_call`** slot or be used in an implementation of `tp_call`. It does not check the **`Py_TPFLAGS_HAVE_VECTORCALL`** flag and it does not fall back to `tp_call`.

Added in version 3.8.

Object Calling API

Various functions are available for calling a Python object. Each converts its arguments to a convention supported by the called object – either *tp_call* or vectorcall. In order to do as little conversion as possible, pick one that best fits the format of data you have available.

The following table summarizes the available functions; please see individual documentation for details.

Function	callable	args	kwargs
`PyObject_Call()`	`PyObject *`	tuple	dict/`NULL`

Function	callable	args	kwargs
`PyObject_CallNoArgs()`	`PyObject *`	—	—
`PyObject_CallOneArg()`	`PyObject *`	1 object	—
`PyObject_CallObject()`	`PyObject *`	tuple/`NULL`	—
`PyObject_CallFunction()`	`PyObject *`	format	—
`PyObject_CallMethod()`	obj + `char*`	format	—
`PyObject_CallFunctionObjArgs()`	`PyObject *`	variadic	—
`PyObject_CallMethodObjArgs()`	obj + name	variadic	—
`PyObject_CallMethodNoArgs()`	obj + name	—	—
`PyObject_CallMethodOneArg()`	obj + name	1 object	—

Function	**callable**	**args**	**kwargs**
`PyObject_Vectorcall()`	`PyObject *`	vectorcall	vectorcall
`PyObject_VectorcallDict()`	`PyObject *`	vectorcall	dict/`NULL`
`PyObject_VectorcallMethod()`	arg + name	vectorcall	vectorcall

PyObject *PyObject_Call(PyObject *callable, PyObject *args, PyObject *kwargs)

Return value: New reference. Part of the Stable ABI.
Call a callable Python object *callable*, with arguments given by the tuple *args*, and named arguments given by the dictionary *kwargs*.

args must not be *NULL*; use an empty tuple if no arguments are needed. If no named arguments are needed, *kwargs* can be *NULL*.

Return the result of the call on success, or raise an exception and return *NULL* on failure.

This is the equivalent of the Python expression: `callable(*args, **kwargs)`.

PyObject *PyObject_CallNoArgs(PyObject *callable)

Return value: New reference. Part of the Stable ABI since version 3.10.

Call a callable Python object *callable* without any arguments. It is the most efficient way to call a callable Python object without any argument.

Return the result of the call on success, or raise an exception and return *NULL* on failure.

Added in version 3.9.

PyObject *PyObject_CallOneArg(PyObject *callable, PyObject *arg)

Return value: New reference.
Call a callable Python object *callable* with exactly 1 positional argument *arg* and no keyword arguments.

Return the result of the call on success, or raise an exception and return *NULL* on failure.

Added in version 3.9.

PyObject *PyObject_CallObject(PyObject *callable, PyObject *args)

Return value: New reference. Part of the Stable ABI.
Call a callable Python object *callable*, with arguments given by the tuple *args*. If no arguments are needed, then *args* can be *NULL*.

Return the result of the call on success, or raise an exception and return *NULL* on failure.

This is the equivalent of the Python expression: `callable(*args)`.

PyObject *PyObject_CallFunction(PyObject *callable, const char *format, ...)

Return value: New reference. Part of the Stable ABI.

Call a callable Python object *callable*, with a variable number of C arguments. The C arguments are described using a **`Py_BuildValue()`** style format string. The format can be *NULL*, indicating that no arguments are provided.

Return the result of the call on success, or raise an exception and return *NULL* on failure.

This is the equivalent of the Python expression: `callable(*args)`.

Note that if you only pass PyObject* args, **`PyObject_CallFunctionObjArgs()`** is a faster alternative.

Changed in version 3.4: The type of *format* was changed from `char *`.

PyObject *PyObject_CallMethod(PyObject *obj, const char *name, const char *format, ...)

Return value: New reference. Part of the Stable ABI.
Call the method named *name* of object *obj* with a variable number of C arguments. The C arguments are described by a **`Py_BuildValue()`** format string that should produce a tuple.

The format can be *NULL*, indicating that no arguments are provided.

Return the result of the call on success, or raise an exception and return *NULL* on failure.

This is the equivalent of the Python expression: `obj.name(arg1, arg2, ...)`.

Note that if you only pass PyObject* args, **`PyObject_CallMethodObjArgs()`** is a faster alternative.

Changed in version 3.4: The types of *name* and *format* were changed from `char *`.

PyObject *PyObject_CallFunctionObjArgs(PyObject *callable, ...)

Return value: New reference. Part of the Stable ABI.
Call a callable Python object *callable*, with a variable number of PyObject* arguments. The arguments are provided as a variable number of parameters followed by *NULL*.

Return the result of the call on success, or raise an exception and return *NULL* on failure.

This is the equivalent of the Python expression: `callable(arg1, arg2, ...)`.

PyObject *PyObject_CallMethodObjArgs(PyObject *obj, PyObject *name, ...)

Return value: New reference. Part of the Stable ABI.
Call a method of the Python object *obj*, where the name of the method is given as a Python string object in *name*. It is called with a variable number of PyObject* arguments. The arguments are provided as a variable number of parameters followed by *NULL*.

Return the result of the call on success, or raise an exception and return *NULL* on failure.

PyObject *PyObject_CallMethodNoArgs(PyObject *obj, PyObject *name)

Call a method of the Python object *obj* without arguments, where the name of the method is given as a Python string object in *name*.

Return the result of the call on success, or raise an exception and return *NULL* on failure.

Added in version 3.9.

PyObject *PyObject_CallMethodOneArg(PyObject *obj, PyObject *name, PyObject *arg)

Call a method of the Python object *obj* with a single positional argument *arg*, where the name of the method is given as a Python string object in *name*.

Return the result of the call on success, or raise an exception and return *NULL* on failure.

Added in version 3.9.

PyObject *PyObject_Vectorcall(PyObject *callable, PyObject *const *args, size_t nargsf, PyObject *kwnames)

Part of the Stable ABI since version 3.12.
Call a callable Python object *callable*. The arguments are the same as for **`vectorcallfunc`**. If *callable* supports vectorcall, this directly calls the vectorcall function stored in *callable*.

Return the result of the call on success, or raise an exception and return *NULL* on failure.

Added in version 3.8: as `_PyObject_Vectorcall`

Changed in version 3.9: Renamed to the current name, without the leading underscore. The old provisional name is soft deprecated.

PyObject *PyObject_VectorcallDict(PyObject *callable, PyObject *const *args, size_t nargsf, PyObject *kwdict)

Call *callable* with positional arguments passed exactly as in the vectorcall protocol, but with keyword arguments passed as a dictionary *kwdict*. The *args* array contains only the positional arguments.

Regardless of which protocol is used internally, a conversion of arguments needs to be done. Therefore, this function should only be used if the caller already has a dictionary ready to use for the keyword arguments, but not a tuple for the positional arguments.

Added in version 3.9.

PyObject *PyObject_VectorcallMethod(PyObject *name, PyObject *const *args, size_t nargsf, PyObject *kwnames)

Part of the Stable ABI since version 3.12.
Call a method using the vectorcall calling convention. The name of the method is given as a Python string *name*. The object whose method is called is *args[0]*, and the *args* array starting at *args[1]* represents the arguments of the call. There must be at least one positional argument. *nargsf* is the number of positional arguments including *args[0]*, plus **`PY_VECTORCALL_ARGUMENTS_OFFSET`** if the value of `args[0]` may temporarily be changed. Keyword arguments can be passed just like in **`PyObject_Vectorcall()`**.

If the object has the **`Py_TPFLAGS_METHOD_DESCRIPTOR`** feature, this will call the unbound method object with the full *args* vector as arguments.

Return the result of the call on success, or raise an exception and return *NULL* on failure.

Added in version 3.9.

Call Support API

int PyCallable_Check(PyObject *o)

Part of the Stable ABI.

Determine if the object *o* is callable. Return `1` if the object is callable and `0` otherwise. This function always succeeds.

Number Protocol

int PyNumber_Check(PyObject *o)

Part of the Stable ABI.

Returns `1` if the object *o* provides numeric protocols, and false otherwise. This function always succeeds.

Changed in version 3.8: Returns `1` if *o* is an index integer.

PyObject *PyNumber_Add(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI.

Returns the result of adding *o1* and *o2*, or `NULL` on failure. This is the equivalent of the Python expression `o1 + o2`.

PyObject *PyNumber_Subtract(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI.

Returns the result of subtracting *o2* from *o1*, or `NULL` on failure. This is the equivalent of the Python expression `o1 - o2`.

PyObject *PyNumber_Multiply(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI.

Returns the result of multiplying *o1* and *o2*, or `NULL` on failure. This is the equivalent of the Python expression `o1 * o2`.

PyObject *PyNumber_MatrixMultiply(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI since version 3.7.

Returns the result of matrix multiplication on *o1* and *o2*, or `NULL` on failure. This is the equivalent of the Python expression `o1 @ o2`.

Added in version 3.5.

PyObject *PyNumber_FloorDivide(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI.
Return the floor of *o1* divided by *o2*, or `NULL` on failure. This is the equivalent of the Python expression `o1 // o2`.

PyObject *PyNumber_TrueDivide(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI.
Return a reasonable approximation for the mathematical value of *o1* divided by *o2*, or `NULL` on failure. The return value is “approximate” because binary floating-point numbers are approximate; it is not possible to represent all real numbers in base two. This function can return a floating-point value when passed two integers. This is the equivalent of the Python expression `o1 / o2`.

PyObject *PyNumber_Remainder(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI.
Returns the remainder of dividing *o1* by *o2*, or `NULL` on failure. This is the equivalent of the Python expression `o1 % o2`.

PyObject *PyNumber_Divmod(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI.
See the built-in function **`divmod()`**. Returns `NULL` on failure. This is the equivalent of the Python expression `divmod(o1, o2)`.

PyObject *PyNumber_Power(PyObject *o1, PyObject *o2, PyObject *o3)

Return value: New reference. Part of the Stable ABI.

See the built-in function **`pow()`**. Returns `NULL` on failure. This is the equivalent of the Python expression `pow(o1, o2, o3)`, where *o3* is optional. If *o3* is to be ignored, pass **`Py_None`** in its place (passing `NULL` for *o3* would cause an illegal memory access).

PyObject *PyNumber_Negative(PyObject *o)

Return value: New reference. Part of the Stable ABI. Returns the negation of *o* on success, or `NULL` on failure. This is the equivalent of the Python expression `-o`.

PyObject *PyNumber_Positive(PyObject *o)

Return value: New reference. Part of the Stable ABI. Returns *o* on success, or `NULL` on failure. This is the equivalent of the Python expression `+o`.

PyObject *PyNumber_Absolute(PyObject *o)

Return value: New reference. Part of the Stable ABI. Returns the absolute value of *o*, or `NULL` on failure. This is the equivalent of the Python expression `abs(o)`.

PyObject *PyNumber_Invert(PyObject *o)

Return value: New reference. Part of the Stable ABI. Returns the bitwise negation of *o* on success, or `NULL` on failure. This is the equivalent of the Python expression `~o`.

PyObject *PyNumber_Lshift(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI. Returns the result of left shifting *o1* by *o2* on success, or `NULL` on failure. This is the equivalent of the Python expression `o1 << o2`.

PyObject *PyNumber_Rshift(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI.

Returns the result of right shifting *o1* by *o2* on success, or `NULL` on failure. This is the equivalent of the Python expression `o1 >> o2`.

PyObject *PyNumber_And(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI. Returns the “bitwise and” of *o1* and *o2* on success and `NULL` on failure. This is the equivalent of the Python expression `o1 & o2`.

PyObject *PyNumber_Xor(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI. Returns the “bitwise exclusive or” of *o1* by *o2* on success, or `NULL` on failure. This is the equivalent of the Python expression `o1 ^ o2`.

PyObject *PyNumber_Or(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI. Returns the “bitwise or” of *o1* and *o2* on success, or `NULL` on failure. This is the equivalent of the Python expression `o1 | o2`.

PyObject *PyNumber_InPlaceAdd(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI. Returns the result of adding *o1* and *o2*, or `NULL` on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement `o1 += o2`.

PyObject *PyNumber_InPlaceSubtract(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI. Returns the result of subtracting *o2* from *o1*, or `NULL` on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement `o1 -= o2`.

PyObject *PyNumber_InPlaceMultiply(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI.
Returns the result of multiplying *o1* and *o2*, or `NULL` on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement `o1 *= o2`.

PyObject *PyNumber_InPlaceMatrixMultiply(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI since version 3.7.
Returns the result of matrix multiplication on *o1* and *o2*, or `NULL` on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement `o1 @= o2`.

Added in version 3.5.

PyObject *PyNumber_InPlaceFloorDivide(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI.
Returns the mathematical floor of dividing *o1* by *o2*, or `NULL` on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement `o1 //= o2`.

PyObject *PyNumber_InPlaceTrueDivide(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI.
Return a reasonable approximation for the mathematical value of *o1* divided by *o2*, or `NULL` on failure. The return value is “approximate” because binary floating-point numbers are approximate; it is not possible to represent all real numbers in base two. This function can return a floating-point value when passed two integers. The

operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement `o1 /= o2`.

PyObject *PyNumber_InPlaceRemainder(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI.
Returns the remainder of dividing *o1* by *o2*, or `NULL` on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement `o1 %= o2`.

PyObject *PyNumber_InPlacePower(PyObject *o1, PyObject *o2, PyObject *o3)

Return value: New reference. Part of the Stable ABI.
See the built-in function **`pow()`**. Returns `NULL` on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement `o1 **= o2` when o3 is **`Py_None`**, or an in-place variant of `pow(o1, o2, o3)` otherwise. If *o3* is to be ignored, pass **`Py_None`** in its place (passing `NULL` for *o3* would cause an illegal memory access).

PyObject *PyNumber_InPlaceLshift(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI.
Returns the result of left shifting *o1* by *o2* on success, or `NULL` on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement `o1 <<= o2`.

PyObject *PyNumber_InPlaceRshift(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI.
Returns the result of right shifting *o1* by *o2* on success, or `NULL` on failure. The operation is done *in-place* when *o1*

supports it. This is the equivalent of the Python statement `o1 >>= o2`.

PyObject *PyNumber_InPlaceAnd(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI. Returns the “bitwise and” of *o1* and *o2* on success and `NULL` on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement `o1 &= o2`.

PyObject *PyNumber_InPlaceXor(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI. Returns the “bitwise exclusive or” of *o1* by *o2* on success, or `NULL` on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement `o1 ^= o2`.

PyObject *PyNumber_InPlaceOr(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI. Returns the “bitwise or” of *o1* and *o2* on success, or `NULL` on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python statement `o1 |= o2`.

PyObject *PyNumber_Long(PyObject *o)

Return value: New reference. Part of the Stable ABI. Returns the *o* converted to an integer object on success, or `NULL` on failure. This is the equivalent of the Python expression `int(o)`.

PyObject *PyNumber_Float(PyObject *o)

Return value: New reference. Part of the Stable ABI.

Returns the *o* converted to a float object on success, or `NULL` on failure. This is the equivalent of the Python expression `float(o)`.

PyObject *PyNumber_Index(PyObject *o)

Return value: New reference. Part of the Stable ABI.
Returns the *o* converted to a Python int on success or `NULL` with a **`TypeError`** exception raised on failure.

Changed in version 3.10: The result always has exact type **`int`**. Previously, the result could have been an instance of a subclass of `int`.

PyObject *PyNumber_ToBase(PyObject *n, int base)

Return value: New reference. Part of the Stable ABI.
Returns the integer *n* converted to base *base* as a string. The *base* argument must be one of 2, 8, 10, or 16. For base 2, 8, or 16, the returned string is prefixed with a base marker of `'0b'`, `'0o'`, or `'0x'`, respectively. If *n* is not a Python int, it is converted with **`PyNumber_Index()`** first.

Py_ssize_t PyNumber_AsSsize_t(PyObject *o, PyObject *exc)

Part of the Stable ABI.
Returns *o* converted to a **`Py_ssize_t`** value if *o* can be interpreted as an integer. If the call fails, an exception is raised and `-1` is returned.

If *o* can be converted to a Python int but the attempt to convert to a **`Py_ssize_t`** value would raise an **`OverflowError`**, then the *exc* argument is the type of exception that will be raised (usually **`IndexError`** or **`OverflowError`**). If *exc* is `NULL`, then the exception is cleared and the value is clipped to `PY_SSIZE_T_MIN` for a negative integer or `PY_SSIZE_T_MAX` for a positive integer.

int PyIndex_Check(PyObject *o)

Part of the Stable ABI since version 3.8.
Returns `1` if *o* is an index integer (has the `nb_index` slot of the `tp_as_number` structure filled in), and `0` otherwise. This function always succeeds.

Sequence Protocol

int PySequence_Check(PyObject *o)

Part of the Stable ABI.

Return `1` if the object provides the sequence protocol, and `0` otherwise. Note that it returns `1` for Python classes with a **`__getitem__()`** method, unless they are **`dict`** subclasses, since in general it is impossible to determine what type of keys the class supports. This function always succeeds.

Py_ssize_t PySequence_Size(PyObject *o)
Py_ssize_t PySequence_Length(PyObject *o)

Part of the Stable ABI.

Returns the number of objects in sequence *o* on success, and `-1` on failure. This is equivalent to the Python expression `len(o)`.

PyObject *PySequence_Concat(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI.

Return the concatenation of *o1* and *o2* on success, and `NULL` on failure. This is the equivalent of the Python expression `o1 + o2`.

PyObject *PySequence_Repeat(PyObject *o, Py_ssize_t count)

Return value: New reference. Part of the Stable ABI.

Return the result of repeating sequence object *o count* times, or `NULL` on failure. This is the equivalent of the Python expression `o * count`.

PyObject *PySequence_InPlaceConcat(PyObject *o1, PyObject *o2)

Return value: New reference. Part of the Stable ABI.
Return the concatenation of *o1* and *o2* on success, and `NULL` on failure. The operation is done *in-place* when *o1* supports it. This is the equivalent of the Python expression `o1 += o2`.

PyObject *PySequence_InPlaceRepeat(PyObject *o, Py_ssize_t count)

Return value: New reference. Part of the Stable ABI.
Return the result of repeating sequence object *o count* times, or `NULL` on failure. The operation is done *in-place* when *o* supports it. This is the equivalent of the Python expression `o *= count`.

PyObject *PySequence_GetItem(PyObject *o, Py_ssize_t i)

Return value: New reference. Part of the Stable ABI.
Return the *i*th element of *o*, or `NULL` on failure. This is the equivalent of the Python expression `o[i]`.

PyObject *PySequence_GetSlice(PyObject *o, Py_ssize_t i1, Py_ssize_t i2)

Return value: New reference. Part of the Stable ABI.
Return the slice of sequence object *o* between *i1* and *i2*, or `NULL` on failure. This is the equivalent of the Python expression `o[i1:i2]`.

int PySequence_SetItem(PyObject *o, Py_ssize_t i, PyObject *v)

Part of the Stable ABI.
Assign object *v* to the *i*th element of *o*. Raise an exception and return `-1` on failure; return `0` on success.

This is the equivalent of the Python statement `o[i] = v`. This function *does not* steal a reference to *v*.

If *v* is `NULL`, the element is deleted, but this feature is deprecated in favour of using **`PySequence_DelItem()`**.

int PySequence_DelItem(PyObject *o, Py_ssize_t i)

Part of the Stable ABI.
Delete the *i*th element of object *o*. Returns `-1` on failure. This is the equivalent of the Python statement `del o[i]`.

int PySequence_SetSlice(PyObject *o, Py_ssize_t i1, Py_ssize_t i2, PyObject *v)

Part of the Stable ABI.
Assign the sequence object *v* to the slice in sequence object *o* from *i1* to *i2*. This is the equivalent of the Python statement `o[i1:i2] = v`.

int PySequence_DelSlice(PyObject *o, Py_ssize_t i1, Py_ssize_t i2)

Part of the Stable ABI.
Delete the slice in sequence object *o* from *i1* to *i2*. Returns `-1` on failure. This is the equivalent of the Python statement `del o[i1:i2]`.

Py_ssize_t PySequence_Count(PyObject *o, PyObject *value)

Part of the Stable ABI.
Return the number of occurrences of *value* in *o*, that is, return the number of keys for which `o[key] == value`. On failure, return `-1`. This is equivalent to the Python expression `o.count(value)`.

int PySequence_Contains(PyObject *o, PyObject *value)

Part of the Stable ABI.

Determine if *o* contains *value*. If an item in *o* is equal to *value*, return `1`, otherwise return `0`. On error, return `-1`. This is equivalent to the Python expression `value in o`.

int PySequence_In(PyObject *o, PyObject *value)

Part of the Stable ABI.

Alias for **`PySequence_Contains()`**.

Deprecated since version 3.14: The function is soft deprecated and should no longer be used to write new code.

Py_ssize_t PySequence_Index(PyObject *o, PyObject *value)

Part of the Stable ABI.

Return the first index *i* for which `o[i] == value`. On error, return `-1`. This is equivalent to the Python expression `o.index(value)`.

PyObject *PySequence_List(PyObject *o)

Return value: New reference. Part of the Stable ABI.

Return a list object with the same contents as the sequence or iterable *o*, or `NULL` on failure. The returned list is guaranteed to be new. This is equivalent to the Python expression `list(o)`.

PyObject *PySequence_Tuple(PyObject *o)

Return value: New reference. Part of the Stable ABI.

Return a tuple object with the same contents as the sequence or iterable *o*, or `NULL` on failure. If *o* is a tuple, a new reference will be returned, otherwise a tuple will be constructed with the appropriate contents. This is equivalent to the Python expression `tuple(o)`.

PyObject *PySequence_Fast(PyObject *o, const char *m)

Return value: New reference. Part of the Stable ABI.

Return the sequence or iterable *o* as an object usable by the other `PySequence_Fast*` family of functions. If the object is not a sequence or iterable, raises **`TypeError`** with *m* as the message text. Returns `NULL` on failure.

The `PySequence_Fast*` functions are thus named because they assume *o* is a **`PyTupleObject`** or a **`PyListObject`** and access the data fields of *o* directly.

As a CPython implementation detail, if *o* is already a sequence or list, it will be returned.

Py_ssize_t PySequence_Fast_GET_SIZE(PyObject *o)

Returns the length of *o*, assuming that *o* was returned by **`PySequence_Fast()`** and that *o* is not `NULL`. The size can also be retrieved by calling **`PySequence_Size()`** on *o*, but **`PySequence_Fast_GET_SIZE()`** is faster because it can assume *o* is a list or tuple.

PyObject *PySequence_Fast_GET_ITEM(PyObject *o, Py_ssize_t i)

Return value: Borrowed reference.
Return the *i*th element of *o*, assuming that *o* was returned by **`PySequence_Fast()`**, *o* is not `NULL`, and that *i* is within bounds.

PyObject **PySequence_Fast_ITEMS(PyObject *o)

Return the underlying array of PyObject pointers. Assumes that *o* was returned by **`PySequence_Fast()`** and *o* is not `NULL`.

Note, if a list gets resized, the reallocation may relocate the items array. So, only use the underlying array pointer in contexts where the sequence cannot change.

PyObject *PySequence_ITEM(PyObject *o, Py_ssize_t i)

Return value: New reference.
Return the *i*th element of *o* or `NULL` on failure. Faster form of **`PySequence_GetItem()`** but without checking that **`PySequence_Check()`** on *o* is true and without adjustment for negative indices.

Mapping Protocol

See also `PyObject_GetItem()`, `PyObject_SetItem()` and `PyObject_DelItem()`.

int PyMapping_Check(PyObject *o)

Part of the Stable ABI.

Return `1` if the object provides the mapping protocol or supports slicing, and `0` otherwise. Note that it returns `1` for Python classes with a `__getitem__()` method, since in general it is impossible to determine what type of keys the class supports. This function always succeeds.

Py_ssize_t PyMapping_Size(PyObject *o)
Py_ssize_t PyMapping_Length(PyObject *o)

Part of the Stable ABI.

Returns the number of keys in object *o* on success, and `-1` on failure. This is equivalent to the Python expression `len(o)`.

PyObject *PyMapping_GetItemString(PyObject *o, const char *key)

Return value: New reference. Part of the Stable ABI.

This is the same as `PyObject_GetItem()`, but *key* is specified as a const char* UTF-8 encoded bytes string, rather than a PyObject*.

int PyMapping_GetOptionalItem(PyObject *obj, PyObject *key, PyObject **result)

Part of the Stable ABI since version 3.13.

Variant of `PyObject_GetItem()` which doesn't raise `KeyError` if the key is not found.

If the key is found, return `1` and set **result* to a new strong reference to the corresponding value. If the key is not found, return `0` and set **result* to `NULL`; the **`KeyError`** is silenced. If an error other than **`KeyError`** is raised, return `-1` and set **result* to `NULL`.

Added in version 3.13.

int PyMapping_GetOptionalItemString(PyObject *obj, const char *key, PyObject **result)

Part of the Stable ABI since version 3.13.
This is the same as **`PyMapping_GetOptionalItem()`**, but *key* is specified as a const char* UTF-8 encoded bytes string, rather than a PyObject*.

Added in version 3.13.

int PyMapping_SetItemString(PyObject *o, const char *key, PyObject *v)

Part of the Stable ABI.
This is the same as **`PyObject_SetItem()`**, but *key* is specified as a const char* UTF-8 encoded bytes string, rather than a PyObject*.

int PyMapping_DelItem(PyObject *o, PyObject *key)

This is an alias of **`PyObject_DelItem()`**.

int PyMapping_DelItemString(PyObject *o, const char *key)

This is the same as **`PyObject_DelItem()`**, but *key* is specified as a const char* UTF-8 encoded bytes string, rather than a PyObject*.

int PyMapping_HasKeyWithError(PyObject *o, PyObject *key)

Part of the Stable ABI since version 3.13.

Return `1` if the mapping object has the key *key* and `0` otherwise. This is equivalent to the Python expression `key in o`. On failure, return `-1`.

Added in version 3.13.

int PyMapping_HasKeyStringWithError(PyObject *o, const char *key)

Part of the Stable ABI since version 3.13.

This is the same as **`PyMapping_HasKeyWithError()`**, but *key* is specified as a const char* UTF-8 encoded bytes string, rather than a PyObject*.

Added in version 3.13.

int PyMapping_HasKey(PyObject *o, PyObject *key)

Part of the Stable ABI.

Return `1` if the mapping object has the key *key* and `0` otherwise. This is equivalent to the Python expression `key in o`. This function always succeeds.

Note

Exceptions which occur when this calls the **`__getitem__()`** method are silently ignored. For proper error handling, use **`PyMapping_HasKeyWithError()`**, **`PyMapping_GetOptionalItem()`** or **`PyObject_GetItem()`** instead.

int PyMapping_HasKeyString(PyObject *o, const char *key)

Part of the Stable ABI.

This is the same as **`PyMapping_HasKey()`**, but *key* is specified as a const char* UTF-8 encoded bytes string, rather than a PyObject*.

Note

Exceptions that occur when this calls the `__getitem__()` method or while creating the temporary `str` object are silently ignored. For proper error handling, use `PyMapping_HasKeyStringWithError()`, `PyMapping_GetOptionalItemString()` or `PyMapping_GetItemString()` instead.

PyObject *PyMapping_Keys(PyObject *o)

Return value: New reference. Part of the Stable ABI.
On success, return a list of the keys in object *o*. On failure, return `NULL`.

Changed in version 3.7: Previously, the function returned a list or a tuple.

PyObject *PyMapping_Values(PyObject *o)

Return value: New reference. Part of the Stable ABI.
On success, return a list of the values in object *o*. On failure, return `NULL`.

Changed in version 3.7: Previously, the function returned a list or a tuple.

PyObject *PyMapping_Items(PyObject *o)

Return value: New reference. Part of the Stable ABI.
On success, return a list of the items in object *o*, where each item is a tuple containing a key-value pair. On failure, return `NULL`.

Changed in version 3.7: Previously, the function returned a list or a tuple.

Iterator Protocol

There are two functions specifically for working with iterators.

int PyIter_Check(PyObject *o)

Part of the Stable ABI since version 3.8.
Return non-zero if the object *o* can be safely passed to **`PyIter_NextItem()`** and `0` otherwise. This function always succeeds.

int PyAIter_Check(PyObject *o)

Part of the Stable ABI since version 3.10.
Return non-zero if the object *o* provides the **`AsyncIterator`** protocol, and `0` otherwise. This function always succeeds.

Added in version 3.10.

int PyIter_NextItem(PyObject *iter, PyObject **item)

Part of the Stable ABI since version 3.14.
Return `1` and set *item* to a strong reference of the next value of the iterator *iter* on success. Return `0` and set *item* to `NULL` if there are no remaining values. Return `-1`, set *item* to `NULL` and set an exception on error.

Added in version 3.14.

PyObject *PyIter_Next(PyObject *o)

Return value: New reference. Part of the Stable ABI.
This is an older version of **`PyIter_NextItem()`**, which is retained for backwards compatibility. Prefer **`PyIter_NextItem()`**.

Return the next value from the iterator *o*. The object must be an iterator according to `PyIter_Check()` (it is up to the caller to check this). If there are no remaining values, returns `NULL` with no exception set. If an error occurs while retrieving the item, returns `NULL` and passes along the exception.

type PySendResult

The enum value used to represent different results of `PyIter_Send()`.

Added in version 3.10.

PySendResult PyIter_Send(PyObject *iter, PyObject *arg, PyObject **presult)

Part of the Stable ABI since version 3.10.

Sends the *arg* value into the iterator *iter*. Returns:

- `PYGEN_RETURN` if iterator returns. Return value is returned via *presult*.
- `PYGEN_NEXT` if iterator yields. Yielded value is returned via *presult*.
- `PYGEN_ERROR` if iterator has raised and exception. *presult* is set to `NULL`.

Added in version 3.10.

Buffer Protocol

Certain objects available in Python wrap access to an underlying memory array or *buffer*. Such objects include the built-in `bytes` and `bytearray`, and some extension types like `array.array`. Third-party libraries may define their own types for special purposes, such as image processing or numeric analysis.

While each of these types have their own semantics, they share the common characteristic of being backed by a possibly large memory buffer. It is then desirable, in some situations, to access that buffer directly and without intermediate copying.

Python provides such a facility at the C and Python level in the form of the buffer protocol. This protocol has two sides:

- on the producer side, a type can export a “buffer interface” which allows objects of that type to expose information about their underlying buffer. This interface is described in the section Buffer Object Structures; for Python see Emulating buffer types.
- on the consumer side, several means are available to obtain a pointer to the raw underlying data of an object (for example a method parameter). For Python see `memoryview`.

Simple objects such as `bytes` and `bytearray` expose their underlying buffer in byte-oriented form. Other forms are possible; for example, the elements exposed by an `array.array` can be multi-byte values.

An example consumer of the buffer interface is the `write()` method of file objects: any object that can export a series of bytes through the buffer interface can be written to a file. While `write()` only needs read-only access to the internal contents of the object passed to it, other methods such as `readinto()` need write access to the contents of their argument. The buffer interface allows objects to selectively allow or reject exporting of read-write and read-only buffers.

There are two ways for a consumer of the buffer interface to acquire a buffer over a target object:

- call `PyObject_GetBuffer()` with the right parameters;
- call `PyArg_ParseTuple()` (or one of its siblings) with one of the `y*`, `w*` or `s*` format codes.

In both cases, `PyBuffer_Release()` must be called when the buffer isn’t needed anymore. Failure to do so could lead to various issues such as resource leaks.

Added in version 3.12: The buffer protocol is now accessible in Python, see Emulating buffer types and `memoryview`.

Buffer structure

Buffer structures (or simply “buffers”) are useful as a way to expose the binary data from another object to the Python programmer. They can also be used as a zero-copy slicing mechanism. Using their ability to reference a block of memory, it is possible to expose any data to the Python programmer quite easily. The memory could be a large, constant array in a C extension, it could be a raw block of memory for manipulation before passing to an operating system library, or it could be used to pass around structured data in its native, in-memory format.

Contrary to most data types exposed by the Python interpreter, buffers are not `PyObject` pointers but rather simple C structures. This allows them to be created and copied very simply. When a generic wrapper around a buffer is needed, a memoryview object can be created.

For short instructions how to write an exporting object, see Buffer Object Structures. For obtaining a buffer, see `PyObject_GetBuffer()`.

type Py_buffer

Part of the Stable ABI (including all members) since version 3.11.

void *buf

A pointer to the start of the logical structure described by the buffer fields. This can be any location within the underlying physical memory block of the exporter. For example, with negative `strides` the value may point to the end of the memory block.

For contiguous arrays, the value points to the beginning of the memory block.

PyObject *obj

A new reference to the exporting object. The reference is owned by the consumer and automatically released (i.e. reference count decremented) and set to `NULL` by `PyBuffer_Release()`. The field is the equivalent of the return value of any standard C-API function.

As a special case, for *temporary* buffers that are wrapped by `PyMemoryView_FromBuffer()` or `PyBuffer_FillInfo()` this field is `NULL`. In general, exporting objects MUST NOT use this scheme.

Py_ssize_t len

`product(shape) * itemsize`. For contiguous arrays, this is the length of the underlying memory block. For non-contiguous arrays, it is the length that the logical structure would have if it were copied to a contiguous representation.

Accessing `((char *)buf)[0] up to ((char *)buf)[len-1]` is only valid if the buffer has been obtained by a request that guarantees contiguity. In most cases such a request will be **`PyBUF_SIMPLE`** or **`PyBUF_WRITABLE`**.

int readonly

An indicator of whether the buffer is read-only. This field is controlled by the **`PyBUF_WRITABLE`** flag.

Py_ssize_t itemsize

Item size in bytes of a single element. Same as the value of **`struct.calcsize()`** called on non-`NULL` **`format`** values.

Important exception: If a consumer requests a buffer without the **`PyBUF_FORMAT`** flag, **`format`** will be set to `NULL`, but **`itemsize`** still has the value for the original format.

If **`shape`** is present, the equality `product(shape) * itemsize == len` still holds and the consumer can use **`itemsize`** to navigate the buffer.

If **`shape`** is `NULL` as a result of a **`PyBUF_SIMPLE`** or a **`PyBUF_WRITABLE`** request, the consumer must disregard **`itemsize`** and assume `itemsize == 1`.

char *format

A *NULL* terminated string in **`struct`** module style syntax describing the contents of a single item. If this is `NULL`, `"B"` (unsigned bytes) is assumed.

This field is controlled by the **`PyBUF_FORMAT`** flag.

int ndim

The number of dimensions the memory represents as an n-dimensional array. If it is `0`, **`buf`** points to a single item representing a scalar. In this case, **`shape`**, **`strides`** and **`suboffsets`** MUST be `NULL`. The maximum number of dimensions is given by **`PyBUF_MAX_NDIM`**.

Py_ssize_t *shape

An array of **`Py_ssize_t`** of length **`ndim`** indicating the shape of the memory as an n-dimensional array. Note that `shape[0] * ... * shape[ndim-1] * itemsize` MUST be equal to **`len`**.

Shape values are restricted to `shape[n] >= 0`. The case `shape[n] == 0` requires special attention. See complex arrays for further information.

The shape array is read-only for the consumer.

Py_ssize_t *strides

An array of **`Py_ssize_t`** of length **`ndim`** giving the number of bytes to skip to get to a new element in each dimension.

Stride values can be any integer. For regular arrays, strides are usually positive, but a consumer MUST be able to handle the case `strides[n] <= 0`. See complex arrays for further information.

The strides array is read-only for the consumer.

Py_ssize_t *suboffsets

An array of **`Py_ssize_t`** of length **`ndim`**. If `suboffsets[n] >= 0`, the values stored along the nth dimension are pointers and the suboffset value dictates how many bytes to add to each pointer after de-referencing. A suboffset value that is negative indicates that no de-referencing should occur (striding in a contiguous memory block).

If all suboffsets are negative (i.e. no de-referencing is needed), then this field must be `NULL` (the default value).

This type of array representation is used by the Python Imaging Library (PIL). See complex arrays for further information how to access elements of such an array.

The suboffsets array is read-only for the consumer.

void *internal

This is for use internally by the exporting object. For example, this might be re-cast as an integer by the exporter and used to store flags about whether or not the shape, strides, and suboffsets arrays must be freed when the buffer is released. The consumer MUST NOT alter this value.

Constants:

PyBUF_MAX_NDIM

Part of the Stable ABI since version 3.11.
The maximum number of dimensions the memory represents. Exporters MUST respect this limit, consumers of multi-dimensional buffers SHOULD be able to handle up to **`PyBUF_MAX_NDIM`** dimensions. Currently set to 64.

Buffer request types

Buffers are usually obtained by sending a buffer request to an exporting object via **`PyObject_GetBuffer()`**. Since the complexity of the logical structure of the memory can vary drastically, the consumer uses the *flags* argument to specify the exact buffer type it can handle.

All **`Py_buffer`** fields are unambiguously defined by the request type.

request-independent fields

The following fields are not influenced by *flags* and must always be filled in with the correct values: `obj`, `buf`, `len`, `itemsize`, `ndim`.

readonly, format

PyBUF_WRITABLE

Part of the Stable ABI since version 3.11.
Controls the `readonly` field. If set, the exporter MUST provide a writable buffer or else report failure. Otherwise, the exporter MAY provide either a read-only or writable buffer, but the choice MUST be consistent for all consumers. For example, PyBUF_SIMPLE | PyBUF_WRITABLE can be used to request a simple writable buffer.

PyBUF_WRITEABLE

This is a soft deprecated alias to `PyBUF_WRITABLE`.

PyBUF_FORMAT

Part of the Stable ABI since version 3.11.
Controls the `format` field. If set, this field MUST be filled in correctly. Otherwise, this field MUST be `NULL`.

`PyBUF_WRITABLE` can be |'d to any of the flags in the next section. Since `PyBUF_SIMPLE` is defined as 0, `PyBUF_WRITABLE` can be used as a stand-alone flag to request a simple writable buffer.

`PyBUF_FORMAT` must be |'d to any of the flags except `PyBUF_SIMPLE`, because the latter already implies format `B` (unsigned bytes). **`PyBUF_FORMAT`** cannot be used on its own.

shape, strides, suboffsets

The flags that control the logical structure of the memory are listed in decreasing order of complexity. Note that each flag contains all bits of the flags below it.

Request	shape	strides	suboffsets
PyBUF_INDIRECT *Part of the Stable ABI since version 3.11.*	yes	yes	if needed
PyBUF_STRIDES *Part of the Stable ABI since version 3.11.*	yes	yes	NULL

Request	shape	strides	suboffsets
PyBUF_ND *Part of the Stable ABI since version 3.11.*	yes	NULL	NULL
PyBUF_SIMPLE *Part of the Stable ABI since version 3.11.*	NULL	NULL	NULL

contiguity requests

C or Fortran contiguity can be explicitly requested, with and without stride information. Without stride information, the buffer must be C-contiguous.

Request	shape	strides	suboffsets	contig
PyBUF_C_CONTIGUOUS *Part of the Stable ABI since version 3.11.*	yes	yes	NULL	C
PyBUF_F_CONTIGUOUS *Part of the Stable ABI since version 3.11.*	yes	yes	NULL	F
PyBUF_ANY_CONTIGUOUS *Part of the Stable ABI since version 3.11.*	yes	yes	NULL	C or F
`PyBUF_ND`	yes	NULL	NULL	C

compound requests

All possible requests are fully defined by some combination of the flags in the previous section. For convenience, the buffer protocol provides frequently used combinations as single flags.

In the following table *U* stands for undefined contiguity. The consumer would have to call `PyBuffer_IsContiguous()` to determine contiguity.

Request	**shape**	**strides**	**suboffsets**	**contig**	**readonly**	**format**
PyBUF_FULL *Part of the Stable ABI since version 3.11.*	yes	yes	if needed	U	0	yes
PyBUF_FULL_RO *Part of the Stable ABI since version 3.11.*	yes	yes	if needed	U	1 or 0	yes
PyBUF_RECORDS *Part of the Stable ABI since version 3.11.*	yes	yes	NULL	U	0	yes
PyBUF_RECORDS_RO *Part of the Stable ABI since version 3.11.*	yes	yes	NULL	U	1 or 0	yes
PyBUF_STRIDED *Part of the Stable ABI since version 3.11.*	yes	yes	NULL	U	0	NULL
PyBUF_STRIDED_RO *Part of the Stable ABI since version 3.11.*	yes	yes	NULL	U	1 or 0	NULL
PyBUF_CONTIG *Part of the Stable ABI since version 3.11.*	yes	NULL	NULL	C	0	NULL
PyBUF_CONTIG_RO *Part of the Stable ABI since version*	yes	NULL	NULL	C	1 or 0	NULL

Request	shape	strides	suboffsets	contig	readonly	format
3.11.						

Complex arrays

NumPy-style: shape and strides

The logical structure of NumPy-style arrays is defined by `itemsize`, `ndim`, `shape` and `strides`.

If `ndim == 0`, the memory location pointed to by `buf` is interpreted as a scalar of size `itemsize`. In that case, both `shape` and `strides` are `NULL`.

If `strides` is `NULL`, the array is interpreted as a standard n-dimensional C-array. Otherwise, the consumer must access an n-dimensional array as follows:

```
ptr = (char *)buf + indices[0] * strides[0] + ... + indices[n-1] * strides[n-1];
item = *((typeof(item) *)ptr);
```

As noted above, `buf` can point to any location within the actual memory block. An exporter can check the validity of a buffer with this function:

```
def verify_structure(memlen, itemsize, ndim, shape, strides, offset):
    """Verify that the parameters represent a valid array within
       the bounds of the allocated memory:
           char *mem: start of the physical memory block
           memlen: length of the physical memory block
           offset: (char *)buf - mem
    """
    if offset % itemsize:
        return False
    if offset < 0 or offset+itemsize > memlen:
        return False
    if any(v % itemsize for v in strides):
        return False

    if ndim <= 0:
        return ndim == 0 and not shape and not strides
    if 0 in shape:
        return True

    imin = sum(strides[j]*(shape[j]-1) for j in range(ndim)
               if strides[j] <= 0)
    imax = sum(strides[j]*(shape[j]-1) for j in range(ndim)
               if strides[j] > 0)

    return 0 <= offset+imin and offset+imax+itemsize <= memlen
```

PIL-style: shape, strides and suboffsets

In addition to the regular items, PIL-style arrays can contain pointers that must be followed in order to get to the next element in a dimension. For example, the regular three-dimensional C-array `char v[2][2][3]` can also be viewed as an array of 2 pointers to 2 two-dimensional arrays: `char (*v[2])[2][3]`. In suboffsets representation, those two pointers can be embedded at the start of **`buf`**, pointing to two `char x[2][3]` arrays that can be located anywhere in memory.

Here is a function that returns a pointer to the element in an N-D array pointed to by an N-dimensional index when there are both non-`NULL` strides and suboffsets:

```
void *get_item_pointer(int ndim, void *buf, Py_ssize_t *strides,
                       Py_ssize_t *suboffsets, Py_ssize_t *indices) {
    char *pointer = (char*)buf;
    int i;
    for (i = 0; i < ndim; i++) {
        pointer += strides[i] * indices[i];
        if (suboffsets[i] >=0 ) {
            pointer = *((char**)pointer) + suboffsets[i];
        }
    }
    return (void*)pointer;
}
```

Buffer-related functions

int PyObject_CheckBuffer(PyObject *obj)

Part of the Stable ABI since version 3.11.
Return `1` if *obj* supports the buffer interface otherwise `0`. When `1` is returned, it doesn't guarantee that **`PyObject_GetBuffer()`** will succeed. This function always succeeds.

int PyObject_GetBuffer(PyObject *exporter, Py_buffer *view, int flags)

Part of the Stable ABI since version 3.11.
Send a request to *exporter* to fill in *view* as specified by *flags*. If the exporter cannot provide a buffer of the exact type, it MUST raise **`BufferError`**, set `view->obj` to `NULL` and return `-1`.

On success, fill in *view*, set `view->obj` to a new reference to *exporter* and return 0. In the case of chained buffer providers that redirect requests to a single object, `view->obj` MAY refer to this object instead of *exporter* (See Buffer Object Structures).

Successful calls to **`PyObject_GetBuffer()`** must be paired with calls to **`PyBuffer_Release()`**, similar to **`malloc()`** and **`free()`**. Thus, after the consumer is done with the buffer, **`PyBuffer_Release()`** must be called exactly once.

void PyBuffer_Release(Py_buffer *view)

Part of the Stable ABI since version 3.11.

Release the buffer *view* and release the strong reference (i.e. decrement the reference count) to the view's supporting object, `view->obj`. This function MUST be called when the buffer is no longer being used, otherwise reference leaks may occur.

It is an error to call this function on a buffer that was not obtained via **`PyObject_GetBuffer()`**.

Py_ssize_t PyBuffer_SizeFromFormat(const char *format)

Part of the Stable ABI since version 3.11.
Return the implied **`itemsize`** from **`format`**. On error, raise an exception and return -1.

Added in version 3.9.

int PyBuffer_IsContiguous(const Py_buffer *view, char order)

Part of the Stable ABI since version 3.11.
Return `1` if the memory defined by the *view* is C-style (*order* is `'C'`) or Fortran-style (*order* is `'F'`) contiguous or either one (*order* is `'A'`). Return `0` otherwise. This function always succeeds.

void *PyBuffer_GetPointer(const Py_buffer *view, const Py_ssize_t *indices)

Part of the Stable ABI since version 3.11.
Get the memory area pointed to by the *indices* inside the given *view*. *indices* must point to an array of `view->ndim` indices.

int PyBuffer_FromContiguous(const Py_buffer *view, const void *buf, Py_ssize_t len, char fort)

Part of the Stable ABI since version 3.11.
Copy contiguous *len* bytes from *buf* to *view*. *fort* can be `'C'` or `'F'` (for C-style or Fortran-style ordering). `0` is returned on success, `-1` on error.

int PyBuffer_ToContiguous(void *buf, const Py_buffer *src, Py_ssize_t len, char order)

Part of the Stable ABI since version 3.11.
Copy *len* bytes from *src* to its contiguous representation in *buf*. *order* can be `'C'` or `'F'` or `'A'` (for C-style or Fortran-style ordering or either one). `0` is returned on success, `-1` on error.

This function fails if *len* != *src->len*.

int PyObject_CopyData(PyObject *dest, PyObject *src)

Part of the Stable ABI since version 3.11.
Copy data from *src* to *dest* buffer. Can convert between C-style and or Fortran-style buffers.

`0` is returned on success, `-1` on error.

void PyBuffer_FillContiguousStrides(int ndims, Py_ssize_t *shape, Py_ssize_t *strides, int itemsize, char order)

Part of the Stable ABI since version 3.11.
Fill the *strides* array with byte-strides of a contiguous (C-style if *order* is `'C'` or Fortran-style if *order* is `'F'`) array of the given shape with the given number of bytes per element.

int PyBuffer_FillInfo(Py_buffer *view, PyObject *exporter, void *buf, Py_ssize_t len, int readonly, int flags)

Part of the Stable ABI since version 3.11.
Handle buffer requests for an exporter that wants to expose *buf* of size *len* with writability set according to *readonly*. *buf* is interpreted as a sequence of unsigned bytes.

The *flags* argument indicates the request type. This function always fills in *view* as specified by flags, unless *buf* has been designated as read-only and **`PyBUF_WRITABLE`** is set in *flags*.

On success, set `view->obj` to a new reference to *exporter* and return 0. Otherwise, raise **`BufferError`**, set `view->obj` to `NULL` and return `-1`;

If this function is used as part of a getbufferproc, *exporter* MUST be set to the exporting object and *flags* must be passed unmodified. Otherwise, *exporter* MUST be `NULL`.

Concrete Objects Layer

The functions in this chapter are specific to certain Python object types. Passing them an object of the wrong type is not a good idea; if you receive an object from a Python program and you are not sure that it has the right type, you must perform a type check first; for example, to check that an object is a dictionary, use `PyDict_Check()`. The chapter is structured like the “family tree” of Python object types.

Warning

While the functions described in this chapter carefully check the type of the objects which are passed in, many of them do not check for `NULL` being passed instead of a valid object. Allowing `NULL` to be passed in can cause memory access violations and immediate termination of the interpreter.

Fundamental Objects

This section describes Python type objects and the singleton object `None`.

- Type Objects
    - Creating Heap-Allocated Types
- The `None` Object

Numeric Objects

- Integer Objects
    - Export API

    - PyLongWriter API
    - Deprecated API
- Boolean Objects
- Floating-Point Objects
    - Pack and Unpack functions
        - Pack functions
        - Unpack functions
- Complex Number Objects
    - Complex Numbers as C Structures
    - Complex Numbers as Python Objects

Sequence Objects

Generic operations on sequence objects were discussed in the previous chapter; this section deals with the specific kinds of sequence objects that are intrinsic to the Python language.

- Bytes Objects
- Byte Array Objects
    - Type check macros
    - Direct API functions
    - Macros
- Unicode Objects and Codecs
    - Unicode Objects
        - Unicode Type
        - Unicode Character Properties
        - Creating and accessing Unicode strings
        - Locale Encoding
        - File System Encoding
        - wchar_t Support
    - Built-in Codecs
        - Generic Codecs
        - UTF-8 Codecs
        - UTF-32 Codecs

        - UTF-16 Codecs
        - UTF-7 Codecs
        - Unicode-Escape Codecs
        - Raw-Unicode-Escape Codecs
        - Latin-1 Codecs
        - ASCII Codecs
        - Character Map Codecs
        - MBCS codecs for Windows
    - Methods and Slot Functions
    - PyUnicodeWriter
    - Deprecated API
- Tuple Objects
- Struct Sequence Objects
- List Objects

Container Objects

- Dictionary Objects
    - Dictionary View Objects
    - Ordered Dictionaries
- Set Objects
    - Deprecated API

Function Objects

- Function Objects
- Instance Method Objects
- Method Objects
- Cell Objects
- Code Objects
- Code Object Flags
- Extra information

Other Objects

- File Objects
    - Deprecated API
- Module Objects
- Module definitions
    - Module slots
- Creating extension modules dynamically
- Support functions
    - Module lookup (single-phase initialization)
- Iterator Objects
    - Range Objects
    - Builtin Iterator Types
    - Other Iterator Objects
- Descriptor Objects
    - Built-in descriptors
- Slice Objects
    - Ellipsis Object
- MemoryView objects
- Pickle buffer objects
- Weak Reference Objects
- Capsules
- Frame Objects
    - Frame Locals Proxies
    - Legacy Local Variable APIs
    - Internal Frames
- Generator Objects
    - Asynchronous Generator Objects
    - Deprecated API
- Coroutine Objects
- Context Variables Objects
- Objects for Type Hinting

C API for extension modules

- Curses C API
- Internal data

- DateTime Objects
- Internal data

Type Objects

type PyTypeObject

Part of the Limited API (as an opaque struct).
The C structure of the objects used to describe built-in types.

PyTypeObject PyType_Type

Part of the Stable ABI.
This is the type object for type objects; it is the same object as **`type`** in the Python layer.

int PyType_Check(PyObject *o)

Return non-zero if the object *o* is a type object, including instances of types derived from the standard type object. Return 0 in all other cases. This function always succeeds.

int PyType_CheckExact(PyObject *o)

Return non-zero if the object *o* is a type object, but not a subtype of the standard type object. Return 0 in all other cases. This function always succeeds.

unsigned int PyType_ClearCache()

Part of the Stable ABI.
Clear the internal lookup cache. Return the current version tag.

unsigned long PyType_GetFlags(PyTypeObject *type)

Part of the Stable ABI.
Return the **`tp_flags`** member of *type*. This function is primarily meant for use with `Py_LIMITED_API`; the individual flag bits are guaranteed to be stable across Python

releases, but access to **`tp_flags`** itself is not part of the limited API.

Added in version 3.2.

Changed in version 3.4: The return type is now `unsigned long` rather than `long`.

PyObject *PyType_GetDict(PyTypeObject *type)

Return the type object's internal namespace, which is otherwise only exposed via a read-only proxy (**`cls.__dict__`**). This is a replacement for accessing **`tp_dict`** directly. The returned dictionary must be treated as read-only.

This function is meant for specific embedding and language-binding cases, where direct access to the dict is necessary and indirect access (e.g. via the proxy or **`PyObject_GetAttr()`**) isn't adequate.

Extension modules should continue to use `tp_dict`, directly or indirectly, when setting up their own types.

Added in version 3.12.

void PyType_Modified(PyTypeObject *type)

Part of the Stable ABI.
Invalidate the internal lookup cache for the type and all of its subtypes. This function must be called after any manual modification of the attributes or base classes of the type.

int PyType_AddWatcher(PyType_WatchCallback callback)

Register *callback* as a type watcher. Return a non-negative integer ID which must be passed to future calls to **`PyType_Watch()`**. In case of error (e.g. no more watcher IDs available), return `-1` and set an exception.

In free-threaded builds, **`PyType_AddWatcher()`** is not thread-safe, so it must be called at start up (before spawning the first thread).

Added in version 3.12.

int PyType_ClearWatcher(int watcher_id)

Clear watcher identified by *watcher_id* (previously returned from **`PyType_AddWatcher()`**). Return `0` on success, `-1` on error (e.g. if *watcher_id* was never registered.)

An extension should never call `PyType_ClearWatcher` with a *watcher_id* that was not returned to it by a previous call to **`PyType_AddWatcher()`**.

Added in version 3.12.

int PyType_Watch(int watcher_id, PyObject *type)

Mark *type* as watched. The callback granted *watcher_id* by **`PyType_AddWatcher()`** will be called whenever **`PyType_Modified()`** reports a change to *type*. (The callback may be called only once for a series of consecutive modifications to *type*, if **`_PyType_Lookup()`** is not called on *type* between the modifications; this is an implementation detail and subject to change.)

An extension should never call `PyType_Watch` with a *watcher_id* that was not returned to it by a previous call to **`PyType_AddWatcher()`**.

Added in version 3.12.

int PyType_Unwatch(int watcher_id, PyObject *type)

Mark *type* as not watched. This undoes a previous call to **`PyType_Watch()`**. *type* must not be `NULL`.

An extension should never call this function with a *watcher_id* that was not returned to it by a previous call to **`PyType_AddWatcher()`**.

On success, this function returns `0`. On failure, this function returns `-1` with an exception set.

Added in version 3.12.

typedef int (*PyType_WatchCallback)(PyObject *type)

Type of a type-watcher callback function.

The callback must not modify *type* or cause **`PyType_Modified()`** to be called on *type* or any type in its MRO; violating this rule could cause infinite recursion.

Added in version 3.12.

int PyType_HasFeature(PyTypeObject *o, int feature)

Return non-zero if the type object *o* sets the feature *feature*. Type features are denoted by single bit flags.

int PyType_FastSubclass(PyTypeObject *type, int flag)

Return non-zero if the type object *type* sets the subclass flag *flag*. Subclass flags are denoted by **`Py_TPFLAGS_*_SUBCLASS`**. This function is used by many `_Check` functions for common types.

See also

`PyObject_TypeCheck()`, which is used as a slower alternative in `_Check` functions for types that don’t come with subclass flags.

int PyType_IS_GC(PyTypeObject *o)

Return true if the type object includes support for the cycle detector; this tests the type flag **`Py_TPFLAGS_HAVE_GC`**.

int PyType_IsSubtype(PyTypeObject *a, PyTypeObject *b)

Part of the Stable ABI.
Return true if *a* is a subtype of *b*.

This function only checks for actual subtypes, which means that **`__subclasscheck__()`** is not called on *b*. Call **`PyObject_IsSubclass()`** to do the same check that **`issubclass()`** would do.

PyObject *PyType_GenericAlloc(PyTypeObject *type, Py_ssize_t nitems)

Return value: New reference. Part of the Stable ABI.
Generic handler for the **`tp_alloc`** slot of a type object. Uses Python's default memory allocation mechanism to allocate memory for a new instance, zeros the memory, then initializes the memory as if by calling **`PyObject_Init()`** or **`PyObject_InitVar()`**.

Do not call this directly to allocate memory for an object; call the type's **`tp_alloc`** slot instead.

For types that support garbage collection (i.e., the **`Py_TPFLAGS_HAVE_GC`** flag is set), this function behaves like **`PyObject_GC_New`** or **`PyObject_GC_NewVar`** (except the memory is guaranteed to be zeroed before initialization), and should be paired with **`PyObject_GC_Del()`** in **`tp_free`**. Otherwise, it behaves like **`PyObject_New`** or **`PyObject_NewVar`** (except the memory is guaranteed to be zeroed before initialization) and should be paired with **`PyObject_Free()`** in **`tp_free`**.

PyObject *PyType_GenericNew(PyTypeObject *type, PyObject *args, PyObject *kwds)

Return value: New reference. Part of the Stable ABI.
Generic handler for the `tp_new` slot of a type object. Creates a new instance using the type’s `tp_alloc` slot and returns the resulting object.

int PyType_Ready(PyTypeObject *type)

Part of the Stable ABI.
Finalize a type object. This should be called on all type objects to finish their initialization. This function is responsible for adding inherited slots from a type’s base class. Return `0` on success, or return `-1` and sets an exception on error.

Note

If some of the base classes implements the GC protocol and the provided type does not include the `Py_TPFLAGS_HAVE_GC` in its flags, then the GC protocol will be automatically implemented from its parents. On the contrary, if the type being created does include `Py_TPFLAGS_HAVE_GC` in its flags then it **must** implement the GC protocol itself by at least implementing the `tp_traverse` handle.

PyObject *PyType_GetName(PyTypeObject *type)

Return value: New reference. Part of the Stable ABI since version 3.11.
Return the type’s name. Equivalent to getting the type’s `__name__` attribute.

Added in version 3.11.

PyObject *PyType_GetQualName(PyTypeObject *type)

Return value: New reference. Part of the Stable ABI since version 3.11.
Return the type’s qualified name. Equivalent to getting the type’s **`__qualname__`** attribute.

Added in version 3.11.

PyObject *PyType_GetFullyQualifiedName(PyTypeObject *type)

Part of the Stable ABI since version 3.13.
Return the type’s fully qualified name. Equivalent to `f"{type.__module__}.{type.__qualname__}"`, or **`type.__qualname__`** if **`type.__module__`** is not a string or is equal to `"builtins"`.

Added in version 3.13.

PyObject *PyType_GetModuleName(PyTypeObject *type)

Part of the Stable ABI since version 3.13.
Return the type’s module name. Equivalent to getting the **`type.__module__`** attribute.

Added in version 3.13.

void *PyType_GetSlot(PyTypeObject *type, int slot)

Part of the Stable ABI since version 3.4.
Return the function pointer stored in the given slot. If the result is `NULL`, this indicates that either the slot is `NULL`, or that the function was called with invalid parameters. Callers will typically cast the result pointer into the appropriate function type.

See **`PyType_Slot.slot`** for possible values of the *slot* argument.

Added in version 3.4.

Changed in version 3.10: **`PyType_GetSlot()`** can now accept all types. Previously, it was limited to heap types.

PyObject *PyType_GetModule(PyTypeObject *type)

Part of the Stable ABI since version 3.10.
Return the module object associated with the given type when the type was created using **`PyType_FromModuleAndSpec()`**.

If no module is associated with the given type, sets **`TypeError`** and returns `NULL`.

This function is usually used to get the module in which a method is defined. Note that in such a method, `PyType_GetModule(Py_TYPE(self))` may not return the intended result. `Py_TYPE(self)` may be a *subclass* of the intended class, and subclasses are not necessarily defined in the same module as their superclass. See **`PyCMethod`** to get the class that defines the method. See **`PyType_GetModuleByDef()`** for cases when **`PyCMethod`** cannot be used.

Added in version 3.9.

void *PyType_GetModuleState(PyTypeObject *type)

Part of the Stable ABI since version 3.10.
Return the state of the module object associated with the given type. This is a shortcut for calling **`PyModule_GetState()`** on the result of **`PyType_GetModule()`**.

If no module is associated with the given type, sets **`TypeError`** and returns `NULL`.

If the *type* has an associated module but its state is `NULL`, returns `NULL` without setting an exception.

Added in version 3.9.

PyObject *PyType_GetModuleByDef(PyTypeObject *type, struct PyModuleDef *def)

Return value: Borrowed reference. Part of the Stable ABI since version 3.13.
Find the first superclass whose module was created from the given **`PyModuleDef`** *def*, and return that module.

If no module is found, raises a **`TypeError`** and returns `NULL`.

This function is intended to be used together with **`PyModule_GetState()`** to get module state from slot methods (such as **`tp_init`** or **`nb_add`**) and other places where a method's defining class cannot be passed using the **`PyCMethod`** calling convention.

The returned reference is borrowed from *type*, and will be valid as long as you hold a reference to *type*. Do not release it with **`Py_DECREF()`** or similar.

Added in version 3.11.

int PyType_GetBaseByToken(PyTypeObject *type, void *token, PyTypeObject **result)

Part of the Stable ABI since version 3.14.
Find the first superclass in *type*'s method resolution order whose **`Py_tp_token`** token is equal to the given one.

- If found, set **result* to a new strong reference to it and return `1`.
- If not found, set **result* to `NULL` and return `0`.
- On error, set **result* to `NULL` and return `-1` with an exception set.

The *result* argument may be `NULL`, in which case **result* is not set. Use this if you need only the return value.

The *token* argument may not be `NULL`.

Added in version 3.14.

int PyUnstable_Type_AssignVersionTag(PyTypeObject *type)

This is Unstable API. It may change without warning in minor releases.

Attempt to assign a version tag to the given type.

Returns 1 if the type already had a valid version tag or a new one was assigned, or 0 if a new tag could not be assigned.

Added in version 3.12.

int PyType_SUPPORTS_WEAKREFS(PyTypeObject *type)

Return true if instances of *type* support creating weak references, false otherwise. This function always succeeds. *type* must not be `NULL`.

See also

- Weak Reference Objects
- **`weakref`**

Creating Heap-Allocated Types

The following functions and structs are used to create heap types.

PyObject *PyType_FromMetaclass(PyTypeObject *metaclass, PyObject *module, PyType_Spec *spec, PyObject *bases)

Part of the Stable ABI since version 3.12.

Create and return a heap type from the *spec* (see **`Py_TPFLAGS_HEAPTYPE`**).

The metaclass *metaclass* is used to construct the resulting type object. When *metaclass* is `NULL`, the metaclass is derived from *bases* (or *Py_tp_base[s]* slots if *bases* is `NULL`, see below).

Metaclasses that override **`tp_new`** are not supported, except if `tp_new` is `NULL`.

The *bases* argument can be used to specify base classes; it can either be only one class or a tuple of classes. If *bases* is `NULL`, the **`Py_tp_bases`** slot is used instead. If that also is `NULL`, the **`Py_tp_base`** slot is used instead. If that also is `NULL`, the new type derives from **`object`**.

The *module* argument can be used to record the module in which the new class is defined. It must be a module object or `NULL`. If not `NULL`, the module is associated with the new type and can later be retrieved with **`PyType_GetModule()`**. The associated module is not inherited by subclasses; it must be specified for each class individually.

This function calls **`PyType_Ready()`** on the new type.

Note that this function does *not* fully match the behavior of calling **`type()`** or using the **`class`** statement. With user-provided base types or metaclasses, prefer calling **`type`** (or the metaclass) over `PyType_From*` functions. Specifically:

- **`__new__()`** is not called on the new class (and it must be set to `type.__new__`).
- **`__init__()`** is not called on the new class.
- **`__init_subclass__()`** is not called on any bases.

- **`__set_name__()`** is not called on new descriptors.

  Added in version 3.12.

PyObject *PyType_FromModuleAndSpec(PyObject *module, PyType_Spec *spec, PyObject *bases)

Return value: New reference. Part of the Stable ABI since version 3.10.
Equivalent to `PyType_FromMetaclass(NULL, module, spec, bases)`.

Added in version 3.9.

Changed in version 3.10: The function now accepts a single class as the *bases* argument and `NULL` as the `tp_doc` slot.

Changed in version 3.12: The function now finds and uses a metaclass corresponding to the provided base classes. Previously, only **`type`** instances were returned.

The **`tp_new`** of the metaclass is *ignored*. which may result in incomplete initialization. Creating classes whose metaclass overrides **`tp_new`** is deprecated.

Changed in version 3.14: Creating classes whose metaclass overrides **`tp_new`** is no longer allowed.

PyObject *PyType_FromSpecWithBases(PyType_Spec *spec, PyObject *bases)

Return value: New reference. Part of the Stable ABI since version 3.3.
Equivalent to `PyType_FromMetaclass(NULL, NULL, spec, bases)`.

Added in version 3.3.

Changed in version 3.12: The function now finds and uses a metaclass corresponding to the provided base classes. Previously, only **`type`** instances were returned.

The **`tp_new`** of the metaclass is *ignored*. which may result in incomplete initialization. Creating classes whose metaclass overrides **`tp_new`** is deprecated.

Changed in version 3.14: Creating classes whose metaclass overrides **`tp_new`** is no longer allowed.

PyObject *PyType_FromSpec(PyType_Spec *spec)

Return value: New reference. Part of the Stable ABI.
Equivalent to `PyType_FromMetaclass(NULL, NULL, spec, NULL)`.

Changed in version 3.12: The function now finds and uses a metaclass corresponding to the base classes provided in *Py_tp_base[s]* slots. Previously, only **`type`** instances were returned.

The **`tp_new`** of the metaclass is *ignored*. which may result in incomplete initialization. Creating classes whose metaclass overrides **`tp_new`** is deprecated.

Changed in version 3.14: Creating classes whose metaclass overrides **`tp_new`** is no longer allowed.

int PyType_Freeze(PyTypeObject *type)

Part of the Stable ABI since version 3.14.
Make a type immutable: set the **`Py_TPFLAGS_IMMUTABLETYPE`** flag.

All base classes of *type* must be immutable.

On success, return `0`. On error, set an exception and return `-1`.

The type must not be used before it’s made immutable. For example, type instances must not be created before the type is made immutable.

Added in version 3.14.

type PyType_Spec

Part of the Stable ABI (including all members).
Structure defining a type’s behavior.

const char *name

Name of the type, used to set `PyTypeObject.tp_name`.

int basicsize

If positive, specifies the size of the instance in bytes. It is used to set `PyTypeObject.tp_basicsize`.

If zero, specifies that `tp_basicsize` should be inherited.

If negative, the absolute value specifies how much space instances of the class need *in addition* to the superclass. Use `PyObject_GetTypeData()` to get a pointer to subclass-specific memory reserved this way. For negative **`basicsize`**, Python will insert padding when needed to meet `tp_basicsize`’s alignment requirements.

Changed in version 3.12: Previously, this field could not be negative.

int itemsize

Size of one element of a variable-size type, in bytes. Used to set `PyTypeObject.tp_itemsize`. See `tp_itemsize` documentation for caveats.

If zero, `tp_itemsize` is inherited. Extending arbitrary variable-sized classes is dangerous, since some types use a fixed offset for variable-sized memory, which can then overlap fixed-sized memory used by a subclass. To help prevent mistakes, inheriting `itemsize` is only possible in the following situations:

- The base is not variable-sized (its **`tp_itemsize`**).
- The requested **`PyType_Spec.basicsize`** is positive, suggesting that the memory layout of the base class is known.
- The requested **`PyType_Spec.basicsize`** is zero, suggesting that the subclass does not access the instance's memory directly.
- With the **`Py_TPFLAGS_ITEMS_AT_END`** flag.

unsigned int flags

Type flags, used to set **`PyTypeObject.tp_flags`**.

If the `Py_TPFLAGS_HEAPTYPE` flag is not set, **`PyType_FromSpecWithBases()`** sets it automatically.

PyType_Slot *slots

Array of **`PyType_Slot`** structures. Terminated by the special slot value `{0, NULL}`.

Each slot ID should be specified at most once.

type PyType_Slot

Part of the Stable ABI (including all members).
Structure defining optional functionality of a type, containing a slot ID and a value pointer.

int slot

A slot ID.

Slot IDs are named like the field names of the structures **`PyTypeObject`**, **`PyNumberMethods`**, `PySequenceMethods`, `PyMappingMethods` and `PyAsyncMethods` with an added `Py_` prefix. For example, use:

- `Py_tp_dealloc` to set `PyTypeObject.tp_dealloc`
- `Py_nb_add` to set `PyNumberMethods.nb_add`
- `Py_sq_length` to set `PySequenceMethods.sq_length`

An additional slot is supported that does not correspond to a **`PyTypeObject`** struct field:

- `Py_tp_token`

The following “offset” fields cannot be set using `PyType_Slot`:

- `tp_weaklistoffset` (use `Py_TPFLAGS_MANAGED_WEAKREF` instead if possible)
- `tp_dictoffset` (use `Py_TPFLAGS_MANAGED_DICT` instead if possible)
- `tp_vectorcall_offset` (use `"__vectorcalloffset__"` in PyMemberDef)

If it is not possible to switch to a `MANAGED` flag (for example, for vectorcall or to support Python older than 3.12), specify the offset in `Py_tp_members`. See PyMemberDef documentation for details.

The following internal fields cannot be set at all when creating a heap type:

- `tp_dict`, `tp_mro`, `tp_cache`, `tp_subclasses`, and `tp_weaklist`.

Setting `Py_tp_bases` or `Py_tp_base` may be problematic on some platforms. To avoid issues, use the *bases* argument of `PyType_FromSpecWithBases()` instead.

Changed in version 3.9: Slots in `PyBufferProcs` may be set in the unlimited API.

Changed in version 3.11: **`bf_getbuffer`** and **`bf_releasebuffer`** are now available under the limited API.

Changed in version 3.14: The field **`tp_vectorcall`** can now be set using **`Py_tp_vectorcall`**. See the field’s documentation for details.

void *pfunc

The desired value of the slot. In most cases, this is a pointer to a function.

pfunc values may not be `NULL`, except for the following slots:

- **`Py_tp_doc`**
- **`Py_tp_token`** (for clarity, prefer **`Py_TP_USE_SPEC`** rather than `NULL`)

Py_tp_token

Part of the Stable ABI since version 3.14.
A **`slot`** that records a static memory layout ID for a class.

If the **`PyType_Spec`** of the class is statically allocated, the token can be set to the spec using the special value **`Py_TP_USE_SPEC`**:

```
static PyType_Slot foo_slots[] = {
   {Py_tp_token, Py_TP_USE_SPEC},
```

It can also be set to an arbitrary pointer, but you must ensure that:

- The pointer outlives the class, so it’s not reused for something else while the class exists.
- It “belongs” to the extension module where the class lives, so it will not clash with other extensions.

Use **`PyType_GetBaseByToken()`** to check if a class's superclass has a given token – that is, check whether the memory layout is compatible.

To get the token for a given class (without considering superclasses), use **`PyType_GetSlot()`** with `Py_tp_token`.

Added in version 3.14.

Py_TP_USE_SPEC

Part of the Stable ABI since version 3.14.

Used as a value with **`Py_tp_token`** to set the token to the class's **`PyType_Spec`**. Expands to `NULL`.

Added in version 3.14.

The `None` Object

Note that the **`PyTypeObject`** for `None` is not directly exposed in the Python/C API. Since `None` is a singleton, testing for object identity (using `==` in C) is sufficient. There is no **`PyNone_Check()`** function for the same reason.

PyObject *Py_None

The Python `None` object, denoting lack of value. This object has no methods and is immortal.

Changed in version 3.12: **`Py_None`** is immortal.

Py_RETURN_NONE

Return **`Py_None`** from a function.

Integer Objects

All integers are implemented as “long” integer objects of arbitrary size.

On error, most `PyLong_As*` APIs return `(return type)-1` which cannot be distinguished from a number. Use **`PyErr_Occurred()`** to disambiguate.

type PyLongObject

Part of the Limited API (as an opaque struct).
This subtype of **`PyObject`** represents a Python integer object.

PyTypeObject PyLong_Type

Part of the Stable ABI.
This instance of **`PyTypeObject`** represents the Python integer type. This is the same object as **`int`** in the Python layer.

int PyLong_Check(PyObject *p)

Return true if its argument is a **`PyLongObject`** or a subtype of **`PyLongObject`**. This function always succeeds.

int PyLong_CheckExact(PyObject *p)

Return true if its argument is a **`PyLongObject`**, but not a subtype of **`PyLongObject`**. This function always succeeds.

PyObject *PyLong_FromLong(long v)

Return value: New reference. Part of the Stable ABI.
Return a new **`PyLongObject`** object from *v*, or `NULL` on failure.

CPython implementation detail: CPython keeps an array of integer objects for all integers between `-5` and `256`. When you create an int in that range you actually just get back a reference to the existing object.

PyObject *PyLong_FromUnsignedLong(unsigned long v)

Return value: New reference. Part of the Stable ABI.
Return a new **`PyLongObject`** object from a C unsigned long, or `NULL` on failure.

PyObject *PyLong_FromSsize_t(Py_ssize_t v)

Return value: New reference. Part of the Stable ABI.
Return a new **`PyLongObject`** object from a C **`Py_ssize_t`**, or `NULL` on failure.

PyObject *PyLong_FromSize_t(size_t v)

Return value: New reference. Part of the Stable ABI.
Return a new **`PyLongObject`** object from a C **`size_t`**, or `NULL` on failure.

PyObject *PyLong_FromLongLong(long long v)

Return value: New reference. Part of the Stable ABI.
Return a new **`PyLongObject`** object from a C long long, or `NULL` on failure.

PyObject *PyLong_FromInt32(int32_t value)
PyObject *PyLong_FromInt64(int64_t value)

Part of the Stable ABI since version 3.14.
Return a new **`PyLongObject`** object from a signed C int32_t or int64_t, or `NULL` with an exception set on failure.

Added in version 3.14.

PyObject *PyLong_FromUnsignedLongLong(unsigned long long v)

Return value: New reference. Part of the Stable ABI.
Return a new `PyLongObject` object from a C unsigned long long, or `NULL` on failure.

PyObject *PyLong_FromUInt32(uint32_t value)
PyObject *PyLong_FromUInt64(uint64_t value)

Part of the Stable ABI since version 3.14.
Return a new `PyLongObject` object from an unsigned C uint32_t or uint64_t, or `NULL` with an exception set on failure.

Added in version 3.14.

PyObject *PyLong_FromDouble(double v)

Return value: New reference. Part of the Stable ABI.
Return a new `PyLongObject` object from the integer part of *v*, or `NULL` on failure.

PyObject *PyLong_FromString(const char *str, char **pend, int base)

Return value: New reference. Part of the Stable ABI.
Return a new `PyLongObject` based on the string value in *str*, which is interpreted according to the radix in *base*, or `NULL` on failure. If *pend* is non-`NULL`, **pend* will point to the end of *str* on success or to the first character that could not be processed on error. If *base* is `0`, *str* is interpreted using the Integer literals definition; in this case, leading zeros in a non-zero decimal number raises a `ValueError`. If *base* is not `0`, it must be between `2` and `36`, inclusive. Leading and trailing whitespace and single underscores after a base specifier and between digits are ignored. If there are no digits or *str* is not NULL-terminated following the digits and trailing whitespace, `ValueError` will be raised.

See also

`PyLong_AsNativeBytes()` and `PyLong_FromNativeBytes()` functions can be used to convert a `PyLongObject` to/from an array of bytes in base `256`.

PyObject *PyLong_FromUnicodeObject(PyObject *u, int base)

Return value: New reference.
Convert a sequence of Unicode digits in the string *u* to a Python integer value.

Added in version 3.3.

PyObject *PyLong_FromVoidPtr(void *p)

Return value: New reference. Part of the Stable ABI.
Create a Python integer from the pointer *p*. The pointer value can be retrieved from the resulting value using `PyLong_AsVoidPtr()`.

PyObject *PyLong_FromNativeBytes(const void *buffer, size_t n_bytes, int flags)

Part of the Stable ABI since version 3.14.
Create a Python integer from the value contained in the first *n_bytes* of *buffer*, interpreted as a two's-complement signed number.

flags are as for `PyLong_AsNativeBytes()`. Passing `-1` will select the native endian that CPython was compiled with and assume that the most-significant bit is a sign bit. Passing `Py_ASNATIVEBYTES_UNSIGNED_BUFFER` will produce the same result as calling `PyLong_FromUnsignedNativeBytes()`. Other flags are ignored.

Added in version 3.13.

PyObject *PyLong_FromUnsignedNativeBytes(const void *buffer, size_t n_bytes, int flags)

Part of the Stable ABI since version 3.14.
Create a Python integer from the value contained in the first *n_bytes* of *buffer*, interpreted as an unsigned number.

flags are as for `PyLong_AsNativeBytes()`. Passing `-1` will select the native endian that CPython was compiled with and assume that the most-significant bit is not a sign bit. Flags other than endian are ignored.

Added in version 3.13.

PyLong_FromPid(pid)

Macro for creating a Python integer from a process identifier.

This can be defined as an alias to `PyLong_FromLong()` or `PyLong_FromLongLong()`, depending on the size of the system's PID type.

Added in version 3.2.

long PyLong_AsLong(PyObject *obj)

Part of the Stable ABI.
Return a C long representation of *obj*. If *obj* is not an instance of `PyLongObject`, first call its `__index__()` method (if present) to convert it to a `PyLongObject`.

Raise `OverflowError` if the value of *obj* is out of range for a long.

Returns `-1` on error. Use `PyErr_Occurred()` to disambiguate.

Changed in version 3.8: Use `__index__()` if available.

Changed in version 3.10: This function will no longer use `__int__()`.

long PyLong_AS_LONG(PyObject *obj)

A soft deprecated alias. Exactly equivalent to the preferred `PyLong_AsLong`. In particular, it can fail with **`OverflowError`** or another exception.

Deprecated since version 3.14: The function is soft deprecated.

int PyLong_AsInt(PyObject *obj)

Part of the Stable ABI since version 3.13.
Similar to `PyLong_AsLong()`, but store the result in a C int instead of a C long.

Added in version 3.13.

long PyLong_AsLongAndOverflow(PyObject *obj, int *overflow)

Part of the Stable ABI.
Return a C long representation of *obj*. If *obj* is not an instance of **`PyLongObject`**, first call its `__index__()` method (if present) to convert it to a **`PyLongObject`**.

If the value of *obj* is greater than **`LONG_MAX`** or less than **`LONG_MIN`**, set **overflow* to `1` or `-1`, respectively, and return `-1`; otherwise, set **overflow* to `0`. If any other exception occurs set **overflow* to `0` and return `-1` as usual.

Returns `-1` on error. Use `PyErr_Occurred()` to disambiguate.

Changed in version 3.8: Use `__index__()` if available.

Changed in version 3.10: This function will no longer use `__int__()`.

long long PyLong_AsLongLong(PyObject *obj)

Part of the Stable ABI.

Return a C long long representation of *obj*. If *obj* is not an instance of `PyLongObject`, first call its `__index__()` method (if present) to convert it to a `PyLongObject`.

Raise `OverflowError` if the value of *obj* is out of range for a long long.

Returns `-1` on error. Use `PyErr_Occurred()` to disambiguate.

Changed in version 3.8: Use `__index__()` if available.

Changed in version 3.10: This function will no longer use `__int__()`.

long long PyLong_AsLongLongAndOverflow(PyObject *obj, int *overflow)

Part of the Stable ABI.

Return a C long long representation of *obj*. If *obj* is not an instance of `PyLongObject`, first call its `__index__()` method (if present) to convert it to a `PyLongObject`.

If the value of *obj* is greater than **`LLONG_MAX`** or less than **`LLONG_MIN`**, set **overflow* to `1` or `-1`, respectively, and return `-1`; otherwise, set **overflow* to `0`. If any other exception occurs set **overflow* to `0` and return `-1` as usual.

Returns `-1` on error. Use `PyErr_Occurred()` to disambiguate.

Added in version 3.2.

Changed in version 3.8: Use `__index__()` if available.

Changed in version 3.10: This function will no longer use `__int__()`.

Py_ssize_t PyLong_AsSsize_t(PyObject *pylong)

Part of the Stable ABI.

Return a C `Py_ssize_t` representation of *pylong*. *pylong* must be an instance of `PyLongObject`.

Raise `OverflowError` if the value of *pylong* is out of range for a `Py_ssize_t`.

Returns `-1` on error. Use `PyErr_Occurred()` to disambiguate.

unsigned long PyLong_AsUnsignedLong(PyObject *pylong)

Part of the Stable ABI.

Return a C unsigned long representation of *pylong*. *pylong* must be an instance of `PyLongObject`.

Raise `OverflowError` if the value of *pylong* is out of range for a unsigned long.

Returns `(unsigned long)-1` on error. Use `PyErr_Occurred()` to disambiguate.

size_t PyLong_AsSize_t(PyObject *pylong)

Part of the Stable ABI.

Return a C **`size_t`** representation of *pylong*. *pylong* must be an instance of `PyLongObject`.

Raise `OverflowError` if the value of *pylong* is out of range for a **`size_t`**.

Returns `(size_t)-1` on error. Use `PyErr_Occurred()` to disambiguate.

unsigned long long PyLong_AsUnsignedLongLong(PyObject *pylong)

Part of the Stable ABI.

Return a C unsigned long long representation of *pylong*. *pylong* must be an instance of **`PyLongObject`**.

Raise **`OverflowError`** if the value of *pylong* is out of range for an unsigned long long.

Returns `(unsigned long long)-1` on error. Use **`PyErr_Occurred()`** to disambiguate.

Changed in version 3.1: A negative *pylong* now raises **`OverflowError`**, not **`TypeError`**.

unsigned long PyLong_AsUnsignedLongMask(PyObject *obj)

Part of the Stable ABI.

Return a C unsigned long representation of *obj*. If *obj* is not an instance of **`PyLongObject`**, first call its **`__index__()`** method (if present) to convert it to a **`PyLongObject`**.

If the value of *obj* is out of range for an unsigned long, return the reduction of that value modulo `ULONG_MAX + 1`.

Returns `(unsigned long)-1` on error. Use **`PyErr_Occurred()`** to disambiguate.

Changed in version 3.8: Use **`__index__()`** if available.

Changed in version 3.10: This function will no longer use **`__int__()`**.

unsigned long long PyLong_AsUnsignedLongLongMask(PyObject *obj)

Part of the Stable ABI.

Return a C unsigned long long representation of *obj*. If *obj* is not an instance of **`PyLongObject`**, first call its **`__index__()`** method (if present) to convert it to a **`PyLongObject`**.

If the value of *obj* is out of range for an unsigned long long, return the reduction of that value modulo `ULLONG_MAX + 1`.

Returns `(unsigned long long)-1` on error. Use **`PyErr_Occurred()`** to disambiguate.

Changed in version 3.8: Use **`__index__()`** if available.

Changed in version 3.10: This function will no longer use **`__int__()`**.

int PyLong_AsInt32(PyObject *obj, int32_t *value)
int PyLong_AsInt64(PyObject *obj, int64_t *value)

Part of the Stable ABI since version 3.14.
Set **value* to a signed C int32_t or int64_t representation of *obj*.

If *obj* is not an instance of **`PyLongObject`**, first call its **`__index__()`** method (if present) to convert it to a **`PyLongObject`**.

If the *obj* value is out of range, raise an **`OverflowError`**.

Set **value* and return `0` on success. Set an exception and return `-1` on error.

value must not be `NULL`.

Added in version 3.14.

int PyLong_AsUInt32(PyObject *obj, uint32_t *value)
int PyLong_AsUInt64(PyObject *obj, uint64_t *value)

Part of the Stable ABI since version 3.14.
Set **value* to an unsigned C uint32_t or uint64_t representation of *obj*.

If *obj* is not an instance of **`PyLongObject`**, first call its **`__index__()`** method (if present) to convert it to a **`PyLongObject`**.

- If *obj* is negative, raise a **`ValueError`**.
- If the *obj* value is out of range, raise an **`OverflowError`**.

Set **value* and return `0` on success. Set an exception and return `-1` on error.

value must not be `NULL`.

Added in version 3.14.

double PyLong_AsDouble(PyObject *pylong)

Part of the Stable ABI.
Return a C double representation of *pylong*. *pylong* must be an instance of **`PyLongObject`**.

Raise **`OverflowError`** if the value of *pylong* is out of range for a double.

Returns `-1.0` on error. Use **`PyErr_Occurred()`** to disambiguate.

void *PyLong_AsVoidPtr(PyObject *pylong)

Part of the Stable ABI.
Convert a Python integer *pylong* to a C void pointer. If *pylong* cannot be converted, an **`OverflowError`** will be raised. This is only assured to produce a usable void pointer for values created with **`PyLong_FromVoidPtr()`**.

Returns `NULL` on error. Use **`PyErr_Occurred()`** to disambiguate.

Py_ssize_t PyLong_AsNativeBytes(PyObject *pylong, void *buffer, Py_ssize_t n_bytes, int flags)

Part of the Stable ABI since version 3.14.
Copy the Python integer value *pylong* to a native *buffer* of size *n_bytes*. The *flags* can be set to `-1` to behave similarly to a C cast, or to values documented below to control the behavior.

Returns `-1` with an exception raised on error. This may happen if *pylong* cannot be interpreted as an integer, or if *pylong* was negative and the `Py_ASNATIVEBYTES_REJECT_NEGATIVE` flag was set.

Otherwise, returns the number of bytes required to store the value. If this is equal to or less than *n_bytes*, the entire value was copied. All *n_bytes* of the buffer are written: remaining bytes filled by copies of the sign bit.

If the returned value is greater than *n_bytes*, the value was truncated: as many of the lowest bits of the value as could fit are written, and the higher bits are ignored. This matches the typical behavior of a C-style downcast.

Note

Overflow is not considered an error. If the returned value is larger than *n_bytes*, most significant bits were discarded.

`0` will never be returned.

Values are always copied as two’s-complement.

Usage example:

```
int32_t value;
Py_ssize_t bytes = PyLong_AsNativeBytes(pylong, &value,
sizeof(value), -1);
if (bytes < 0) {
    // Failed. A Python exception was set with the reason.
    return NULL;
}
else if (bytes <= (Py_ssize_t)sizeof(value)) {
    // Success!
}
else {
    // Overflow occurred, but 'value' contains the truncated
    // lowest bits of pylong.
}
```

Passing zero to *n_bytes* will return the size of a buffer that would be large enough to hold the value. This may be larger than technically necessary, but not unreasonably so. If *n_bytes=0*, *buffer* may be `NULL`.

Note

Passing *n_bytes=0* to this function is not an accurate way to determine the bit length of the value.

To get at the entire Python value of an unknown size, the function can be called twice: first to determine the buffer size, then to fill it:

```
// Ask how much space we need.
Py_ssize_t expected = PyLong_AsNativeBytes(pylong, NULL, 0,
-1);
if (expected < 0) {
    // Failed. A Python exception was set with the reason.
    return NULL;
}
assert(expected != 0);  // Impossible per the API
definition.
uint8_t *bignum = malloc(expected);
if (!bignum) {
    PyErr_SetString(PyExc_MemoryError, "bignum malloc
failed.");
    return NULL;
}
// Safely get the entire value.
```

```
Py_ssize_t bytes = PyLong_AsNativeBytes(pylong, bignum,
expected, -1);
if (bytes < 0) {  // Exception has been set.
    free(bignum);
    return NULL;
}
else if (bytes > expected) {  // This should not be
possible.
    PyErr_SetString(PyExc_RuntimeError,
        "Unexpected bignum truncation after a size check.");
    free(bignum);
    return NULL;
}
// The expected success given the above pre-check.
// ... use bignum ...
free(bignum);
```

flags is either `-1` (`Py_ASNATIVEBYTES_DEFAULTS`) to select defaults that behave most like a C cast, or a combination of the other flags in the table below. Note that `-1` cannot be combined with other flags.

Currently, `-1` corresponds to `Py_ASNATIVEBYTES_NATIVE_ENDIAN | Py_ASNATIVEBYTES_UNSIGNED_BUFFER`.

Flag	Value
Py_ASNATIVEBYTES_DEFAULTS *Part of the Stable ABI since version 3.14.*	`-1`
Py_ASNATIVEBYTES_BIG_ENDIAN *Part of the Stable ABI since version 3.14.*	`0`
Py_ASNATIVEBYTES_LITTLE_ENDIAN *Part of the Stable ABI since version 3.14.*	`1`
Py_ASNATIVEBYTES_NATIVE_ENDIAN *Part of the Stable ABI since version 3.14.*	`3`
Py_ASNATIVEBYTES_UNSIGNED_BUFFER	`4`

Flag	Value
Part of the Stable ABI since version 3.14.	
Py_ASNATIVEBYTES_REJECT_NEGATIVE *Part of the Stable ABI since version 3.14.*	8
Py_ASNATIVEBYTES_ALLOW_INDEX *Part of the Stable ABI since version 3.14.*	16

Specifying `Py_ASNATIVEBYTES_NATIVE_ENDIAN` will override any other endian flags. Passing `2` is reserved.

By default, sufficient buffer will be requested to include a sign bit. For example, when converting 128 with *n_bytes=1*, the function will return 2 (or more) in order to store a zero sign bit.

If `Py_ASNATIVEBYTES_UNSIGNED_BUFFER` is specified, a zero sign bit will be omitted from size calculations. This allows, for example, 128 to fit in a single-byte buffer. If the destination buffer is later treated as signed, a positive input value may become negative. Note that the flag does not affect handling of negative values: for those, space for a sign bit is always requested.

Specifying `Py_ASNATIVEBYTES_REJECT_NEGATIVE` causes an exception to be set if *pylong* is negative. Without this flag, negative values will be copied provided there is enough space for at least one sign bit, regardless of whether `Py_ASNATIVEBYTES_UNSIGNED_BUFFER` was specified.

If `Py_ASNATIVEBYTES_ALLOW_INDEX` is specified and a non-integer value is passed, its `__index__()` method will be called first. This may result in Python code executing and other threads being allowed to run, which could cause changes to other objects or values in use. When *flags* is `-1`, this option is not set, and non-integer values will raise `TypeError`.

Note

With the default *flags* (`-1`, or *UNSIGNED_BUFFER* without *REJECT_NEGATIVE*), multiple Python integers can map to a single value without overflow. For example, both `255` and `-1` fit a single-byte buffer and set all its bits. This matches typical C cast behavior.

Added in version 3.13.

PyLong_AsPid(pid)

Macro for converting a Python integer into a process identifier.

This can be defined as an alias to `PyLong_AsLong()`, `PyLong_FromLongLong()`, or `PyLong_AsInt()`, depending on the size of the system's PID type.

Added in version 3.2.

int PyLong_GetSign(PyObject *obj, int *sign)

Get the sign of the integer object *obj*.

On success, set **sign* to the integer sign (0, -1 or +1 for zero, negative or positive integer, respectively) and return 0.

On failure, return -1 with an exception set. This function always succeeds if *obj* is a `PyLongObject` or its subtype.

Added in version 3.14.

int PyLong_IsPositive(PyObject *obj)

Check if the integer object *obj* is positive (`obj > 0`).

If *obj* is an instance of **`PyLongObject`** or its subtype, return `1` when it's positive and `0` otherwise. Else set an exception and return `-1`.

Added in version 3.14.

int PyLong_IsNegative(PyObject *obj)

Check if the integer object *obj* is negative (`obj < 0`).

If *obj* is an instance of **`PyLongObject`** or its subtype, return `1` when it's negative and `0` otherwise. Else set an exception and return `-1`.

Added in version 3.14.

int PyLong_IsZero(PyObject *obj)

Check if the integer object *obj* is zero.

If *obj* is an instance of **`PyLongObject`** or its subtype, return `1` when it's zero and `0` otherwise. Else set an exception and return `-1`.

Added in version 3.14.

PyObject *PyLong_GetInfo(void)

Part of the Stable ABI.

On success, return a read only named tuple, that holds information about Python's internal representation of integers. See **`sys.int_info`** for description of individual fields.

On failure, return `NULL` with an exception set.

Added in version 3.1.

int PyUnstable_Long_IsCompact(const PyLongObject *op)

This is Unstable API. It may change without warning in minor releases.

Return 1 if *op* is compact, 0 otherwise.

This function makes it possible for performance-critical code to implement a “fast path” for small integers. For compact values use `PyUnstable_Long_CompactValue()`; for others fall back to a `PyLong_As*` function or `PyLong_AsNativeBytes()`.

The speedup is expected to be negligible for most users.

Exactly what values are considered compact is an implementation detail and is subject to change.

Added in version 3.12.

Py_ssize_t PyUnstable_Long_CompactValue(const PyLongObject *op)

This is Unstable API. It may change without warning in minor releases.

If *op* is compact, as determined by `PyUnstable_Long_IsCompact()`, return its value.

Otherwise, the return value is undefined.

Added in version 3.12.

Export API

Added in version 3.14.

struct PyLongLayout

Layout of an array of “digits” (“limbs” in the GMP terminology), used to represent absolute value for arbitrary precision integers.

Use `PyLong_GetNativeLayout()` to get the native layout of Python `int` objects, used internally for integers with “big enough” absolute value.

See also `sys.int_info` which exposes similar information in Python.

uint8_t bits_per_digit

Bits per digit. For example, a 15 bit digit means that bits 0-14 contain meaningful information.

uint8_t digit_size

Digit size in bytes. For example, a 15 bit digit will require at least 2 bytes.

int8_t digits_order

Digits order:

- `1` for most significant digit first
- `-1` for least significant digit first

int8_t digit_endianness

Digit endianness:

- `1` for most significant byte first (big endian)
- `-1` for least significant byte first (little endian)

const PyLongLayout *PyLong_GetNativeLayout(void)

Get the native layout of Python `int` objects.

See the `PyLongLayout` structure.

The function must not be called before Python initialization nor after Python finalization. The returned layout is valid until Python is finalized. The layout is the same for all Python sub-interpreters in a process, and so it can be cached.

struct PyLongExport

Export of a Python `int` object.

There are two cases:

- If `digits` is `NULL`, only use the `value` member.
- If `digits` is not `NULL`, use `negative`, `ndigits` and `digits` members.

int64_t value

The native integer value of the exported `int` object. Only valid if `digits` is `NULL`.

uint8_t negative

`1` if the number is negative, `0` otherwise. Only valid if `digits` is not `NULL`.

Py_ssize_t ndigits

Number of digits in `digits` array. Only valid if `digits` is not `NULL`.

const void *digits

Read-only array of unsigned digits. Can be `NULL`.

int PyLong_Export(PyObject *obj, PyLongExport *export_long)

Export a Python `int` object.

export_long must point to a **`PyLongExport`** structure allocated by the caller. It must not be `NULL`.

On success, fill in **export_long* and return `0`. On error, set an exception and return `-1`.

`PyLong_FreeExport()` must be called when the export is no longer needed.

> **CPython implementation detail:** This function always succeeds if *obj* is a Python **`int`** object or a subclass.

void PyLong_FreeExport(PyLongExport *export_long)

Release the export *export_long* created by **`PyLong_Export()`**.

CPython implementation detail: Calling **`PyLong_FreeExport()`** is optional if *export_long->digits* is `NULL`.

PyLongWriter API

The **`PyLongWriter`** API can be used to import an integer.

Added in version 3.14.

struct PyLongWriter

A Python **`int`** writer instance.

The instance must be destroyed by **`PyLongWriter_Finish()`** or **`PyLongWriter_Discard()`**.

PyLongWriter *PyLongWriter_Create(int negative, Py_ssize_t ndigits, void **digits)

Create a **`PyLongWriter`**.

On success, allocate **digits* and return a writer. On error, set an exception and return `NULL`.

negative is `1` if the number is negative, or `0` otherwise.

ndigits is the number of digits in the *digits* array. It must be greater than 0.

digits must not be NULL.

After a successful call to this function, the caller should fill in the array of digits *digits* and then call **`PyLongWriter_Finish()`** to get a Python **`int`**. The layout of *digits* is described by **`PyLong_GetNativeLayout()`**.

Digits must be in the range [`0`; `(1 << bits_per_digit) - 1`] (where the **`bits_per_digit`** is the number of bits per digit). Any unused most significant digits must be set to `0`.

Alternately, call **`PyLongWriter_Discard()`** to destroy the writer instance without creating an **`int`** object.

PyObject *PyLongWriter_Finish(PyLongWriter *writer)

Return value: New reference.
Finish a **`PyLongWriter`** created by **`PyLongWriter_Create()`**.

On success, return a Python **`int`** object. On error, set an exception and return `NULL`.

The function takes care of normalizing the digits and converts the object to a compact integer if needed.

The writer instance and the *digits* array are invalid after the call.

void PyLongWriter_Discard(PyLongWriter *writer)

Discard a **`PyLongWriter`** created by **`PyLongWriter_Create()`**.

If *writer* is `NULL`, no operation is performed.

The writer instance and the *digits* array are invalid after the call.

Deprecated API

These macros are soft deprecated. They describe parameters of the internal representation of **`PyLongObject`** instances.

Use **`PyLong_GetNativeLayout()`** instead, along with **`PyLong_Export()`** to read integer data or **`PyLongWriter`** to write it. These currently use the same layout, but are designed to continue working correctly even if CPython's internal integer representation changes.

PyLong_SHIFT

This is equivalent to **`bits_per_digit`** in the output of **`PyLong_GetNativeLayout()`**.

PyLong_BASE

This is currently equivalent to 1 << PyLong_SHIFT.

PyLong_MASK

This is currently equivalent to (1 << PyLong_SHIFT) - 1

Boolean Objects

Booleans in Python are implemented as a subclass of integers. There are only two booleans, **`Py_False`** and **`Py_True`**. As such, the normal creation and deletion functions don't apply to booleans. The following macros are available, however.

PyTypeObject PyBool_Type

Part of the Stable ABI.

This instance of **`PyTypeObject`** represents the Python boolean type; it is the same object as **`bool`** in the Python layer.

int PyBool_Check(PyObject *o)

Return true if *o* is of type **`PyBool_Type`**. This function always succeeds.

PyObject *Py_False

The Python `False` object. This object has no methods and is immortal.

Changed in version 3.12: **`Py_False`** is immortal.

PyObject *Py_True

The Python `True` object. This object has no methods and is immortal.

Changed in version 3.12: **`Py_True`** is immortal.

Py_RETURN_FALSE

Return **`Py_False`** from a function.

Py_RETURN_TRUE

Return `Py_True` from a function.

PyObject *PyBool_FromLong(long v)

Return value: New reference. Part of the Stable ABI.

Return `Py_True` or `Py_False`, depending on the truth value of *v*.

Floating-Point Objects

type PyFloatObject

This subtype of **`PyObject`** represents a Python floating-point object.

PyTypeObject PyFloat_Type

Part of the Stable ABI.

This instance of **`PyTypeObject`** represents the Python floating-point type. This is the same object as **`float`** in the Python layer.

int PyFloat_Check(PyObject *p)

Return true if its argument is a **`PyFloatObject`** or a subtype of **`PyFloatObject`**. This function always succeeds.

int PyFloat_CheckExact(PyObject *p)

Return true if its argument is a **`PyFloatObject`**, but not a subtype of **`PyFloatObject`**. This function always succeeds.

PyObject *PyFloat_FromString(PyObject *str)

Return value: New reference. Part of the Stable ABI.

Create a **`PyFloatObject`** object based on the string value in *str*, or `NULL` on failure.

PyObject *PyFloat_FromDouble(double v)

Return value: New reference. Part of the Stable ABI.

Create a **`PyFloatObject`** object from *v*, or `NULL` on failure.

double PyFloat_AsDouble(PyObject *pyfloat)

Part of the Stable ABI.

Return a C double representation of the contents of *pyfloat*. If *pyfloat* is not a Python floating-point object but has a `__float__()` method, this method will first be called to convert *pyfloat* into a float. If `__float__()` is not defined then it falls back to `__index__()`. This method returns `-1.0` upon failure, so one should call `PyErr_Occurred()` to check for errors.

Changed in version 3.8: Use `__index__()` if available.

double PyFloat_AS_DOUBLE(PyObject *pyfloat)

Return a C double representation of the contents of *pyfloat*, but without error checking.

PyObject *PyFloat_GetInfo(void)

Return value: New reference. Part of the Stable ABI.
Return a structseq instance which contains information about the precision, minimum and maximum values of a float. It's a thin wrapper around the header file `float.h`.

double PyFloat_GetMax()

Part of the Stable ABI.
Return the maximum representable finite float *DBL_MAX* as C double.

double PyFloat_GetMin()

Part of the Stable ABI.
Return the minimum normalized positive float *DBL_MIN* as C double.

Py_INFINITY

This macro expands a to constant expression of type double, that represents the positive infinity.

On most platforms, this is equivalent to the **`INFINITY`** macro from the C11 standard `<math.h>` header.

Py_NAN

This macro expands a to constant expression of type double, that represents a quiet not-a-number (qNaN) value.

On most platforms, this is equivalent to the **`NAN`** macro from the C11 standard `<math.h>` header.

Py_HUGE_VAL

Equivalent to **`INFINITY`**.

Deprecated since version 3.14: The macro is soft deprecated.

Py_MATH_E

The definition (accurate for a double type) of the **`math.e`** constant.

Py_MATH_El

High precision (long double) definition of **`e`** constant.

Py_MATH_PI

The definition (accurate for a double type) of the **`math.pi`** constant.

Py_MATH_PIl

High precision (long double) definition of **`pi`** constant.

Py_MATH_TAU

The definition (accurate for a double type) of the **`math.tau`** constant.

Added in version 3.6.

Py_RETURN_NAN

Return **`math.nan`** from a function.

On most platforms, this is equivalent to `return PyFloat_FromDouble(NAN)`.

Py_RETURN_INF(sign)

Return **`math.inf`** or **`-math.inf`** from a function, depending on the sign of *sign*.

On most platforms, this is equivalent to the following:

```
return PyFloat_FromDouble(copysign(INFINITY, sign));
```

Py_IS_FINITE(X)

Return `1` if the given floating-point number *X* is finite, that is, it is normal, subnormal or zero, but not infinite or NaN. Return `0` otherwise.

Deprecated since version 3.14: The macro is soft deprecated. Use **`isfinite`** instead.

Py_IS_INFINITY(X)

Return `1` if the given floating-point number *X* is positive or negative infinity. Return `0` otherwise.

Deprecated since version 3.14: The macro is soft deprecated. Use **`isinf`** instead.

Py_IS_NAN(X)

Return `1` if the given floating-point number *X* is a not-a-number (NaN) value. Return `0` otherwise.

Deprecated since version 3.14: The macro is soft deprecated. Use **`isnan`** instead.

Pack and Unpack functions

The pack and unpack functions provide an efficient platform-independent way to store floating-point values as byte strings. The Pack routines produce a bytes string from a C double, and the Unpack routines produce a C double from such a bytes string. The suffix (2, 4 or 8) specifies the number of bytes in the bytes string.

On platforms that appear to use IEEE 754 formats these functions work by copying bits. On other platforms, the 2-byte format is identical to the IEEE 754 binary16 half-precision format, the 4-byte format (32-bit) is identical to the IEEE 754 binary32 single precision format, and the 8-byte format to the IEEE 754 binary64 double precision format, although the packing of INFs and NaNs (if such things exist on the platform) isn't handled correctly, and attempting to unpack a bytes string containing an IEEE INF or NaN will raise an exception.

Note that NaNs type may not be preserved on IEEE platforms (signaling NaN become quiet NaN), for example on x86 systems in 32-bit mode.

On non-IEEE platforms with more precision, or larger dynamic range, than IEEE 754 supports, not all values can be packed; on non-IEEE platforms with less precision, or smaller dynamic range, not all values can be unpacked. What happens in such cases is partly accidental (alas).

Added in version 3.11.

Pack functions

The pack routines write 2, 4 or 8 bytes, starting at *p*. *le* is an int argument, non-zero if you want the bytes string in little-endian format (exponent last, at `p+1`, `p+3`, or `p+6` `p+7`), zero if you want big-endian format (exponent first, at *p*). The

`PY_BIG_ENDIAN` constant can be used to use the native endian: it is equal to `1` on big endian processor, or `0` on little endian processor.

Return value: `0` if all is OK, `-1` if error (and an exception is set, most likely `OverflowError`).

There are two problems on non-IEEE platforms:

- What this does is undefined if *x* is a NaN or infinity.
- `-0.0` and `+0.0` produce the same bytes string.

int PyFloat_Pack2(double x, char *p, int le)

Pack a C double as the IEEE 754 binary16 half-precision format.

int PyFloat_Pack4(double x, char *p, int le)

Pack a C double as the IEEE 754 binary32 single precision format.

int PyFloat_Pack8(double x, char *p, int le)

Pack a C double as the IEEE 754 binary64 double precision format.

Unpack functions

The unpack routines read 2, 4 or 8 bytes, starting at *p*. *le* is an int argument, non-zero if the bytes string is in little-endian format (exponent last, at `p+1`, `p+3` or `p+6` and `p+7`), zero if big-endian (exponent first, at *p*). The **`PY_BIG_ENDIAN`** constant can be used to use the native endian: it is equal to `1` on big endian processor, or `0` on little endian processor.

Return value: The unpacked double. On error, this is `-1.0` and `PyErr_Occurred()` is true (and an exception is set, most likely `OverflowError`).

Note that on a non-IEEE platform this will refuse to unpack a bytes string that represents a NaN or infinity.

double PyFloat_Unpack2(const char *p, int le)

Unpack the IEEE 754 binary16 half-precision format as a C double.

double PyFloat_Unpack4(const char *p, int le)

Unpack the IEEE 754 binary32 single precision format as a C double.

double PyFloat_Unpack8(const char *p, int le)

Unpack the IEEE 754 binary64 double precision format as a C double.

Complex Number Objects

Python’s complex number objects are implemented as two distinct types when viewed from the C API: one is the Python object exposed to Python programs, and the other is a C structure which represents the actual complex number value. The API provides functions for working with both.

Complex Numbers as C Structures

Note that the functions which accept these structures as parameters and return them as results do so *by value* rather than dereferencing them through pointers. This is consistent throughout the API.

type Py_complex

The C structure which corresponds to the value portion of a Python complex number object. Most of the functions for dealing with complex number objects use structures of this type as input or output values, as appropriate.

double real
double imag

The structure is defined as:

```
typedef struct {
    double real;
    double imag;
} Py_complex;
```

Py_complex _Py_c_sum(Py_complex left, Py_complex right)

Return the sum of two complex numbers, using the C **`Py_complex`** representation.

Py_complex _Py_c_diff(Py_complex left, Py_complex right)

Return the difference between two complex numbers, using the C `Py_complex` representation.

Py_complex _Py_c_neg(Py_complex num)

Return the negation of the complex number *num*, using the C `Py_complex` representation.

Py_complex _Py_c_prod(Py_complex left, Py_complex right)

Return the product of two complex numbers, using the C `Py_complex` representation.

Py_complex _Py_c_quot(Py_complex dividend, Py_complex divisor)

Return the quotient of two complex numbers, using the C `Py_complex` representation.

If *divisor* is null, this method returns zero and sets `errno` to `EDOM`.

Py_complex _Py_c_pow(Py_complex num, Py_complex exp)

Return the exponentiation of *num* by *exp*, using the C `Py_complex` representation.

If *num* is null and *exp* is not a positive real number, this method returns zero and sets `errno` to `EDOM`.

Set `errno` to `ERANGE` on overflows.

Complex Numbers as Python Objects

type PyComplexObject

This subtype of `PyObject` represents a Python complex number object.

PyTypeObject PyComplex_Type

Part of the Stable ABI.

This instance of `PyTypeObject` represents the Python complex number type. It is the same object as `complex` in the Python layer.

int PyComplex_Check(PyObject *p)

Return true if its argument is a `PyComplexObject` or a subtype of `PyComplexObject`. This function always succeeds.

int PyComplex_CheckExact(PyObject *p)

Return true if its argument is a `PyComplexObject`, but not a subtype of `PyComplexObject`. This function always succeeds.

PyObject *PyComplex_FromCComplex(Py_complex v)

Return value: New reference.

Create a new Python complex number object from a C `Py_complex` value. Return `NULL` with an exception set on error.

PyObject *PyComplex_FromDoubles(double real, double imag)

Return value: New reference. Part of the Stable ABI.

Return a new `PyComplexObject` object from *real* and *imag*. Return `NULL` with an exception set on error.

double PyComplex_RealAsDouble(PyObject *op)

Part of the Stable ABI.

Return the real part of *op* as a C double.

If *op* is not a Python complex number object but has a `__complex__()` method, this method will first be called to convert *op* to a Python complex number object. If `__complex__()` is not defined then it falls back to call `PyFloat_AsDouble()` and returns its result.

Upon failure, this method returns `-1.0` with an exception set, so one should call **`PyErr_Occurred()`** to check for errors.

Changed in version 3.13: Use **`__complex__()`** if available.

double PyComplex_ImagAsDouble(PyObject *op)

Part of the Stable ABI.

Return the imaginary part of *op* as a C double.

If *op* is not a Python complex number object but has a **`__complex__()`** method, this method will first be called to convert *op* to a Python complex number object. If **`__complex__()`** is not defined then it falls back to call **`PyFloat_AsDouble()`** and returns `0.0` on success.

Upon failure, this method returns `-1.0` with an exception set, so one should call **`PyErr_Occurred()`** to check for errors.

Changed in version 3.13: Use **`__complex__()`** if available.

Py_complex PyComplex_AsCComplex(PyObject *op)

Return the **`Py_complex`** value of the complex number *op*.

If *op* is not a Python complex number object but has a **`__complex__()`** method, this method will first be called to convert *op* to a Python complex number object. If **`__complex__()`** is not defined then it falls back to **`__float__()`**. If **`__float__()`** is not defined then it falls back to **`__index__()`**.

Upon failure, this method returns **`Py_complex`** with **`real`** set to `-1.0` and with an exception set, so one should call **`PyErr_Occurred()`** to check for errors.

Changed in version 3.8: Use **`__index__()`** if available.

Bytes Objects

These functions raise `TypeError` when expecting a bytes parameter and called with a non-bytes parameter.

type PyBytesObject

This subtype of `PyObject` represents a Python bytes object.

PyTypeObject PyBytes_Type

Part of the Stable ABI.

This instance of `PyTypeObject` represents the Python bytes type; it is the same object as `bytes` in the Python layer.

int PyBytes_Check(PyObject *o)

Return true if the object *o* is a bytes object or an instance of a subtype of the bytes type. This function always succeeds.

int PyBytes_CheckExact(PyObject *o)

Return true if the object *o* is a bytes object, but not an instance of a subtype of the bytes type. This function always succeeds.

PyObject *PyBytes_FromString(const char *v)

Return value: New reference. Part of the Stable ABI.

Return a new bytes object with a copy of the string *v* as value on success, and `NULL` on failure. The parameter *v* must not be `NULL`; it will not be checked.

PyObject *PyBytes_FromStringAndSize(const char *v, Py_ssize_t len)

Return value: New reference. Part of the Stable ABI.

Return a new bytes object with a copy of the string *v* as value and length *len* on success, and `NULL` on failure. If *v* is `NULL`, the contents of the bytes object are uninitialized.

PyObject *PyBytes_FromFormat(const char *format, ...)

Return value: New reference. Part of the Stable ABI.
Take a C **`printf()`**-style *format* string and a variable number of arguments, calculate the size of the resulting Python bytes object and return a bytes object with the values formatted into it. The variable arguments must be C types and must correspond exactly to the format characters in the *format* string. The following format characters are allowed:

Format Characters	**Type**	**Comment**
`%%`	*n/a*	The literal % character.
`%c`	int	A single byte, represented as a C int.
`%d`	int	Equivalent to `printf("%d")`. [[1]]
`%u`	unsigned int	Equivalent to `printf("%u")`. [[1]]
`%ld`	long	Equivalent to `printf("%ld")`. [[1]]
`%lu`	unsigned long	Equivalent to `printf("%lu")`. [[1]]
`%zd`	**`Py_ssize_t`**	Equivalent to `printf("%zd")`. [[1]]

Format Characters	Type	Comment
`%zu`	size_t	Equivalent to `printf("%zu")`. [[1]]
`%i`	int	Equivalent to `printf("%i")`. [[1]]
`%x`	int	Equivalent to `printf("%x")`. [[1]]
`%s`	const char*	A null-terminated C character array.
`%p`	const void*	The hex representation of a C pointer. Mostly equivalent to `printf("%p")` except that it is guaranteed to start with the literal `0x` regardless of what the platform's `printf` yields.

An unrecognized format character causes all the rest of the format string to be copied as-is to the result object, and any extra arguments discarded.

[1] (1,2,3,4,5,6,7,8)
For integer specifiers (d, u, ld, lu, zd, zu, i, x): the 0-conversion flag has effect even when a precision is given.

PyObject *PyBytes_FromFormatV(const char *format, va_list vargs)

Return value: New reference. Part of the Stable ABI.
Identical to **`PyBytes_FromFormat()`** except that it takes exactly two arguments.

PyObject *PyBytes_FromObject(PyObject *o)

Return value: New reference. Part of the Stable ABI.
Return the bytes representation of object *o* that implements the buffer protocol.

Py_ssize_t PyBytes_Size(PyObject *o)

Part of the Stable ABI.
Return the length of the bytes in bytes object *o*.

Py_ssize_t PyBytes_GET_SIZE(PyObject *o)

Similar to **`PyBytes_Size()`**, but without error checking.

char *PyBytes_AsString(PyObject *o)

Part of the Stable ABI.
Return a pointer to the contents of *o*. The pointer refers to the internal buffer of *o*, which consists of `len(o) + 1` bytes. The last byte in the buffer is always null, regardless of whether there are any other null bytes. The data must not be modified in any way, unless the object was just created using `PyBytes_FromStringAndSize(NULL, size)`. It must not be deallocated. If *o* is not a bytes object at all, **`PyBytes_AsString()`** returns `NULL` and raises **`TypeError`**.

char *PyBytes_AS_STRING(PyObject *string)

Similar to **`PyBytes_AsString()`**, but without error checking.

int PyBytes_AsStringAndSize(PyObject *obj, char **buffer, Py_ssize_t *length)

Part of the Stable ABI.
Return the null-terminated contents of the object *obj* through the output variables *buffer* and *length*. Returns `0` on success.

If *length* is `NULL`, the bytes object may not contain embedded null bytes; if it does, the function returns `-1` and a `ValueError` is raised.

The buffer refers to an internal buffer of *obj*, which includes an additional null byte at the end (not counted in *length*). The data must not be modified in any way, unless the object was just created using `PyBytes_FromStringAndSize(NULL, size)`. It must not be deallocated. If *obj* is not a bytes object at all, `PyBytes_AsStringAndSize()` returns `-1` and raises `TypeError`.

Changed in version 3.5: Previously, `TypeError` was raised when embedded null bytes were encountered in the bytes object.

void PyBytes_Concat(PyObject **bytes, PyObject *newpart)

Part of the Stable ABI.

Create a new bytes object in **bytes* containing the contents of *newpart* appended to *bytes*; the caller will own the new reference. The reference to the old value of *bytes* will be stolen. If the new object cannot be created, the old reference to *bytes* will still be discarded and the value of **bytes* will be set to `NULL`; the appropriate exception will be set.

void PyBytes_ConcatAndDel(PyObject **bytes, PyObject *newpart)

Part of the Stable ABI.

Create a new bytes object in **bytes* containing the contents of *newpart* appended to *bytes*. This version releases the strong reference to *newpart* (i.e. decrements its reference count).

PyObject *PyBytes_Join(PyObject *sep, PyObject *iterable)

Similar to `sep.join(iterable)` in Python.

sep must be Python **`bytes`** object. (Note that **`PyUnicode_Join()`** accepts `NULL` separator and treats it as a space, whereas **`PyBytes_Join()`** doesn't accept `NULL` separator.)

iterable must be an iterable object yielding objects that implement the buffer protocol.

On success, return a new **`bytes`** object. On error, set an exception and return `NULL`.

Added in version 3.14.

int _PyBytes_Resize(PyObject **bytes, Py_ssize_t newsize)

Resize a bytes object. *newsize* will be the new length of the bytes object. You can think of it as creating a new bytes object and destroying the old one, only more efficiently. Pass the address of an existing bytes object as an lvalue (it may be written into), and the new size desired. On success, **bytes* holds the resized bytes object and `0` is returned; the address in **bytes* may differ from its input value. If the reallocation fails, the original bytes object at **bytes* is deallocated, **bytes* is set to `NULL`, **`MemoryError`** is set, and `-1` is returned.

PyObject *PyBytes_Repr(PyObject *bytes, int smartquotes)

Part of the Stable ABI.

Get the string representation of *bytes*. This function is currently used to implement **`bytes.__repr__()`** in Python.

This function does not do type checking; it is undefined behavior to pass *bytes* as a non-bytes object or `NULL`.

If *smartquotes* is true, the representation will use a double-quoted string instead of single-quoted string when single-quotes are present in *bytes*. For example, the byte string `'Python'` would be represented as `b"'Python'"` when *smartquotes* is true, or `b'\'Python\''` when it is false.

On success, this function returns a strong reference to a **`str`** object containing the representation. On failure, this returns `NULL` with an exception set.

PyObject *PyBytes_DecodeEscape(const char *s, Py_ssize_t len, const char *errors, Py_ssize_t unicode, const char *recode_encoding)

Part of the Stable ABI.
Unescape a backslash-escaped string *s*. *s* must not be `NULL`. *len* must be the size of *s*.

errors must be one of `"strict"`, `"replace"`, or `"ignore"`. If *errors* is `NULL`, then `"strict"` is used by default.

On success, this function returns a strong reference to a Python **`bytes`** object containing the unescaped string. On failure, this function returns `NULL` with an exception set.

Changed in version 3.9: unicode and *recode_encoding* are now unused.

Byte Array Objects

type PyByteArrayObject

This subtype of **`PyObject`** represents a Python bytearray object.

PyTypeObject PyByteArray_Type

Part of the Stable ABI.

This instance of **`PyTypeObject`** represents the Python bytearray type; it is the same object as **`bytearray`** in the Python layer.

Type check macros

int PyByteArray_Check(PyObject *o)

Return true if the object *o* is a bytearray object or an instance of a subtype of the bytearray type. This function always succeeds.

int PyByteArray_CheckExact(PyObject *o)

Return true if the object *o* is a bytearray object, but not an instance of a subtype of the bytearray type. This function always succeeds.

Direct API functions

PyObject *PyByteArray_FromObject(PyObject *o)

Return value: New reference. Part of the Stable ABI.

Return a new bytearray object from any object, *o*, that implements the buffer protocol.

On failure, return `NULL` with an exception set.

PyObject *PyByteArray_FromStringAndSize(const char *string, Py_ssize_t len)

Return value: New reference. Part of the Stable ABI.
Create a new bytearray object from *string* and its length, *len*.

On failure, return `NULL` with an exception set.

PyObject *PyByteArray_Concat(PyObject *a, PyObject *b)

Return value: New reference. Part of the Stable ABI.
Concat bytearrays *a* and *b* and return a new bytearray with the result.

On failure, return `NULL` with an exception set.

Py_ssize_t PyByteArray_Size(PyObject *bytearray)

Part of the Stable ABI.
Return the size of *bytearray* after checking for a `NULL` pointer.

char *PyByteArray_AsString(PyObject *bytearray)

Part of the Stable ABI.
Return the contents of *bytearray* as a char array after checking for a `NULL` pointer. The returned array always has an extra null byte appended.

int PyByteArray_Resize(PyObject *bytearray, Py_ssize_t len)

Part of the Stable ABI.
Resize the internal buffer of *bytearray* to *len*. Failure is a `-1` return with an exception set.

Changed in version 3.14: A negative *len* will now result in an exception being set and -1 returned.

Macros

These macros trade safety for speed and they don’t check pointers.

char *PyByteArray_AS_STRING(PyObject *bytearray)

Similar to `PyByteArray_AsString()`, but without error checking.

Py_ssize_t PyByteArray_GET_SIZE(PyObject *bytearray)

Similar to `PyByteArray_Size()`, but without error checking.

Unicode Objects and Codecs

Unicode Objects

Since the implementation of **PEP 393** [https://peps.python.org/pep-0393/] in Python 3.3, Unicode objects internally use a variety of representations, in order to allow handling the complete range of Unicode characters while staying memory efficient. There are special cases for strings where all code points are below 128, 256, or 65536; otherwise, code points must be below 1114112 (which is the full Unicode range).

UTF-8 representation is created on demand and cached in the Unicode object.

Note

The `Py_UNICODE` representation has been removed since Python 3.12 with deprecated APIs. See **PEP 623** [https://peps.python.org/pep-0623/] for more information.

Unicode Type

These are the basic Unicode object types used for the Unicode implementation in Python:

PyTypeObject PyUnicode_Type

Part of the Stable ABI.
This instance of `PyTypeObject` represents the Python Unicode type. It is exposed to Python code as `str`.

PyTypeObject PyUnicodeIter_Type

Part of the Stable ABI.

This instance of `PyTypeObject` represents the Python Unicode iterator type. It is used to iterate over Unicode string objects.

type Py_UCS4
type Py_UCS2
type Py_UCS1

Part of the Stable ABI.

These types are typedefs for unsigned integer types wide enough to contain characters of 32 bits, 16 bits and 8 bits, respectively. When dealing with single Unicode characters, use `Py_UCS4`.

Added in version 3.3.

type PyASCIIObject
type PyCompactUnicodeObject
type PyUnicodeObject

These subtypes of `PyObject` represent a Python Unicode object. In almost all cases, they shouldn't be used directly, since all API functions that deal with Unicode objects take and return `PyObject` pointers.

Added in version 3.3.

The structure of a particular object can be determined using the following macros. The macros cannot fail; their behavior is undefined if their argument is not a Python Unicode object.

PyUnicode_IS_COMPACT(o)

True if *o* uses the `PyCompactUnicodeObject` structure.

Added in version 3.3.

PyUnicode_IS_COMPACT_ASCII(o)

True if *o* uses the **`PyASCIIObject`** structure.

Added in version 3.3.

The following APIs are C macros and static inlined functions for fast checks and access to internal read-only data of Unicode objects:

int PyUnicode_Check(PyObject *obj)

Return true if the object *obj* is a Unicode object or an instance of a Unicode subtype. This function always succeeds.

int PyUnicode_CheckExact(PyObject *obj)

Return true if the object *obj* is a Unicode object, but not an instance of a subtype. This function always succeeds.

Py_ssize_t PyUnicode_GET_LENGTH(PyObject *unicode)

Return the length of the Unicode string, in code points. *unicode* has to be a Unicode object in the “canonical” representation (not checked).

Added in version 3.3.

Py_UCS1 *PyUnicode_1BYTE_DATA(PyObject *unicode)
Py_UCS2 *PyUnicode_2BYTE_DATA(PyObject *unicode)
Py_UCS4 *PyUnicode_4BYTE_DATA(PyObject *unicode)

Return a pointer to the canonical representation cast to UCS1, UCS2 or UCS4 integer types for direct character access. No checks are performed if the canonical representation has the correct character size; use **`PyUnicode_KIND()`** to select the right function.

Added in version 3.3.

PyUnicode_1BYTE_KIND

PyUnicode_2BYTE_KIND
PyUnicode_4BYTE_KIND

Return values of the `PyUnicode_KIND()` macro.

Added in version 3.3.

Changed in version 3.12: `PyUnicode_WCHAR_KIND` has been removed.

int PyUnicode_KIND(PyObject *unicode)

Return one of the PyUnicode kind constants (see above) that indicate how many bytes per character this Unicode object uses to store its data. *unicode* has to be a Unicode object in the “canonical” representation (not checked).

Added in version 3.3.

void *PyUnicode_DATA(PyObject *unicode)

Return a void pointer to the raw Unicode buffer. *unicode* has to be a Unicode object in the “canonical” representation (not checked).

Added in version 3.3.

void PyUnicode_WRITE(int kind, void *data, Py_ssize_t index, Py_UCS4 value)

Write the code point *value* to the given zero-based *index* in a string.

The *kind* value and *data* pointer must have been obtained from a string using `PyUnicode_KIND()` and `PyUnicode_DATA()` respectively. You must hold a reference to that string while calling **`PyUnicode_WRITE()`**. All requirements of `PyUnicode_WriteChar()` also apply.

The function performs no checks for any of its requirements, and is intended for usage in loops.

Added in version 3.3.

Py_UCS4 PyUnicode_READ(int kind, void *data, Py_ssize_t index)

Read a code point from a canonical representation *data* (as obtained with `PyUnicode_DATA()`). No checks or ready calls are performed.

Added in version 3.3.

Py_UCS4 PyUnicode_READ_CHAR(PyObject *unicode, Py_ssize_t index)

Read a character from a Unicode object *unicode*, which must be in the “canonical” representation. This is less efficient than `PyUnicode_READ()` if you do multiple consecutive reads.

Added in version 3.3.

Py_UCS4 PyUnicode_MAX_CHAR_VALUE(PyObject *unicode)

Return the maximum code point that is suitable for creating another string based on *unicode*, which must be in the “canonical” representation. This is always an approximation but more efficient than iterating over the string.

Added in version 3.3.

int PyUnicode_IsIdentifier(PyObject *unicode)

Part of the Stable ABI.

Return `1` if the string is a valid identifier according to the language definition, section Names (identifiers and keywords). Return `0` otherwise.

Changed in version 3.9: The function does not call `Py_FatalError()` anymore if the string is not ready.

unsigned int PyUnicode_IS_ASCII(PyObject *unicode)

Return true if the string only contains ASCII characters. Equivalent to `str.isascii()`.

Added in version 3.2.

Unicode Character Properties

Unicode provides many different character properties. The most often needed ones are available through these macros which are mapped to C functions depending on the Python configuration.

int Py_UNICODE_ISSPACE(Py_UCS4 ch)

Return `1` or `0` depending on whether *ch* is a whitespace character.

int Py_UNICODE_ISLOWER(Py_UCS4 ch)

Return `1` or `0` depending on whether *ch* is a lowercase character.

int Py_UNICODE_ISUPPER(Py_UCS4 ch)

Return `1` or `0` depending on whether *ch* is an uppercase character.

int Py_UNICODE_ISTITLE(Py_UCS4 ch)

Return `1` or `0` depending on whether *ch* is a titlecase character.

int Py_UNICODE_ISLINEBREAK(Py_UCS4 ch)

Return `1` or `0` depending on whether *ch* is a linebreak character.

int Py_UNICODE_ISDECIMAL(Py_UCS4 ch)

Return `1` or `0` depending on whether *ch* is a decimal character.

int Py_UNICODE_ISDIGIT(Py_UCS4 ch)

Return `1` or `0` depending on whether *ch* is a digit character.

int Py_UNICODE_ISNUMERIC(Py_UCS4 ch)

Return `1` or `0` depending on whether *ch* is a numeric character.

int Py_UNICODE_ISALPHA(Py_UCS4 ch)

Return `1` or `0` depending on whether *ch* is an alphabetic character.

int Py_UNICODE_ISALNUM(Py_UCS4 ch)

Return `1` or `0` depending on whether *ch* is an alphanumeric character.

int Py_UNICODE_ISPRINTABLE(Py_UCS4 ch)

Return `1` or `0` depending on whether *ch* is a printable character, in the sense of **`str.isprintable()`**.

These APIs can be used for fast direct character conversions:

Py_UCS4 Py_UNICODE_TOLOWER(Py_UCS4 ch)

Return the character *ch* converted to lower case.

Py_UCS4 Py_UNICODE_TOUPPER(Py_UCS4 ch)

Return the character *ch* converted to upper case.

Py_UCS4 Py_UNICODE_TOTITLE(Py_UCS4 ch)

Return the character *ch* converted to title case.

int Py_UNICODE_TODECIMAL(Py_UCS4 ch)

Return the character *ch* converted to a decimal positive integer. Return `-1` if this is not possible. This function does not raise exceptions.

int Py_UNICODE_TODIGIT(Py_UCS4 ch)

Return the character *ch* converted to a single digit integer. Return `-1` if this is not possible. This function does not raise exceptions.

double Py_UNICODE_TONUMERIC(Py_UCS4 ch)

Return the character *ch* converted to a double. Return `-1.0` if this is not possible. This function does not raise exceptions.

These APIs can be used to work with surrogates:

int Py_UNICODE_IS_SURROGATE(Py_UCS4 ch)

Check if *ch* is a surrogate (`0xD800 <= ch <= 0xDFFF`).

int Py_UNICODE_IS_HIGH_SURROGATE(Py_UCS4 ch)

Check if *ch* is a high surrogate (`0xD800 <= ch <= 0xDBFF`).

int Py_UNICODE_IS_LOW_SURROGATE(Py_UCS4 ch)

Check if *ch* is a low surrogate (`0xDC00 <= ch <= 0xDFFF`).

Py_UCS4 Py_UNICODE_HIGH_SURROGATE(Py_UCS4 ch)

Return the high UTF-16 surrogate (`0xD800` to `0xDBFF`) for a Unicode code point in the range `[0x10000; 0x10FFFF]`.

Py_UCS4 Py_UNICODE_LOW_SURROGATE(Py_UCS4 ch)

Return the low UTF-16 surrogate (`0xDC00` to `0xDFFF`) for a Unicode code point in the range `[0x10000; 0x10FFFF]`.

Py_UCS4 Py_UNICODE_JOIN_SURROGATES(Py_UCS4 high, Py_UCS4 low)

Join two surrogate code points and return a single **`Py_UCS4`** value. *high* and *low* are respectively the leading and trailing surrogates in a surrogate pair. *high* must be in the range `[0xD800; 0xDBFF]` and *low* must be in the range `[0xDC00; 0xDFFF]`.

Creating and accessing Unicode strings

To create Unicode objects and access their basic sequence properties, use these APIs:

PyObject *PyUnicode_New(Py_ssize_t size, Py_UCS4 maxchar)

Return value: New reference.
Create a new Unicode object. *maxchar* should be the true maximum code point to be placed in the string. As an approximation, it can be rounded up to the nearest value in the sequence 127, 255, 65535, 1114111.

On error, set an exception and return `NULL`.

After creation, the string can be filled by **`PyUnicode_WriteChar()`**, **`PyUnicode_CopyCharacters()`**, **`PyUnicode_Fill()`**, **`PyUnicode_WRITE()`** or similar. Since strings are supposed to be immutable, take care to not “use” the result while it is being modified. In particular, before it’s filled with its final contents, a string:

- must not be hashed,
- must not be **`converted to UTF-8`**, or another non-“canonical” representation,
- must not have its reference count changed,
- must not be shared with code that might do one of the above.

This list is not exhaustive. Avoiding these uses is your responsibility; Python does not always check these requirements.

To avoid accidentally exposing a partially-written string object, prefer using the **`PyUnicodeWriter`** API, or one of the `PyUnicode_From*` functions below.

Added in version 3.3.

PyObject *PyUnicode_FromKindAndData(int kind, const void *buffer, Py_ssize_t size)

Return value: New reference.
Create a new Unicode object with the given *kind* (possible values are **`PyUnicode_1BYTE_KIND`** etc., as returned by **`PyUnicode_KIND()`**). The *buffer* must point to an array of *size* units of 1, 2 or 4 bytes per character, as given by the kind.

If necessary, the input *buffer* is copied and transformed into the canonical representation. For example, if the *buffer* is a UCS4 string (**`PyUnicode_4BYTE_KIND`**) and it consists only of codepoints in the UCS1 range, it will be transformed into UCS1 (**`PyUnicode_1BYTE_KIND`**).

Added in version 3.3.

PyObject *PyUnicode_FromStringAndSize(const char *str, Py_ssize_t size)

Return value: New reference. Part of the Stable ABI.
Create a Unicode object from the char buffer *str*. The bytes will be interpreted as being UTF-8 encoded. The buffer is copied into the new object. The return value might be a shared object, i.e. modification of the data is not allowed.

This function raises **`SystemError`** when:

- *size* < 0,
- *str* is `NULL` and *size* > 0

Changed in version 3.12: str == `NULL` with *size* > 0 is not allowed anymore.

PyObject *PyUnicode_FromString(const char *str)

Return value: New reference. Part of the Stable ABI.
Create a Unicode object from a UTF-8 encoded null-terminated char buffer *str*.

PyObject *PyUnicode_FromFormat(const char *format, ...)

Return value: New reference. Part of the Stable ABI.

Take a C **`printf()`**-style *format* string and a variable number of arguments, calculate the size of the resulting Python Unicode string and return a string with the values formatted into it. The variable arguments must be C types and must correspond exactly to the format characters in the *format* ASCII-encoded string.

A conversion specifier contains two or more characters and has the following components, which must occur in this order:

1. The `'%'` character, which marks the start of the specifier.
2. Conversion flags (optional), which affect the result of some conversion types.
3. Minimum field width (optional). If specified as an `'*'` (asterisk), the actual width is given in the next argument, which must be of type int, and the object to convert comes after the minimum field width and optional precision.
4. Precision (optional), given as a `'.'` (dot) followed by the precision. If specified as `'*'` (an asterisk), the actual precision is given in the next argument, which must be of type int, and the value to convert comes after the precision.
5. Length modifier (optional).
6. Conversion type.

The conversion flag characters are:

Flag	Meaning
`0`	The conversion will be zero padded for numeric values.

Flag	Meaning
`-`	The converted value is left adjusted (overrides the `0` flag if both are given).

The length modifiers for following integer conversions (`d`, `i`, `o`, `u`, `x`, or `X`) specify the type of the argument (int by default):

Modifier	Types
`l`	long or unsigned long
`ll`	long long or unsigned long long
`j`	**`intmax_t`** or **`uintmax_t`**
`z`	**`size_t`** or **`ssize_t`**
`t`	**`ptrdiff_t`**

The length modifier `l` for following conversions `s` or `V` specify that the type of the argument is const wchar_t*.

The conversion specifiers are:

Conversion Specifier	Type	Comment
`%`	*n/a*	The literal `%` character.
`d`, `i`	Specified by the length modifier	The decimal representation of a signed C integer.
`u`	Specified by the length	The decimal representation of an unsigned C integer.

Conversion Specifier	Type	Comment
	modifier	
`o`	Specified by the length modifier	The octal representation of an unsigned C integer.
`x`	Specified by the length modifier	The hexadecimal representation of an unsigned C integer (lowercase).
`X`	Specified by the length modifier	The hexadecimal representation of an unsigned C integer (uppercase).
`c`	int	A single character.
`s`	const char* or const wchar_t*	A null-terminated C character array.
`p`	const void*	The hex representation of a C pointer. Mostly equivalent to `printf("%p")` except that it is guaranteed to start with the literal `0x` regardless of what the platform's `printf` yields.
`A`	PyObject*	The result of calling **`ascii()`**.
`U`	PyObject*	A Unicode object.

Conversion Specifier	Type	Comment
`V`	PyObject*, const char* or const wchar_t*	A Unicode object (which may be `NULL`) and a null-terminated C character array as a second parameter (which will be used, if the first parameter is `NULL`).
`S`	PyObject*	The result of calling **`PyObject_Str()`**.
`R`	PyObject*	The result of calling **`PyObject_Repr()`**.
`T`	PyObject*	Get the fully qualified name of an object type; call **`PyType_GetFullyQualifiedName()`**.
`#T`	PyObject*	Similar to `T` format, but use a colon (`:`) as separator between the module name and the qualified name.
`N`	PyTypeObject*	Get the fully qualified name of a type; call **`PyType_GetFullyQualifiedName()`**.
`#N`	PyTypeObject*	Similar to `N` format, but use a colon (`:`) as separator between the module name and the qualified name.

Note

The width formatter unit is number of characters rather than bytes. The precision formatter unit is number of bytes or **`wchar_t`** items (if the length modifier `l` is used) for `"%s"` and `"%V"` (if the `PyObject*` argument is `NULL`), and a number of characters for `"%A"`, `"%U"`, `"%S"`, `"%R"` and `"%V"` (if the `PyObject*` argument is not `NULL`).

Note

Unlike to C **`printf()`** the `0` flag has effect even when a precision is given for integer conversions (`d`, `i`, `u`, `o`, `x`, or `X`).

Changed in version 3.2: Support for `"%lld"` and `"%llu"` added.

Changed in version 3.3: Support for `"%li"`, `"%lli"` and `"%zi"` added.

Changed in version 3.4: Support width and precision formatter for `"%s"`, `"%A"`, `"%U"`, `"%V"`, `"%S"`, `"%R"` added.

Changed in version 3.12: Support for conversion specifiers `o` and `X`. Support for length modifiers `j` and `t`. Length modifiers are now applied to all integer conversions. Length modifier `l` is now applied to conversion specifiers `s` and `V`. Support for variable width and precision `*`. Support for flag `-`.

An unrecognized format character now sets a `SystemError`. In previous versions it caused all the rest of the format string to be copied as-is to the result string, and any extra arguments discarded.

Changed in version 3.13: Support for `%T`, `%#T`, `%N` and `%#N` formats added.

PyObject *PyUnicode_FromFormatV(const char *format, va_list vargs)

Return value: New reference. Part of the Stable ABI.
Identical to **`PyUnicode_FromFormat()`** except that it takes exactly two arguments.

PyObject *PyUnicode_FromObject(PyObject *obj)

Return value: New reference. Part of the Stable ABI.
Copy an instance of a Unicode subtype to a new true Unicode object if necessary. If *obj* is already a true Unicode object (not a subtype), return a new strong reference to the object.

Objects other than Unicode or its subtypes will cause a **`TypeError`**.

PyObject *PyUnicode_FromOrdinal(int ordinal)

Return value: New reference. Part of the Stable ABI.
Create a Unicode Object from the given Unicode code point *ordinal*.

The ordinal must be in `range(0x110000)`. A **`ValueError`** is raised in the case it is not.

PyObject *PyUnicode_FromEncodedObject(PyObject *obj, const char *encoding, const char *errors)

Return value: New reference. Part of the Stable ABI.
Decode an encoded object *obj* to a Unicode object.

`bytes`, **`bytearray`** and other bytes-like objects are decoded according to the given *encoding* and using the error handling defined by *errors*. Both can be `NULL` to have the interface use the default values (see Built-in Codecs for details).

All other objects, including Unicode objects, cause a `TypeError` to be set.

The API returns `NULL` if there was an error. The caller is responsible for decref'ing the returned objects.

void PyUnicode_Append(PyObject **p_left, PyObject *right)

Part of the Stable ABI.

Append the string *right* to the end of *p_left*. *p_left* must point to a strong reference to a Unicode object; **`PyUnicode_Append()`** releases ("steals") this reference.

On error, set **p_left* to `NULL` and set an exception.

On success, set **p_left* to a new strong reference to the result.

void PyUnicode_AppendAndDel(PyObject **p_left, PyObject *right)

Part of the Stable ABI.

The function is similar to `PyUnicode_Append()`, with the only difference being that it decrements the reference count of *right* by one.

PyObject *PyUnicode_BuildEncodingMap(PyObject *string)

Return value: New reference. Part of the Stable ABI.

Return a mapping suitable for decoding a custom single-byte encoding. Given a Unicode string *string* of up to 256 characters representing an encoding table, returns either a compact internal mapping object or a dictionary mapping character ordinals to byte values. Raises a `TypeError` and return `NULL` on invalid input.

Added in version 3.2.

const char *PyUnicode_GetDefaultEncoding(void)

Part of the Stable ABI.

Return the name of the default string encoding, `"utf-8"`. See `sys.getdefaultencoding()`.

The returned string does not need to be freed, and is valid until interpreter shutdown.

Py_ssize_t PyUnicode_GetLength(PyObject *unicode)

Part of the Stable ABI since version 3.7.
Return the length of the Unicode object, in code points.

On error, set an exception and return `-1`.

Added in version 3.3.

Py_ssize_t PyUnicode_CopyCharacters(PyObject *to, Py_ssize_t to_start, PyObject *from, Py_ssize_t from_start, Py_ssize_t how_many)

Copy characters from one Unicode object into another. This function performs character conversion when necessary and falls back to **`memcpy()`** if possible. Returns `-1` and sets an exception on error, otherwise returns the number of copied characters.

The string must not have been “used” yet. See `PyUnicode_New()` for details.

Added in version 3.3.

int PyUnicode_Resize(PyObject **unicode, Py_ssize_t length);

Part of the Stable ABI.
Resize a Unicode object **unicode* to the new *length* in code points.

Try to resize the string in place (which is usually faster than allocating a new string and copying characters), or create a new string.

**unicode* is modified to point to the new (resized) object and `0` is returned on success. Otherwise, `-1` is returned and an exception is set, and **unicode* is left untouched.

The function doesn’t check string content, the result may not be a string in canonical representation.

Py_ssize_t PyUnicode_Fill(PyObject *unicode, Py_ssize_t start, Py_ssize_t length, Py_UCS4 fill_char)

Fill a string with a character: write *fill_char* into `unicode[start:start+length]`.

Fail if *fill_char* is bigger than the string maximum character, or if the string has more than 1 reference.

The string must not have been “used” yet. See **`PyUnicode_New()`** for details.

Return the number of written character, or return `-1` and raise an exception on error.

Added in version 3.3.

int PyUnicode_WriteChar(PyObject *unicode, Py_ssize_t index, Py_UCS4 character)

Part of the Stable ABI since version 3.7.
Write a *character* to the string *unicode* at the zero-based *index*. Return `0` on success, `-1` on error with an exception set.

This function checks that *unicode* is a Unicode object, that the index is not out of bounds, and that the object’s reference count is one. See **`PyUnicode_WRITE()`** for a version that skips these checks, making them your responsibility.

The string must not have been “used” yet. See **`PyUnicode_New()`** for details.

Added in version 3.3.

Py_UCS4 PyUnicode_ReadChar(PyObject *unicode, Py_ssize_t index)

Part of the Stable ABI since version 3.7.
Read a character from a string. This function checks that *unicode* is a Unicode object and the index is not out of bounds, in contrast to **`PyUnicode_READ_CHAR()`**, which performs no error checking.

Return character on success, `-1` on error with an exception set.

Added in version 3.3.

PyObject *PyUnicode_Substring(PyObject *unicode, Py_ssize_t start, Py_ssize_t end)

Return value: New reference. Part of the Stable ABI since version 3.7.
Return a substring of *unicode*, from character index *start* (included) to character index *end* (excluded). Negative indices are not supported. On error, set an exception and return `NULL`.

Added in version 3.3.

Py_UCS4 *PyUnicode_AsUCS4(PyObject *unicode, Py_UCS4 *buffer, Py_ssize_t buflen, int copy_null)

Part of the Stable ABI since version 3.7.
Copy the string *unicode* into a UCS4 buffer, including a null character, if *copy_null* is set. Returns `NULL` and sets an exception on error (in particular, a **`SystemError`** if *buflen* is smaller than the length of *unicode*). *buffer* is returned on success.

Added in version 3.3.

Py_UCS4 *PyUnicode_AsUCS4Copy(PyObject *unicode)

Part of the Stable ABI since version 3.7.
Copy the string *unicode* into a new UCS4 buffer that is allocated using **`PyMem_Malloc()`**. If this fails, `NULL` is returned with a **`MemoryError`** set. The returned buffer always has an extra null code point appended.

Added in version 3.3.

Locale Encoding

The current locale encoding can be used to decode text from the operating system.

PyObject *PyUnicode_DecodeLocaleAndSize(const char *str, Py_ssize_t length, const char *errors)

Return value: New reference. Part of the Stable ABI since version 3.7.
Decode a string from UTF-8 on Android and VxWorks, or from the current locale encoding on other platforms. The supported error handlers are `"strict"` and `"surrogateescape"` (**PEP 383** [https://peps.python.org/pep-0383/]). The decoder uses `"strict"` error handler if *errors* is `NULL`. *str* must end with a null character but cannot contain embedded null characters.

Use **`PyUnicode_DecodeFSDefaultAndSize()`** to decode a string from the filesystem encoding and error handler.

This function ignores the Python UTF-8 Mode.

See also

The **`Py_DecodeLocale()`** function.

Added in version 3.3.

Changed in version 3.7: The function now also uses the current locale encoding for the `surrogateescape` error handler, except on Android. Previously, **`Py_DecodeLocale()`** was used for the `surrogateescape`, and the current locale encoding was used for `strict`.

PyObject *PyUnicode_DecodeLocale(const char *str, const char *errors)

Return value: New reference. Part of the Stable ABI since version 3.7.
Similar to **`PyUnicode_DecodeLocaleAndSize()`**, but compute the string length using **`strlen()`**.

Added in version 3.3.

PyObject *PyUnicode_EncodeLocale(PyObject *unicode, const char *errors)

Return value: New reference. Part of the Stable ABI since version 3.7.
Encode a Unicode object to UTF-8 on Android and VxWorks, or to the current locale encoding on other platforms. The supported error handlers are `"strict"` and `"surrogateescape"` (**PEP 383** [https://peps.python.org/pep-0383/]). The encoder uses `"strict"` error handler if *errors* is `NULL`. Return a **`bytes`** object. *unicode* cannot contain embedded null characters.

Use **`PyUnicode_EncodeFSDefault()`** to encode a string to the filesystem encoding and error handler.

This function ignores the Python UTF-8 Mode.

See also

The **`Py_EncodeLocale()`** function.

Added in version 3.3.

Changed in version 3.7: The function now also uses the current locale encoding for the `surrogateescape` error handler, except on Android. Previously, **`Py_EncodeLocale()`** was used for the `surrogateescape`, and the current locale encoding was used for `strict`.

File System Encoding

Functions encoding to and decoding from the filesystem encoding and error handler (**PEP 383** [https://peps.python.org/pep-0383/] and **PEP 529** [https://peps.python.org/pep-0529/]).

To encode file names to **`bytes`** during argument parsing, the `"O&"` converter should be used, passing **`PyUnicode_FSConverter()`** as the conversion function:

int PyUnicode_FSConverter(PyObject *obj, void *result)

Part of the Stable ABI.

PyArg_Parse* converter: encode **`str`** objects – obtained directly or through the **`os.PathLike`** interface – to **`bytes`** using **`PyUnicode_EncodeFSDefault()`**; **`bytes`** objects are output as-is. *result* must be an address of a C variable of type PyObject* (or PyBytesObject*). On success, set the variable to a new strong reference to a bytes object which must be released when it is no longer used and return a non-zero value (**`Py_CLEANUP_SUPPORTED`**). Embedded null bytes are not allowed in the result. On failure, return `0` with an exception set.

If *obj* is `NULL`, the function releases a strong reference stored in the variable referred by *result* and returns `1`.

Added in version 3.1.

Changed in version 3.6: Accepts a path-like object.

To decode file names to **`str`** during argument parsing, the `"O&"` converter should be used, passing **`PyUnicode_FSDecoder()`** as the conversion function:

int PyUnicode_FSDecoder(PyObject *obj, void *result)

Part of the Stable ABI.

PyArg_Parse* converter: decode `bytes` objects – obtained either directly or indirectly through the `os.PathLike` interface – to `str` using `PyUnicode_DecodeFSDefaultAndSize()`; `str` objects are output as-is. *result* must be an address of a C variable of type PyObject* (or PyUnicodeObject*). On success, set the variable to a new strong reference to a Unicode object which must be released when it is no longer used and return a non-zero value (`Py_CLEANUP_SUPPORTED`). Embedded null characters are not allowed in the result. On failure, return `0` with an exception set.

If *obj* is `NULL`, release the strong reference to the object referred to by *result* and return `1`.

Added in version 3.2.

Changed in version 3.6: Accepts a path-like object.

PyObject *PyUnicode_DecodeFSDefaultAndSize(const char *str, Py_ssize_t size)

Return value: New reference. Part of the Stable ABI.

Decode a string from the filesystem encoding and error handler.

If you need to decode a string from the current locale encoding, use `PyUnicode_DecodeLocaleAndSize()`.

See also

The `Py_DecodeLocale()` function.

Changed in version 3.6: The filesystem error handler is now used.

PyObject *PyUnicode_DecodeFSDefault(const char *str)

Return value: New reference. Part of the Stable ABI.
Decode a null-terminated string from the filesystem encoding and error handler.

If the string length is known, use `PyUnicode_DecodeFSDefaultAndSize()`.

Changed in version 3.6: The filesystem error handler is now used.

PyObject *PyUnicode_EncodeFSDefault(PyObject *unicode)

Return value: New reference. Part of the Stable ABI.
Encode a Unicode object to the filesystem encoding and error handler, and return `bytes`. Note that the resulting `bytes` object can contain null bytes.

If you need to encode a string to the current locale encoding, use `PyUnicode_EncodeLocale()`.

See also

The `Py_EncodeLocale()` function.

Added in version 3.2.

Changed in version 3.6: The filesystem error handler is now used.

wchar_t Support

`wchar_t` support for platforms which support it:

PyObject *PyUnicode_FromWideChar(const wchar_t *wstr, Py_ssize_t size)

Return value: New reference. Part of the Stable ABI.

Create a Unicode object from the **`wchar_t`** buffer *wstr* of the given *size*. Passing `-1` as the *size* indicates that the function must itself compute the length, using **`wcslen()`**. Return `NULL` on failure.

Py_ssize_t PyUnicode_AsWideChar(PyObject *unicode, wchar_t *wstr, Py_ssize_t size)

Part of the Stable ABI.

Copy the Unicode object contents into the **`wchar_t`** buffer *wstr*. At most *size* **`wchar_t`** characters are copied (excluding a possibly trailing null termination character). Return the number of **`wchar_t`** characters copied or `-1` in case of an error.

When *wstr* is `NULL`, instead return the *size* that would be required to store all of *unicode* including a terminating null.

Note that the resulting wchar_t* string may or may not be null-terminated. It is the responsibility of the caller to make sure that the wchar_t* string is null-terminated in case this is required by the application. Also, note that the wchar_t* string might contain null characters, which would cause the string to be truncated when used with most C functions.

wchar_t *PyUnicode_AsWideCharString(PyObject *unicode, Py_ssize_t *size)

Part of the Stable ABI since version 3.7.

Convert the Unicode object to a wide character string. The output string always ends with a null character. If *size* is not `NULL`, write the number of wide characters (excluding the trailing null termination character) into **size*. Note that the resulting **`wchar_t`** string might contain null characters, which would cause the string to be truncated when used with most C functions. If *size* is `NULL` and the wchar_t* string contains null characters a **`ValueError`** is raised.

Returns a buffer allocated by `PyMem_New` (use `PyMem_Free()` to free it) on success. On error, returns `NULL` and **size* is undefined. Raises a `MemoryError` if memory allocation is failed.

Added in version 3.2.

Changed in version 3.7: Raises a `ValueError` if *size* is `NULL` and the wchar_t* string contains null characters.

Built-in Codecs

Python provides a set of built-in codecs which are written in C for speed. All of these codecs are directly usable via the following functions.

Many of the following APIs take two arguments encoding and errors, and they have the same semantics as the ones of the built-in `str()` string object constructor.

Setting encoding to `NULL` causes the default encoding to be used which is UTF-8. The file system calls should use `PyUnicode_FSConverter()` for encoding file names. This uses the filesystem encoding and error handler internally.

Error handling is set by errors which may also be set to `NULL` meaning to use the default handling defined for the codec. Default error handling for all built-in codecs is “strict” (`ValueError` is raised).

The codecs all use a similar interface. Only deviations from the following generic ones are documented for simplicity.

Generic Codecs

The following macro is provided:

Py_UNICODE_REPLACEMENT_CHARACTER

The Unicode code point `U+FFFD` (replacement character).

This Unicode character is used as the replacement character during decoding if the *errors* argument is set to “replace”.

These are the generic codec APIs:

PyObject *PyUnicode_Decode(const char *str, Py_ssize_t size, const char *encoding, const char *errors)

Return value: New reference. Part of the Stable ABI. Create a Unicode object by decoding *size* bytes of the encoded string *str*. *encoding* and *errors* have the same meaning as the parameters of the same name in the **`str()`** built-in function. The codec to be used is looked up using the Python codec registry. Return `NULL` if an exception was raised by the codec.

PyObject *PyUnicode_AsEncodedString(PyObject *unicode, const char *encoding, const char *errors)

Return value: New reference. Part of the Stable ABI. Encode a Unicode object and return the result as Python bytes object. *encoding* and *errors* have the same meaning as the parameters of the same name in the Unicode **`encode()`** method. The codec to be used is looked up using the Python codec registry. Return `NULL` if an exception was raised by the codec.

UTF-8 Codecs

These are the UTF-8 codec APIs:

PyObject *PyUnicode_DecodeUTF8(const char *str, Py_ssize_t size, const char *errors)

Return value: New reference. Part of the Stable ABI.

Create a Unicode object by decoding *size* bytes of the UTF-8 encoded string *str*. Return `NULL` if an exception was raised by the codec.

PyObject *PyUnicode_DecodeUTF8Stateful(const char *str, Py_ssize_t size, const char *errors, Py_ssize_t *consumed)

Return value: New reference. Part of the Stable ABI.
If *consumed* is `NULL`, behave like **`PyUnicode_DecodeUTF8()`**. If *consumed* is not `NULL`, trailing incomplete UTF-8 byte sequences will not be treated as an error. Those bytes will not be decoded and the number of bytes that have been decoded will be stored in *consumed*.

PyObject *PyUnicode_AsUTF8String(PyObject *unicode)

Return value: New reference. Part of the Stable ABI.
Encode a Unicode object using UTF-8 and return the result as Python bytes object. Error handling is “strict”. Return `NULL` if an exception was raised by the codec.

The function fails if the string contains surrogate code points (`U+D800` - `U+DFFF`).

const char *PyUnicode_AsUTF8AndSize(PyObject *unicode, Py_ssize_t *size)

Part of the Stable ABI since version 3.10.
Return a pointer to the UTF-8 encoding of the Unicode object, and store the size of the encoded representation (in bytes) in *size*. The *size* argument can be `NULL`; in this case no size will be stored. The returned buffer always has an extra null byte appended (not included in *size*), regardless of whether there are any other null code points.

On error, set an exception, set *size* to `-1` (if it’s not NULL) and return `NULL`.

The function fails if the string contains surrogate code points (`U+D800` - `U+DFFF`).

This caches the UTF-8 representation of the string in the Unicode object, and subsequent calls will return a pointer to the same buffer. The caller is not responsible for deallocating the buffer. The buffer is deallocated and pointers to it become invalid when the Unicode object is garbage collected.

Added in version 3.3.

Changed in version 3.7: The return type is now `const char *` rather of `char *`.

Changed in version 3.10: This function is a part of the limited API.

const char *PyUnicode_AsUTF8(PyObject *unicode)

As **`PyUnicode_AsUTF8AndSize()`**, but does not store the size.

Warning

This function does not have any special behavior for null characters [https://en.wikipedia.org/wiki/Null_character] embedded within *unicode*. As a result, strings containing null characters will remain in the returned string, which some C functions might interpret as the end of the string, leading to truncation. If truncation is an issue, it is recommended to use **`PyUnicode_AsUTF8AndSize()`** instead.

Added in version 3.3.

Changed in version 3.7: The return type is now `const char *` rather of `char *`.

UTF-32 Codecs

These are the UTF-32 codec APIs:

PyObject *PyUnicode_DecodeUTF32(const char *str, Py_ssize_t size, const char *errors, int *byteorder)

Return value: New reference. Part of the Stable ABI.

Decode *size* bytes from a UTF-32 encoded buffer string and return the corresponding Unicode object. *errors* (if non-`NULL`) defines the error handling. It defaults to “strict”.

If *byteorder* is non-`NULL`, the decoder starts decoding using the given byte order:

```
*byteorder == -1: little endian
*byteorder == 0:  native order
*byteorder == 1:  big endian
```

If `*byteorder` is zero, and the first four bytes of the input data are a byte order mark (BOM), the decoder switches to this byte order and the BOM is not copied into the resulting Unicode string. If `*byteorder` is `-1` or `1`, any byte order mark is copied to the output.

After completion, **byteorder* is set to the current byte order at the end of input data.

If *byteorder* is `NULL`, the codec starts in native order mode.

Return `NULL` if an exception was raised by the codec.

PyObject *PyUnicode_DecodeUTF32Stateful(const char *str, Py_ssize_t size, const char *errors, int *byteorder, Py_ssize_t *consumed)

Return value: New reference. Part of the Stable ABI.

If *consumed* is `NULL`, behave like **`PyUnicode_DecodeUTF32()`**. If *consumed* is not `NULL`, **`PyUnicode_DecodeUTF32Stateful()`** will not treat trailing incomplete UTF-32 byte sequences (such as a number of bytes not divisible by four) as an error. Those bytes will not be decoded and the number of bytes that have been decoded will be stored in *consumed*.

PyObject *PyUnicode_AsUTF32String(PyObject *unicode)

Return value: New reference. Part of the Stable ABI.
Return a Python byte string using the UTF-32 encoding in native byte order. The string always starts with a BOM mark. Error handling is “strict”. Return `NULL` if an exception was raised by the codec.

UTF-16 Codecs

These are the UTF-16 codec APIs:

PyObject *PyUnicode_DecodeUTF16(const char *str, Py_ssize_t size, const char *errors, int *byteorder)

Return value: New reference. Part of the Stable ABI.
Decode *size* bytes from a UTF-16 encoded buffer string and return the corresponding Unicode object. *errors* (if non-`NULL`) defines the error handling. It defaults to “strict”.

If *byteorder* is non-`NULL`, the decoder starts decoding using the given byte order:

```
*byteorder == -1: little endian
*byteorder == 0:  native order
*byteorder == 1:  big endian
```

If `*byteorder` is zero, and the first two bytes of the input data are a byte order mark (BOM), the decoder switches to this byte order and the BOM is not copied into the resulting Unicode string. If `*byteorder` is `-1` or `1`, any byte order mark is copied to the output (where it will result in either a `\ufeff` or a `\ufffe` character).

After completion, `*byteorder` is set to the current byte order at the end of input data.

If *byteorder* is `NULL`, the codec starts in native order mode.

Return `NULL` if an exception was raised by the codec.

PyObject *PyUnicode_DecodeUTF16Stateful(const char *str, Py_ssize_t size, const char *errors, int *byteorder, Py_ssize_t *consumed)

Return value: New reference. Part of the Stable ABI.
If *consumed* is `NULL`, behave like **`PyUnicode_DecodeUTF16()`**. If *consumed* is not `NULL`, **`PyUnicode_DecodeUTF16Stateful()`** will not treat trailing incomplete UTF-16 byte sequences (such as an odd number of bytes or a split surrogate pair) as an error. Those bytes will not be decoded and the number of bytes that have been decoded will be stored in *consumed*.

PyObject *PyUnicode_AsUTF16String(PyObject *unicode)

Return value: New reference. Part of the Stable ABI.
Return a Python byte string using the UTF-16 encoding in native byte order. The string always starts with a BOM mark. Error handling is “strict”. Return `NULL` if an exception was raised by the codec.

UTF-7 Codecs

These are the UTF-7 codec APIs:

PyObject *PyUnicode_DecodeUTF7(const char *str, Py_ssize_t size, const char *errors)

Return value: New reference. Part of the Stable ABI.
Create a Unicode object by decoding *size* bytes of the UTF-7 encoded string *str*. Return `NULL` if an exception was raised by the codec.

PyObject *PyUnicode_DecodeUTF7Stateful(const char *str, Py_ssize_t size, const char *errors, Py_ssize_t *consumed)

Return value: New reference. Part of the Stable ABI.
If *consumed* is `NULL`, behave like **`PyUnicode_DecodeUTF7()`**. If *consumed* is not `NULL`, trailing incomplete UTF-7 base-64 sections will not be treated as an error. Those bytes will not

be decoded and the number of bytes that have been decoded will be stored in *consumed*.

Unicode-Escape Codecs

These are the “Unicode Escape” codec APIs:

PyObject *PyUnicode_DecodeUnicodeEscape(const char *str, Py_ssize_t size, const char *errors)

Return value: New reference. Part of the Stable ABI.
Create a Unicode object by decoding *size* bytes of the Unicode-Escape encoded string *str*. Return `NULL` if an exception was raised by the codec.

PyObject *PyUnicode_AsUnicodeEscapeString(PyObject *unicode)

Return value: New reference. Part of the Stable ABI.
Encode a Unicode object using Unicode-Escape and return the result as a bytes object. Error handling is “strict”. Return `NULL` if an exception was raised by the codec.

Raw-Unicode-Escape Codecs

These are the “Raw Unicode Escape” codec APIs:

PyObject *PyUnicode_DecodeRawUnicodeEscape(const char *str, Py_ssize_t size, const char *errors)

Return value: New reference. Part of the Stable ABI.
Create a Unicode object by decoding *size* bytes of the Raw-Unicode-Escape encoded string *str*. Return `NULL` if an exception was raised by the codec.

PyObject *PyUnicode_AsRawUnicodeEscapeString(PyObject *unicode)

Return value: New reference. Part of the Stable ABI.

Encode a Unicode object using Raw-Unicode-Escape and return the result as a bytes object. Error handling is “strict”. Return `NULL` if an exception was raised by the codec.

Latin-1 Codecs

These are the Latin-1 codec APIs: Latin-1 corresponds to the first 256 Unicode ordinals and only these are accepted by the codecs during encoding.

PyObject *PyUnicode_DecodeLatin1(const char *str, Py_ssize_t size, const char *errors)

Return value: New reference. Part of the Stable ABI.
Create a Unicode object by decoding *size* bytes of the Latin-1 encoded string *str*. Return `NULL` if an exception was raised by the codec.

PyObject *PyUnicode_AsLatin1String(PyObject *unicode)

Return value: New reference. Part of the Stable ABI.
Encode a Unicode object using Latin-1 and return the result as Python bytes object. Error handling is “strict”. Return `NULL` if an exception was raised by the codec.

ASCII Codecs

These are the ASCII codec APIs. Only 7-bit ASCII data is accepted. All other codes generate errors.

PyObject *PyUnicode_DecodeASCII(const char *str, Py_ssize_t size, const char *errors)

Return value: New reference. Part of the Stable ABI.
Create a Unicode object by decoding *size* bytes of the ASCII encoded string *str*. Return `NULL` if an exception was raised by the codec.

PyObject *PyUnicode_AsASCIIString(PyObject *unicode)

Return value: New reference. Part of the Stable ABI.
Encode a Unicode object using ASCII and return the result as Python bytes object. Error handling is “strict”. Return `NULL` if an exception was raised by the codec.

Character Map Codecs

This codec is special in that it can be used to implement many different codecs (and this is in fact what was done to obtain most of the standard codecs included in the **`encodings`** package). The codec uses mappings to encode and decode characters. The mapping objects provided must support the **`__getitem__()`** mapping interface; dictionaries and sequences work well.

These are the mapping codec APIs:

PyObject *PyUnicode_DecodeCharmap(const char *str, Py_ssize_t length, PyObject *mapping, const char *errors)

Return value: New reference. Part of the Stable ABI.
Create a Unicode object by decoding *size* bytes of the encoded string *str* using the given *mapping* object. Return `NULL` if an exception was raised by the codec.

If *mapping* is `NULL`, Latin-1 decoding will be applied. Else *mapping* must map bytes ordinals (integers in the range from 0 to 255) to Unicode strings, integers (which are then interpreted as Unicode ordinals) or `None`. Unmapped data bytes – ones which cause a **`LookupError`**, as well as ones which get mapped to `None`, `0xFFFE` or `'\ufffe'`, are treated as undefined mappings and cause an error.

PyObject *PyUnicode_AsCharmapString(PyObject *unicode, PyObject *mapping)

Return value: New reference. Part of the Stable ABI.

Encode a Unicode object using the given *mapping* object and return the result as a bytes object. Error handling is "strict". Return `NULL` if an exception was raised by the codec.

The *mapping* object must map Unicode ordinal integers to bytes objects, integers in the range from 0 to 255 or `None`. Unmapped character ordinals (ones which cause a **`LookupError`**) as well as mapped to `None` are treated as "undefined mapping" and cause an error.

The following codec API is special in that maps Unicode to Unicode.

PyObject *PyUnicode_Translate(PyObject *unicode, PyObject *table, const char *errors)

Return value: New reference. Part of the Stable ABI.
Translate a string by applying a character mapping table to it and return the resulting Unicode object. Return `NULL` if an exception was raised by the codec.

The mapping table must map Unicode ordinal integers to Unicode ordinal integers or `None` (causing deletion of the character).

Mapping tables need only provide the **`__getitem__()`** interface; dictionaries and sequences work well. Unmapped character ordinals (ones which cause a **`LookupError`**) are left untouched and are copied as-is.

errors has the usual meaning for codecs. It may be `NULL` which indicates to use the default error handling.

MBCS codecs for Windows

These are the MBCS codec APIs. They are currently only available on Windows and use the Win32 MBCS converters to implement the conversions. Note that MBCS (or DBCS) is a class of encodings, not just one. The target encoding is defined by the user settings on the machine running the codec.

PyObject *PyUnicode_DecodeMBCS(const char *str, Py_ssize_t size, const char *errors)

Return value: New reference. Part of the Stable ABI on Windows since version 3.7.

Create a Unicode object by decoding *size* bytes of the MBCS encoded string *str*. Return `NULL` if an exception was raised by the codec.

PyObject *PyUnicode_DecodeMBCSStateful(const char *str, Py_ssize_t size, const char *errors, Py_ssize_t *consumed)

Return value: New reference. Part of the Stable ABI on Windows since version 3.7.

If *consumed* is `NULL`, behave like **`PyUnicode_DecodeMBCS()`**. If *consumed* is not `NULL`, **`PyUnicode_DecodeMBCSStateful()`** will not decode trailing lead byte and the number of bytes that have been decoded will be stored in *consumed*.

PyObject *PyUnicode_DecodeCodePageStateful(int code_page, const char *str, Py_ssize_t size, const char *errors, Py_ssize_t *consumed)

Return value: New reference. Part of the Stable ABI on Windows since version 3.7.

Similar to **`PyUnicode_DecodeMBCSStateful()`**, except uses the code page specified by *code_page*.

PyObject *PyUnicode_AsMBCSString(PyObject *unicode)

Return value: New reference. Part of the Stable ABI on Windows since version 3.7.

Encode a Unicode object using MBCS and return the result as Python bytes object. Error handling is “strict”. Return `NULL` if an exception was raised by the codec.

PyObject *PyUnicode_EncodeCodePage(int code_page, PyObject *unicode, const char *errors)

Return value: New reference. Part of the Stable ABI on Windows since version 3.7.
Encode the Unicode object using the specified code page and return a Python bytes object. Return `NULL` if an exception was raised by the codec. Use **`CP_ACP`** code page to get the MBCS encoder.

Added in version 3.3.

Methods and Slot Functions

The following APIs are capable of handling Unicode objects and strings on input (we refer to them as strings in the descriptions) and return Unicode objects or integers as appropriate.

They all return `NULL` or `-1` if an exception occurs.

PyObject *PyUnicode_Concat(PyObject *left, PyObject *right)

Return value: New reference. Part of the Stable ABI.
Concat two strings giving a new Unicode string.

PyObject *PyUnicode_Split(PyObject *unicode, PyObject *sep, Py_ssize_t maxsplit)

Return value: New reference. Part of the Stable ABI.
Split a string giving a list of Unicode strings. If *sep* is `NULL`, splitting will be done at all whitespace substrings. Otherwise, splits occur at the given separator. At most *maxsplit* splits will be done. If negative, no limit is set. Separators are not included in the resulting list.

On error, return `NULL` with an exception set.

Equivalent to **`str.split()`**.

PyObject *PyUnicode_RSplit(PyObject *unicode, PyObject *sep, Py_ssize_t maxsplit)

Return value: New reference. Part of the Stable ABI.
Similar to `PyUnicode_Split()`, but splitting will be done beginning at the end of the string.

On error, return `NULL` with an exception set.

Equivalent to `str.rsplit()`.

PyObject *PyUnicode_Splitlines(PyObject *unicode, int keepends)

Return value: New reference. Part of the Stable ABI.
Split a Unicode string at line breaks, returning a list of Unicode strings. CRLF is considered to be one line break. If *keepends* is `0`, the Line break characters are not included in the resulting strings.

PyObject *PyUnicode_Partition(PyObject *unicode, PyObject *sep)

Return value: New reference. Part of the Stable ABI.
Split a Unicode string at the first occurrence of *sep*, and return a 3-tuple containing the part before the separator, the separator itself, and the part after the separator. If the separator is not found, return a 3-tuple containing the string itself, followed by two empty strings.

sep must not be empty.

On error, return `NULL` with an exception set.

Equivalent to `str.partition()`.

PyObject *PyUnicode_RPartition(PyObject *unicode, PyObject *sep)

Return value: New reference. Part of the Stable ABI.

Similar to `PyUnicode_Partition()`, but split a Unicode string at the last occurrence of *sep*. If the separator is not found, return a 3-tuple containing two empty strings, followed by the string itself.

sep must not be empty.

On error, return `NULL` with an exception set.

Equivalent to `str.rpartition()`.

PyObject *PyUnicode_Join(PyObject *separator, PyObject *seq)

Return value: New reference. Part of the Stable ABI.
Join a sequence of strings using the given *separator* and return the resulting Unicode string.

Py_ssize_t PyUnicode_Tailmatch(PyObject *unicode, PyObject *substr, Py_ssize_t start, Py_ssize_t end, int direction)

Part of the Stable ABI.
Return `1` if *substr* matches `unicode[start:end]` at the given tail end (*direction* == `-1` means to do a prefix match, *direction* == `1` a suffix match), `0` otherwise. Return `-1` if an error occurred.

Py_ssize_t PyUnicode_Find(PyObject *unicode, PyObject *substr, Py_ssize_t start, Py_ssize_t end, int direction)

Part of the Stable ABI.
Return the first position of *substr* in `unicode[start:end]` using the given *direction* (*direction* == `1` means to do a forward search, *direction* == `-1` a backward search). The return value is the index of the first match; a value of `-1` indicates that no match was found, and `-2` indicates that an error occurred and an exception has been set.

Py_ssize_t PyUnicode_FindChar(PyObject *unicode, Py_UCS4 ch, Py_ssize_t start, Py_ssize_t end, int direction)

Part of the Stable ABI since version 3.7.
Return the first position of the character *ch* in `unicode[start:end]` using the given *direction* (*direction* == `1` means to do a forward search, *direction* == `-1` a backward search). The return value is the index of the first match; a value of `-1` indicates that no match was found, and `-2` indicates that an error occurred and an exception has been set.

Added in version 3.3.

Changed in version 3.7: start and *end* are now adjusted to behave like `unicode[start:end]`.

Py_ssize_t PyUnicode_Count(PyObject *unicode, PyObject *substr, Py_ssize_t start, Py_ssize_t end)

Part of the Stable ABI.
Return the number of non-overlapping occurrences of *substr* in `unicode[start:end]`. Return `-1` if an error occurred.

PyObject *PyUnicode_Replace(PyObject *unicode, PyObject *substr, PyObject *replstr, Py_ssize_t maxcount)

Return value: New reference. Part of the Stable ABI.
Replace at most *maxcount* occurrences of *substr* in *unicode* with *replstr* and return the resulting Unicode object. *maxcount* == `-1` means replace all occurrences.

int PyUnicode_Compare(PyObject *left, PyObject *right)

Part of the Stable ABI.
Compare two strings and return `-1`, `0`, `1` for less than, equal, and greater than, respectively.

This function returns `-1` upon failure, so one should call **`PyErr_Occurred()`** to check for errors.

See also

The `PyUnicode_Equal()` function.

int PyUnicode_Equal(PyObject *a, PyObject *b)

Part of the Stable ABI since version 3.14.

Test if two strings are equal:

- Return `1` if *a* is equal to *b*.
- Return `0` if *a* is not equal to *b*.
- Set a `TypeError` exception and return `-1` if *a* or *b* is not a `str` object.

The function always succeeds if *a* and *b* are `str` objects.

The function works for `str` subclasses, but does not honor custom `__eq__()` method.

See also

The `PyUnicode_Compare()` function.

Added in version 3.14.

int PyUnicode_EqualToUTF8AndSize(PyObject *unicode, const char *string, Py_ssize_t size)

Part of the Stable ABI since version 3.13.

Compare a Unicode object with a char buffer which is interpreted as being UTF-8 or ASCII encoded and return true (`1`) if they are equal, or false (`0`) otherwise. If the Unicode object contains surrogate code points (`U+D800` - `U+DFFF`) or the C string is not valid UTF-8, false (`0`) is returned.

This function does not raise exceptions.

Added in version 3.13.

int PyUnicode_EqualToUTF8(PyObject *unicode, const char *string)

Part of the Stable ABI since version 3.13.
Similar to **`PyUnicode_EqualToUTF8AndSize()`**, but compute *string* length using **`strlen()`**. If the Unicode object contains null characters, false (`0`) is returned.

Added in version 3.13.

int PyUnicode_CompareWithASCIIString(PyObject *unicode, const char *string)

Part of the Stable ABI.
Compare a Unicode object, *unicode*, with *string* and return `-1`, `0`, `1` for less than, equal, and greater than, respectively. It is best to pass only ASCII-encoded strings, but the function interprets the input string as ISO-8859-1 if it contains non-ASCII characters.

This function does not raise exceptions.

PyObject *PyUnicode_RichCompare(PyObject *left, PyObject *right, int op)

Return value: New reference. Part of the Stable ABI.
Rich compare two Unicode strings and return one of the following:

- `NULL` in case an exception was raised
- **`Py_True`** or **`Py_False`** for successful comparisons
- **`Py_NotImplemented`** in case the type combination is unknown

Possible values for *op* are **`Py_GT`**, **`Py_GE`**, **`Py_EQ`**, **`Py_NE`**, **`Py_LT`**, and **`Py_LE`**.

PyObject *PyUnicode_Format(PyObject *format, PyObject *args)

Return value: New reference. Part of the Stable ABI.

Return a new string object from *format* and *args*; this is analogous to `format % args`.

int PyUnicode_Contains(PyObject *unicode, PyObject *substr)

Part of the Stable ABI.

Check whether *substr* is contained in *unicode* and return true or false accordingly.

substr has to coerce to a one element Unicode string. `-1` is returned if there was an error.

void PyUnicode_InternInPlace(PyObject **p_unicode)

Part of the Stable ABI.

Intern the argument *p_unicode in place. The argument must be the address of a pointer variable pointing to a Python Unicode string object. If there is an existing interned string that is the same as *p_unicode, it sets *p_unicode to it (releasing the reference to the old string object and creating a new strong reference to the interned string object), otherwise it leaves *p_unicode alone and interns it.

(Clarification: even though there is a lot of talk about references, think of this function as reference-neutral. You must own the object you pass in; after the call you no longer own the passed-in reference, but you newly own the result.)

This function never raises an exception. On error, it leaves its argument unchanged without interning it.

Instances of subclasses of **`str`** may not be interned, that is, PyUnicode_CheckExact(*p_unicode) must be true. If it is not, then – as with any other error – the argument is left unchanged.

Note that interned strings are not “immortal”. You must keep a reference to the result to benefit from interning.

PyObject *PyUnicode_InternFromString(const char *str)

Return value: New reference. Part of the Stable ABI.

A combination of `PyUnicode_FromString()` and `PyUnicode_InternInPlace()`, meant for statically allocated strings.

Return a new (“owned”) reference to either a new Unicode string object that has been interned, or an earlier interned string object with the same value.

Python may keep a reference to the result, or make it immortal, preventing it from being garbage-collected promptly. For interning an unbounded number of different strings, such as ones coming from user input, prefer calling `PyUnicode_FromString()` and `PyUnicode_InternInPlace()` directly.

unsigned int PyUnicode_CHECK_INTERNED(PyObject *str)

Return a non-zero value if *str* is interned, zero if not. The *str* argument must be a string; this is not checked. This function always succeeds.

CPython implementation detail: A non-zero return value may carry additional information about *how* the string is interned. The meaning of such non-zero values, as well as each specific string’s intern-related details, may change between CPython versions.

PyUnicodeWriter

The `PyUnicodeWriter` API can be used to create a Python `str` object.

Added in version 3.14.

type PyUnicodeWriter

A Unicode writer instance.

The instance must be destroyed by `PyUnicodeWriter_Finish()` on success, or `PyUnicodeWriter_Discard()` on error.

PyUnicodeWriter *PyUnicodeWriter_Create(Py_ssize_t length)

Create a Unicode writer instance.

length must be greater than or equal to `0`.

If *length* is greater than `0`, preallocate an internal buffer of *length* characters.

Set an exception and return `NULL` on error.

PyObject *PyUnicodeWriter_Finish(PyUnicodeWriter *writer)

Return the final Python `str` object and destroy the writer instance.

Set an exception and return `NULL` on error.

The writer instance is invalid after this call.

void PyUnicodeWriter_Discard(PyUnicodeWriter *writer)

Discard the internal Unicode buffer and destroy the writer instance.

If *writer* is `NULL`, no operation is performed.

The writer instance is invalid after this call.

int PyUnicodeWriter_WriteChar(PyUnicodeWriter *writer, Py_UCS4 ch)

Write the single Unicode character *ch* into *writer*.

On success, return `0`. On error, set an exception, leave the writer unchanged, and return `-1`.

int PyUnicodeWriter_WriteUTF8(PyUnicodeWriter *writer, const char *str, Py_ssize_t size)

Decode the string *str* from UTF-8 in strict mode and write the output into *writer*.

size is the string length in bytes. If *size* is equal to `-1`, call `strlen(str)` to get the string length.

On success, return `0`. On error, set an exception, leave the writer unchanged, and return `-1`.

See also **`PyUnicodeWriter_DecodeUTF8Stateful()`**.

int PyUnicodeWriter_WriteASCII(PyUnicodeWriter *writer, const char *str, Py_ssize_t size)

Write the ASCII string *str* into *writer*.

size is the string length in bytes. If *size* is equal to `-1`, call `strlen(str)` to get the string length.

str must only contain ASCII characters. The behavior is undefined if *str* contains non-ASCII characters.

On success, return `0`. On error, set an exception, leave the writer unchanged, and return `-1`.

Added in version 3.14.

int PyUnicodeWriter_WriteWideChar(PyUnicodeWriter *writer, const wchar_t *str, Py_ssize_t size)

Write the wide string *str* into *writer*.

size is a number of wide characters. If *size* is equal to `-1`, call `wcslen(str)` to get the string length.

On success, return `0`. On error, set an exception, leave the writer unchanged, and return `-1`.

int PyUnicodeWriter_WriteUCS4(PyUnicodeWriter *writer, Py_UCS4 *str, Py_ssize_t size)

Writer the UCS4 string *str* into *writer*.

size is a number of UCS4 characters.

On success, return `0`. On error, set an exception, leave the writer unchanged, and return `-1`.

int PyUnicodeWriter_WriteStr(PyUnicodeWriter *writer, PyObject *obj)

Call **`PyObject_Str()`** on *obj* and write the output into *writer*.

On success, return `0`. On error, set an exception, leave the writer unchanged, and return `-1`.

int PyUnicodeWriter_WriteRepr(PyUnicodeWriter *writer, PyObject *obj)

Call **`PyObject_Repr()`** on *obj* and write the output into *writer*.

On success, return `0`. On error, set an exception, leave the writer unchanged, and return `-1`.

int PyUnicodeWriter_WriteSubstring(PyUnicodeWriter *writer, PyObject *str, Py_ssize_t start, Py_ssize_t end)

Write the substring `str[start:end]` into *writer*.

str must be Python **`str`** object. *start* must be greater than or equal to 0, and less than or equal to *end*. *end* must be less than or equal to *str* length.

On success, return `0`. On error, set an exception, leave the writer unchanged, and return `-1`.

int PyUnicodeWriter_Format(PyUnicodeWriter *writer, const char *format, ...)

Similar to `PyUnicode_FromFormat()`, but write the output directly into *writer*.

On success, return `0`. On error, set an exception, leave the writer unchanged, and return `-1`.

int PyUnicodeWriter_DecodeUTF8Stateful(PyUnicodeWriter *writer, const char *string, Py_ssize_t length, const char *errors, Py_ssize_t *consumed)

Decode the string *str* from UTF-8 with *errors* error handler and write the output into *writer*.

size is the string length in bytes. If *size* is equal to `-1`, call `strlen(str)` to get the string length.

errors is an error handler name, such as `"replace"`. If *errors* is `NULL`, use the strict error handler.

If *consumed* is not `NULL`, set **consumed* to the number of decoded bytes on success. If *consumed* is `NULL`, treat trailing incomplete UTF-8 byte sequences as an error.

On success, return `0`. On error, set an exception, leave the writer unchanged, and return `-1`.

See also `PyUnicodeWriter_WriteUTF8()`.

Deprecated API

The following API is deprecated.

type Py_UNICODE

This is a typedef of **`wchar_t`**, which is a 16-bit type or 32-bit type depending on the platform. Please use **`wchar_t`** directly instead.

Changed in version 3.3: In previous versions, this was a 16-bit type or a 32-bit type depending on whether you selected a “narrow” or “wide” Unicode version of Python at build time.

Deprecated since version 3.13, will be removed in version 3.15.

int PyUnicode_READY(PyObject *unicode)

Do nothing and return `0`. This API is kept only for backward compatibility, but there are no plans to remove it.

Added in version 3.3.

Deprecated since version 3.10: This API does nothing since Python 3.12. Previously, this needed to be called for each string created using the old API (**`PyUnicode_FromUnicode()`** or similar).

unsigned int PyUnicode_IS_READY(PyObject *unicode)

Do nothing and return `1`. This API is kept only for backward compatibility, but there are no plans to remove it.

Added in version 3.3.

Deprecated since version 3.14: This API does nothing since Python 3.12. Previously, this could be called to check if **`PyUnicode_READY()`** is necessary.

Tuple Objects

type PyTupleObject

This subtype of **`PyObject`** represents a Python tuple object.

PyTypeObject PyTuple_Type

Part of the Stable ABI.

This instance of **`PyTypeObject`** represents the Python tuple type; it is the same object as **`tuple`** in the Python layer.

int PyTuple_Check(PyObject *p)

Return true if *p* is a tuple object or an instance of a subtype of the tuple type. This function always succeeds.

int PyTuple_CheckExact(PyObject *p)

Return true if *p* is a tuple object, but not an instance of a subtype of the tuple type. This function always succeeds.

PyObject *PyTuple_New(Py_ssize_t len)

Return value: New reference. Part of the Stable ABI.

Return a new tuple object of size *len*, or `NULL` with an exception set on failure.

PyObject *PyTuple_Pack(Py_ssize_t n, ...)

Return value: New reference. Part of the Stable ABI.

Return a new tuple object of size *n*, or `NULL` with an exception set on failure. The tuple values are initialized to the subsequent *n* C arguments pointing to Python objects. `PyTuple_Pack(2, a, b)` is equivalent to `Py_BuildValue("(OO)", a, b)`.

Py_ssize_t PyTuple_Size(PyObject *p)

Part of the Stable ABI.

Take a pointer to a tuple object, and return the size of that tuple. On error, return `-1` with an exception set.

Py_ssize_t PyTuple_GET_SIZE(PyObject *p)

Like **`PyTuple_Size()`**, but without error checking.

PyObject *PyTuple_GetItem(PyObject *p, Py_ssize_t pos)

Return value: Borrowed reference. Part of the Stable ABI.
Return the object at position *pos* in the tuple pointed to by *p*. If *pos* is negative or out of bounds, return `NULL` and set an **`IndexError`** exception.

The returned reference is borrowed from the tuple *p* (that is: it is only valid as long as you hold a reference to *p*). To get a strong reference, use **`Py_NewRef(PyTuple_GetItem(...))`** or **`PySequence_GetItem()`**.

PyObject *PyTuple_GET_ITEM(PyObject *p, Py_ssize_t pos)

Return value: Borrowed reference.
Like **`PyTuple_GetItem()`**, but does no checking of its arguments.

PyObject *PyTuple_GetSlice(PyObject *p, Py_ssize_t low, Py_ssize_t high)

Return value: New reference. Part of the Stable ABI.
Return the slice of the tuple pointed to by *p* between *low* and *high*, or `NULL` with an exception set on failure.

This is the equivalent of the Python expression `p[low:high]`. Indexing from the end of the tuple is not supported.

int PyTuple_SetItem(PyObject *p, Py_ssize_t pos, PyObject *o)

Part of the Stable ABI.

Insert a reference to object *o* at position *pos* of the tuple pointed to by *p*. Return `0` on success. If *pos* is out of bounds, return `-1` and set an **`IndexError`** exception.

Note

This function “steals” a reference to *o* and discards a reference to an item already in the tuple at the affected position.

void PyTuple_SET_ITEM(PyObject *p, Py_ssize_t pos, PyObject *o)

Like **`PyTuple_SetItem()`**, but does no error checking, and should *only* be used to fill in brand new tuples.

Bounds checking is performed as an assertion if Python is built in debug mode or **`with assertions`**.

Note

This function “steals” a reference to *o*, and, unlike **`PyTuple_SetItem()`**, does *not* discard a reference to any item that is being replaced; any reference in the tuple at position *pos* will be leaked.

Warning

This macro should *only* be used on tuples that are newly created. Using this macro on a tuple that is already in use (or in other words, has a refcount > 1) could lead to undefined behavior.

int _PyTuple_Resize(PyObject **p, Py_ssize_t newsize)

Can be used to resize a tuple. *newsize* will be the new length of the tuple. Because tuples are *supposed* to be immutable, this should only be used if there is only one reference to the object. Do *not* use this if the tuple may already be known to some other part of the code. The tuple will always grow or shrink at the end. Think of this as destroying the old tuple and creating a new one, only more efficiently. Returns `0` on success. Client code should never assume that the resulting value of `*p` will be the same as before calling this function. If the object referenced by `*p` is replaced, the original `*p` is destroyed. On failure, returns `-1` and sets `*p` to `NULL`, and raises **`MemoryError`** or **`SystemError`**.

Struct Sequence Objects

Struct sequence objects are the C equivalent of **`namedtuple()`** objects, i.e. a sequence whose items can also be accessed through attributes. To create a struct sequence, you first have to create a specific struct sequence type.

PyTypeObject *PyStructSequence_NewType(PyStructSequence_Desc *desc)

Return value: New reference. Part of the Stable ABI.
Create a new struct sequence type from the data in *desc*, described below. Instances of the resulting type can be created with **`PyStructSequence_New()`**.

Return `NULL` with an exception set on failure.

void PyStructSequence_InitType(PyTypeObject *type, PyStructSequence_Desc *desc)

Initializes a struct sequence type *type* from *desc* in place.

int PyStructSequence_InitType2(PyTypeObject *type, PyStructSequence_Desc *desc)

Like `PyStructSequence_InitType()`, but returns `0` on success and `-1` with an exception set on failure.

Added in version 3.4.

type PyStructSequence_Desc

Part of the Stable ABI (including all members).
Contains the meta information of a struct sequence type to create.

const char *name

Fully qualified name of the type; null-terminated UTF-8 encoded. The name must contain the module name.

const char *doc

Pointer to docstring for the type or `NULL` to omit.

PyStructSequence_Field *fields

Pointer to `NULL`-terminated array with field names of the new type.

int n_in_sequence

Number of fields visible to the Python side (if used as tuple).

type PyStructSequence_Field

Part of the Stable ABI (including all members).
Describes a field of a struct sequence. As a struct sequence is modeled as a tuple, all fields are typed as PyObject*. The index in the `fields` array of the `PyStructSequence_Desc` determines which field of the struct sequence is described.

const char *name

Name for the field or `NULL` to end the list of named fields, set to **`PyStructSequence_UnnamedField`** to leave unnamed.

const char *doc

Field docstring or `NULL` to omit.

const char *const PyStructSequence_UnnamedField

Part of the Stable ABI since version 3.11.

Special value for a field name to leave it unnamed.

Changed in version 3.9: The type was changed from `char *`.

PyObject *PyStructSequence_New(PyTypeObject *type)

Return value: New reference. Part of the Stable ABI.

Creates an instance of *type*, which must have been created with **`PyStructSequence_NewType()`**.

Return `NULL` with an exception set on failure.

PyObject *PyStructSequence_GetItem(PyObject *p, Py_ssize_t pos)

Return value: Borrowed reference. Part of the Stable ABI.

Return the object at position *pos* in the struct sequence pointed to by *p*.

Bounds checking is performed as an assertion if Python is built in debug mode or **`with assertions`**.

PyObject *PyStructSequence_GET_ITEM(PyObject *p, Py_ssize_t pos)

Return value: Borrowed reference.

Alias to **`PyStructSequence_GetItem()`**.

Changed in version 3.13: Now implemented as an alias to `PyStructSequence_GetItem()`.

void PyStructSequence_SetItem(PyObject *p, Py_ssize_t pos, PyObject *o)

Part of the Stable ABI.

Sets the field at index *pos* of the struct sequence *p* to value *o*. Like `PyTuple_SET_ITEM()`, this should only be used to fill in brand new instances.

Bounds checking is performed as an assertion if Python is built in debug mode or `with assertions`.

Note

This function “steals” a reference to *o*.

void PyStructSequence_SET_ITEM(PyObject *p, Py_ssize_t *pos, PyObject *o)

Alias to `PyStructSequence_SetItem()`.

Changed in version 3.13: Now implemented as an alias to `PyStructSequence_SetItem()`.

List Objects

type PyListObject

This subtype of `PyObject` represents a Python list object.

PyTypeObject PyList_Type

Part of the Stable ABI.

This instance of `PyTypeObject` represents the Python list type. This is the same object as `list` in the Python layer.

int PyList_Check(PyObject *p)

Return true if *p* is a list object or an instance of a subtype of the list type. This function always succeeds.

int PyList_CheckExact(PyObject *p)

Return true if *p* is a list object, but not an instance of a subtype of the list type. This function always succeeds.

PyObject *PyList_New(Py_ssize_t len)

Return value: New reference. Part of the Stable ABI.

Return a new list of length *len* on success, or `NULL` on failure.

Note

If *len* is greater than zero, the returned list object's items are set to `NULL`. Thus you cannot use abstract API functions such as `PySequence_SetItem()` or expose the object to Python code before setting all items to a real object with `PyList_SetItem()` or `PyList_SET_ITEM()`. The following APIs are safe APIs before the list is fully initialized: `PyList_SetItem()` and `PyList_SET_ITEM()`.

Py_ssize_t PyList_Size(PyObject *list)

Part of the Stable ABI.

Return the length of the list object in *list*; this is equivalent to `len(list)` on a list object.

Py_ssize_t PyList_GET_SIZE(PyObject *list)

Similar to **`PyList_Size()`**, but without error checking.

PyObject *PyList_GetItemRef(PyObject *list, Py_ssize_t index)

Return value: New reference. Part of the Stable ABI since version 3.13.

Return the object at position *index* in the list pointed to by *list*. The position must be non-negative; indexing from the end of the list is not supported. If *index* is out of bounds (`<0 or >=len(list)`), return `NULL` and set an **`IndexError`** exception.

Added in version 3.13.

PyObject *PyList_GetItem(PyObject *list, Py_ssize_t index)

Return value: Borrowed reference. Part of the Stable ABI.

Like **`PyList_GetItemRef()`**, but returns a borrowed reference instead of a strong reference.

PyObject *PyList_GET_ITEM(PyObject *list, Py_ssize_t i)

Return value: Borrowed reference.

Similar to **`PyList_GetItem()`**, but without error checking.

int PyList_SetItem(PyObject *list, Py_ssize_t index, PyObject *item)

Part of the Stable ABI.

Set the item at index *index* in list to *item*. Return `0` on success. If *index* is out of bounds, return `-1` and set an **`IndexError`** exception.

Note

This function “steals” a reference to *item* and discards a reference to an item already in the list at the affected position.

void PyList_SET_ITEM(PyObject *list, Py_ssize_t i, PyObject *o)

Macro form of **`PyList_SetItem()`** without error checking. This is normally only used to fill in new lists where there is no previous content.

Bounds checking is performed as an assertion if Python is built in debug mode or **`with assertions`**.

Note

This macro “steals” a reference to *item*, and, unlike **`PyList_SetItem()`**, does *not* discard a reference to any item that is being replaced; any reference in *list* at position *i* will be leaked.

int PyList_Insert(PyObject *list, Py_ssize_t index, PyObject *item)

Part of the Stable ABI.

Insert the item *item* into list *list* in front of index *index*. Return `0` if successful; return `-1` and set an exception if unsuccessful. Analogous to `list.insert(index, item)`.

int PyList_Append(PyObject *list, PyObject *item)

Part of the Stable ABI.

Append the object *item* at the end of list *list*. Return `0` if successful; return `-1` and set an exception if unsuccessful. Analogous to `list.append(item)`.

PyObject *PyList_GetSlice(PyObject *list, Py_ssize_t low, Py_ssize_t high)

Return value: New reference. Part of the Stable ABI.
Return a list of the objects in *list* containing the objects *between low* and *high*. Return `NULL` and set an exception if unsuccessful. Analogous to `list[low:high]`. Indexing from the end of the list is not supported.

int PyList_SetSlice(PyObject *list, Py_ssize_t low, Py_ssize_t high, PyObject *itemlist)

Part of the Stable ABI.
Set the slice of *list* between *low* and *high* to the contents of *itemlist*. Analogous to `list[low:high] = itemlist`. The *itemlist* may be `NULL`, indicating the assignment of an empty list (slice deletion). Return `0` on success, `-1` on failure. Indexing from the end of the list is not supported.

int PyList_Extend(PyObject *list, PyObject *iterable)

Extend *list* with the contents of *iterable*. This is the same as `PyList_SetSlice(list, PY_SSIZE_T_MAX, PY_SSIZE_T_MAX, iterable)` and analogous to `list.extend(iterable)` or `list += iterable`.

Raise an exception and return `-1` if *list* is not a **`list`** object. Return 0 on success.

Added in version 3.13.

int PyList_Clear(PyObject *list)

Remove all items from *list*. This is the same as `PyList_SetSlice(list, 0, PY_SSIZE_T_MAX, NULL)` and analogous to `list.clear()` or `del list[:]`.

Raise an exception and return `-1` if *list* is not a **`list`** object. Return 0 on success.

Added in version 3.13.

int PyList_Sort(PyObject *list)

Part of the Stable ABI.

Sort the items of *list* in place. Return `0` on success, `-1` on failure. This is equivalent to `list.sort()`.

int PyList_Reverse(PyObject *list)

Part of the Stable ABI.

Reverse the items of *list* in place. Return `0` on success, `-1` on failure. This is the equivalent of `list.reverse()`.

PyObject *PyList_AsTuple(PyObject *list)

Return value: New reference. Part of the Stable ABI.

Return a new tuple object containing the contents of *list*; equivalent to `tuple(list)`.

Dictionary Objects

type PyDictObject

This subtype of `PyObject` represents a Python dictionary object.

PyTypeObject PyDict_Type

Part of the Stable ABI.

This instance of `PyTypeObject` represents the Python dictionary type. This is the same object as `dict` in the Python layer.

int PyDict_Check(PyObject *p)

Return true if *p* is a dict object or an instance of a subtype of the dict type. This function always succeeds.

int PyDict_CheckExact(PyObject *p)

Return true if *p* is a dict object, but not an instance of a subtype of the dict type. This function always succeeds.

PyObject *PyDict_New()

Return value: New reference. Part of the Stable ABI.

Return a new empty dictionary, or `NULL` on failure.

PyObject *PyDictProxy_New(PyObject *mapping)

Return value: New reference. Part of the Stable ABI.

Return a `types.MappingProxyType` object for a mapping which enforces read-only behavior. This is normally used to create a view to prevent modification of the dictionary for non-dynamic class types.

PyTypeObject PyDictProxy_Type

Part of the Stable ABI.

The type object for mapping proxy objects created by `PyDictProxy_New()` and for the read-only `__dict__` attribute of many built-in types. A `PyDictProxy_Type` instance provides a dynamic, read-only view of an underlying dictionary: changes to the underlying dictionary are reflected in the proxy, but the proxy itself does not support mutation operations. This corresponds to `types.MappingProxyType` in Python.

void PyDict_Clear(PyObject *p)

Part of the Stable ABI.
Empty an existing dictionary of all key-value pairs.

int PyDict_Contains(PyObject *p, PyObject *key)

Part of the Stable ABI.
Determine if dictionary *p* contains *key*. If an item in *p* matches *key*, return `1`, otherwise return `0`. On error, return `-1`. This is equivalent to the Python expression `key in p`.

int PyDict_ContainsString(PyObject *p, const char *key)

This is the same as `PyDict_Contains()`, but *key* is specified as a const char* UTF-8 encoded bytes string, rather than a PyObject*.

Added in version 3.13.

PyObject *PyDict_Copy(PyObject *p)

Return value: New reference. Part of the Stable ABI.
Return a new dictionary that contains the same key-value pairs as *p*.

int PyDict_SetItem(PyObject *p, PyObject *key, PyObject *val)

Part of the Stable ABI.

Insert *val* into the dictionary *p* with a key of *key*. *key* must be hashable; if it isn't, **`TypeError`** will be raised. Return `0` on success or `-1` on failure. This function *does not* steal a reference to *val*.

int PyDict_SetItemString(PyObject *p, const char *key, PyObject *val)

Part of the Stable ABI.

This is the same as **`PyDict_SetItem()`**, but *key* is specified as a const char* UTF-8 encoded bytes string, rather than a PyObject*.

int PyDict_DelItem(PyObject *p, PyObject *key)

Part of the Stable ABI.

Remove the entry in dictionary *p* with key *key*. *key* must be hashable; if it isn't, **`TypeError`** is raised. If *key* is not in the dictionary, **`KeyError`** is raised. Return `0` on success or `-1` on failure.

int PyDict_DelItemString(PyObject *p, const char *key)

Part of the Stable ABI.

This is the same as **`PyDict_DelItem()`**, but *key* is specified as a const char* UTF-8 encoded bytes string, rather than a PyObject*.

int PyDict_GetItemRef(PyObject *p, PyObject *key, PyObject **result)

Part of the Stable ABI since version 3.13.

Return a new strong reference to the object from dictionary *p* which has a key *key*:

- If the key is present, set **result* to a new strong reference to the value and return `1`.
- If the key is missing, set **result* to `NULL` and return `0`.
- On error, raise an exception and return `-1`.

Added in version 3.13.

See also the `PyObject_GetItem()` function.

PyObject *PyDict_GetItem(PyObject *p, PyObject *key)

Return value: Borrowed reference. Part of the Stable ABI. Return a borrowed reference to the object from dictionary *p* which has a key *key*. Return `NULL` if the key *key* is missing *without* setting an exception.

Note

Exceptions that occur while this calls `__hash__()` and `__eq__()` methods are silently ignored. Prefer the `PyDict_GetItemWithError()` function instead.

Changed in version 3.10: Calling this API without an attached thread state had been allowed for historical reason. It is no longer allowed.

PyObject *PyDict_GetItemWithError(PyObject *p, PyObject *key)

Return value: Borrowed reference. Part of the Stable ABI. Variant of `PyDict_GetItem()` that does not suppress exceptions. Return `NULL` **with** an exception set if an exception occurred. Return `NULL` **without** an exception set if the key wasn't present.

PyObject *PyDict_GetItemString(PyObject *p, const char *key)

Return value: Borrowed reference. Part of the Stable ABI. This is the same as `PyDict_GetItem()`, but *key* is specified as a const char* UTF-8 encoded bytes string, rather than a PyObject*.

Note

Exceptions that occur while this calls `__hash__()` and `__eq__()` methods or while creating the temporary `str` object are silently ignored. Prefer using the `PyDict_GetItemWithError()` function with your own `PyUnicode_FromString()` *key* instead.

int PyDict_GetItemStringRef(PyObject *p, const char *key, PyObject **result)

Part of the Stable ABI since version 3.13.
Similar to `PyDict_GetItemRef()`, but *key* is specified as a const char* UTF-8 encoded bytes string, rather than a PyObject*.

Added in version 3.13.

PyObject *PyDict_SetDefault(PyObject *p, PyObject *key, PyObject *defaultobj)

Return value: Borrowed reference.
This is the same as the Python-level `dict.setdefault()`. If present, it returns the value corresponding to *key* from the dictionary *p*. If the key is not in the dict, it is inserted with value *defaultobj* and *defaultobj* is returned. This function evaluates the hash function of *key* only once, instead of evaluating it independently for the lookup and the insertion.

Added in version 3.4.

int PyDict_SetDefaultRef(PyObject *p, PyObject *key, PyObject *default_value, PyObject **result)

Inserts *default_value* into the dictionary *p* with a key of *key* if the key is not already present in the dictionary. If *result* is not `NULL`, then **result* is set to a strong reference to either *default_value*, if the key was not present, or the existing value, if *key* was already present in the dictionary. Returns `1` if the key was present and *default_value* was not inserted, or `0` if the key was not present and *default_value* was inserted. On failure, returns `-1`, sets an exception, and sets `*result` to `NULL`.

For clarity: if you have a strong reference to *default_value* before calling this function, then after it returns, you hold a strong reference to both *default_value* and **result* (if it's not `NULL`). These may refer to the same object: in that case you hold two separate references to it.

Added in version 3.13.

int PyDict_Pop(PyObject *p, PyObject *key, PyObject **result)

Remove *key* from dictionary *p* and optionally return the removed value. Do not raise **`KeyError`** if the key is missing.

- If the key is present, set **result* to a new reference to the removed value if *result* is not `NULL`, and return `1`.
- If the key is missing, set **result* to `NULL` if *result* is not `NULL`, and return `0`.
- On error, raise an exception and return `-1`.

Similar to **`dict.pop()`**, but without the default value and not raising **`KeyError`** if the key is missing.

Added in version 3.13.

int PyDict_PopString(PyObject *p, const char *key, PyObject **result)

Similar to **`PyDict_Pop()`**, but *key* is specified as a const char* UTF-8 encoded bytes string, rather than a

PyObject*.

Added in version 3.13.

PyObject *PyDict_Items(PyObject *p)

Return value: New reference. Part of the Stable ABI.

Return a **`PyListObject`** containing all the items from the dictionary.

PyObject *PyDict_Keys(PyObject *p)

Return value: New reference. Part of the Stable ABI.

Return a **`PyListObject`** containing all the keys from the dictionary.

PyObject *PyDict_Values(PyObject *p)

Return value: New reference. Part of the Stable ABI.

Return a **`PyListObject`** containing all the values from the dictionary *p*.

Py_ssize_t PyDict_Size(PyObject *p)

Part of the Stable ABI.

Return the number of items in the dictionary. This is equivalent to `len(p)` on a dictionary.

Py_ssize_t PyDict_GET_SIZE(PyObject *p)

Similar to **`PyDict_Size()`**, but without error checking.

int PyDict_Next(PyObject *p, Py_ssize_t *ppos, PyObject **pkey, PyObject **pvalue)

Part of the Stable ABI.

Iterate over all key-value pairs in the dictionary *p*. The **`Py_ssize_t`** referred to by *ppos* must be initialized to `0` prior to the first call to this function to start the iteration; the function returns true for each pair in the dictionary, and false once all pairs have been reported. The parameters *pkey* and *pvalue* should either point to PyObject* variables that will be filled in with each key and value, respectively, or may be `NULL`. Any references returned through them are borrowed. *ppos* should not be altered during iteration. Its value represents offsets within the internal dictionary structure, and since the structure is sparse, the offsets are not consecutive.

For example:

```
PyObject *key, *value;
Py_ssize_t pos = 0;

while (PyDict_Next(self->dict, &pos, &key, &value)) {
    /* do something interesting with the values... */
    ...
}
```

The dictionary *p* should not be mutated during iteration. It is safe to modify the values of the keys as you iterate over the dictionary, but only so long as the set of keys does not change. For example:

```
PyObject *key, *value;
Py_ssize_t pos = 0;

while (PyDict_Next(self->dict, &pos, &key, &value)) {
    long i = PyLong_AsLong(value);
    if (i == -1 && PyErr_Occurred()) {
        return -1;
    }
    PyObject *o = PyLong_FromLong(i + 1);
    if (o == NULL)
        return -1;
    if (PyDict_SetItem(self->dict, key, o) < 0) {
        Py_DECREF(o);
        return -1;
    }
    Py_DECREF(o);
}
```

The function is not thread-safe in the free-threaded build without external synchronization. You can use `Py_BEGIN_CRITICAL_SECTION` to lock the dictionary while iterating over it:

```
Py_BEGIN_CRITICAL_SECTION(self->dict);
while (PyDict_Next(self->dict, &pos, &key, &value)) {
    ...
}
Py_END_CRITICAL_SECTION();
```

Note

On the free-threaded build, this function can be used safely inside a critical section. However, the references returned for *pkey* and *pvalue* are borrowed and are only valid while the critical section is held. If you need to use these objects outside the critical section or when the critical section can be suspended, create a strong reference (for example, using `Py_NewRef()`).

int PyDict_Merge(PyObject *a, PyObject *b, int override)

Part of the Stable ABI.

Iterate over mapping object *b* adding key-value pairs to dictionary *a*. *b* may be a dictionary, or any object supporting `PyMapping_Keys()` and `PyObject_GetItem()`. If *override* is true, existing pairs in *a* will be replaced if a matching key is found in *b*, otherwise pairs will only be added if there is not a matching key in *a*. Return `0` on success or `-1` if an exception was raised.

int PyDict_Update(PyObject *a, PyObject *b)

Part of the Stable ABI.

This is the same as `PyDict_Merge(a, b, 1)` in C, and is similar to `a.update(b)` in Python except that `PyDict_Update()` doesn’t fall back to the iterating over a sequence of key value pairs if the second argument has no “keys” attribute. Return `0` on success or `-1` if an exception was raised.

int PyDict_MergeFromSeq2(PyObject *a, PyObject *seq2, int override)

Part of the Stable ABI.

Update or merge into dictionary *a*, from the key-value pairs in *seq2*. *seq2* must be an iterable object producing iterable objects of length 2, viewed as key-value pairs. In case of duplicate keys, the last wins if *override* is true, else the first wins. Return `0` on success or `-1` if an exception was raised. Equivalent Python (except for the return value):

```
def PyDict_MergeFromSeq2(a, seq2, override):
    for key, value in seq2:
        if override or key not in a:
            a[key] = value
```

int PyDict_AddWatcher(PyDict_WatchCallback callback)

Register *callback* as a dictionary watcher. Return a non-negative integer id which must be passed to future calls to **`PyDict_Watch()`**. In case of error (e.g. no more watcher IDs available), return `-1` and set an exception.

Added in version 3.12.

int PyDict_ClearWatcher(int watcher_id)

Clear watcher identified by *watcher_id* previously returned from **`PyDict_AddWatcher()`**. Return `0` on success, `-1` on error (e.g. if the given *watcher_id* was never registered.)

Added in version 3.12.

int PyDict_Watch(int watcher_id, PyObject *dict)

Mark dictionary *dict* as watched. The callback granted *watcher_id* by **`PyDict_AddWatcher()`** will be called when *dict* is modified or deallocated. Return `0` on success or `-1` on error.

Added in version 3.12.

int PyDict_Unwatch(int watcher_id, PyObject *dict)

Mark dictionary *dict* as no longer watched. The callback granted *watcher_id* by **`PyDict_AddWatcher()`** will no longer be called when *dict* is modified or deallocated. The dict must previously have been watched by this watcher. Return `0` on success or `-1` on error.

Added in version 3.12.

type PyDict_WatchEvent

Enumeration of possible dictionary watcher events: `PyDict_EVENT_ADDED`, `PyDict_EVENT_MODIFIED`, `PyDict_EVENT_DELETED`, `PyDict_EVENT_CLONED`, `PyDict_EVENT_CLEARED`, or `PyDict_EVENT_DEALLOCATED`.

Added in version 3.12.

typedef int (*PyDict_WatchCallback)(PyDict_WatchEvent event, PyObject *dict, PyObject *key, PyObject *new_value)

Type of a dict watcher callback function.

If *event* is `PyDict_EVENT_CLEARED` or `PyDict_EVENT_DEALLOCATED`, both *key* and *new_value* will be `NULL`. If *event* is `PyDict_EVENT_ADDED` or `PyDict_EVENT_MODIFIED`, *new_value* will be the new value for *key*. If *event* is `PyDict_EVENT_DELETED`, *key* is being deleted from the dictionary and *new_value* will be `NULL`.

`PyDict_EVENT_CLONED` occurs when *dict* was previously empty and another dict is merged into it. To maintain efficiency of this operation, per-key `PyDict_EVENT_ADDED` events are not issued in this case; instead a single `PyDict_EVENT_CLONED` is issued, and *key* will be the source dictionary.

The callback may inspect but must not modify *dict*; doing so could have unpredictable effects, including infinite recursion. Do not trigger Python code execution in the callback, as it could modify the dict as a side effect.

If *event* is `PyDict_EVENT_DEALLOCATED`, taking a new reference in the callback to the about-to-be-destroyed dictionary will resurrect it and prevent it from being freed at this time. When the resurrected object is destroyed later, any watcher callbacks active at that time will be called again.

Callbacks occur before the notified modification to *dict* takes place, so the prior state of *dict* can be inspected.

If the callback sets an exception, it must return `-1`; this exception will be printed as an unraisable exception using **`PyErr_WriteUnraisable()`**. Otherwise it should return `0`.

There may already be a pending exception set on entry to the callback. In this case, the callback should return `0` with the same exception still set. This means the callback may not call any other API that can set an exception unless it saves and clears the exception state first, and restores it before returning.

Added in version 3.12.

Dictionary View Objects

int PyDictViewSet_Check(PyObject *op)

Return true if *op* is a view of a set inside a dictionary. This is currently equivalent to PyDictKeys_Check(op) || PyDictItems_Check(op). This function always succeeds.

PyTypeObject PyDictKeys_Type

Part of the Stable ABI.

Type object for a view of dictionary keys. In Python, this is the type of the object returned by **`dict.keys()`**.

int PyDictKeys_Check(PyObject *op)

Return true if *op* is an instance of a dictionary keys view. This function always succeeds.

PyTypeObject PyDictValues_Type

Part of the Stable ABI.

Type object for a view of dictionary values. In Python, this is the type of the object returned by **`dict.values()`**.

int PyDictValues_Check(PyObject *op)

Return true if *op* is an instance of a dictionary values view. This function always succeeds.

PyTypeObject PyDictItems_Type

Part of the Stable ABI.

Type object for a view of dictionary items. In Python, this is the type of the object returned by **`dict.items()`**.

int PyDictItems_Check(PyObject *op)

Return true if *op* is an instance of a dictionary items view. This function always succeeds.

Ordered Dictionaries

Python’s C API provides interface for **`collections.OrderedDict`** from C. Since Python 3.7, dictionaries are ordered by default, so there is usually little need for these functions; prefer `PyDict*` where possible.

PyTypeObject PyODict_Type

Type object for ordered dictionaries. This is the same object as **`collections.OrderedDict`** in the Python layer.

int PyODict_Check(PyObject *od)

Return true if *od* is an ordered dictionary object or an instance of a subtype of the **`OrderedDict`** type. This function always succeeds.

int PyODict_CheckExact(PyObject *od)

Return true if *od* is an ordered dictionary object, but not an instance of a subtype of the **`OrderedDict`** type. This function always succeeds.

PyTypeObject PyODictKeys_Type

Analogous to **`PyDictKeys_Type`** for ordered dictionaries.

PyTypeObject PyODictValues_Type

Analogous to **`PyDictValues_Type`** for ordered dictionaries.

PyTypeObject PyODictItems_Type

Analogous to **`PyDictItems_Type`** for ordered dictionaries.

PyObject *PyODict_New(void)

Return a new empty ordered dictionary, or `NULL` on failure.

This is analogous to **`PyDict_New()`**.

int PyODict_SetItem(PyObject *od, PyObject *key, PyObject *value)

Insert *value* into the ordered dictionary *od* with a key of *key*. Return `0` on success or `-1` with an exception set on failure.

This is analogous to **`PyDict_SetItem()`**.

int PyODict_DelItem(PyObject *od, PyObject *key)

Remove the entry in the ordered dictionary *od* with key *key*. Return `0` on success or `-1` with an exception set on failure.

This is analogous to **`PyDict_DelItem()`**.

These are soft deprecated aliases to `PyDict` APIs:

`PyODict`	**`PyDict`**
PyODict_GetItem(od, key)	**`PyDict_GetItem()`**
PyODict_GetItemWithError(od, key)	**`PyDict_GetItemWithError()`**
PyODict_GetItemString(od, key)	**`PyDict_GetItemString()`**
PyODict_Contains(od, key)	**`PyDict_Contains()`**
PyODict_Size(od)	**`PyDict_Size()`**
PyODict_SIZE(od)	**`PyDict_GET_SIZE()`**

Set Objects

This section details the public API for `set` and `frozenset` objects. Any functionality not listed below is best accessed using either the abstract object protocol (including `PyObject_CallMethod()`, `PyObject_RichCompareBool()`, `PyObject_Hash()`, `PyObject_Repr()`, `PyObject_IsTrue()`, `PyObject_Print()`, and `PyObject_GetIter()`) or the abstract number protocol (including `PyNumber_And()`, `PyNumber_Subtract()`, `PyNumber_Or()`, `PyNumber_Xor()`, `PyNumber_InPlaceAnd()`, `PyNumber_InPlaceSubtract()`, `PyNumber_InPlaceOr()`, and `PyNumber_InPlaceXor()`).

type PySetObject

This subtype of `PyObject` is used to hold the internal data for both `set` and `frozenset` objects. It is like a `PyDictObject` in that it is a fixed size for small sets (much like tuple storage) and will point to a separate, variable sized block of memory for medium and large sized sets (much like list storage). None of the fields of this structure should be considered public and all are subject to change. All access should be done through the documented API rather than by manipulating the values in the structure.

PyTypeObject PySet_Type

Part of the Stable ABI.

This is an instance of `PyTypeObject` representing the Python `set` type.

PyTypeObject PyFrozenSet_Type

Part of the Stable ABI.

This is an instance of `PyTypeObject` representing the Python `frozenset` type.

The following type check macros work on pointers to any Python object. Likewise, the constructor functions work with any iterable Python object.

int PySet_Check(PyObject *p)

Return true if *p* is a **`set`** object or an instance of a subtype. This function always succeeds.

int PyFrozenSet_Check(PyObject *p)

Return true if *p* is a **`frozenset`** object or an instance of a subtype. This function always succeeds.

int PyAnySet_Check(PyObject *p)

Return true if *p* is a **`set`** object, a **`frozenset`** object, or an instance of a subtype. This function always succeeds.

int PySet_CheckExact(PyObject *p)

Return true if *p* is a **`set`** object but not an instance of a subtype. This function always succeeds.

Added in version 3.10.

int PyAnySet_CheckExact(PyObject *p)

Return true if *p* is a **`set`** object or a **`frozenset`** object but not an instance of a subtype. This function always succeeds.

int PyFrozenSet_CheckExact(PyObject *p)

Return true if *p* is a **`frozenset`** object but not an instance of a subtype. This function always succeeds.

PyObject *PySet_New(PyObject *iterable)

Return value: New reference. Part of the Stable ABI.
Return a new **`set`** containing objects returned by the *iterable*. The *iterable* may be `NULL` to create a new empty

set. Return the new set on success or `NULL` on failure. Raise **`TypeError`** if *iterable* is not actually iterable. The constructor is also useful for copying a set (`c=set(s)`).

PyObject *PyFrozenSet_New(PyObject *iterable)

Return value: New reference. Part of the Stable ABI.
Return a new **`frozenset`** containing objects returned by the *iterable*. The *iterable* may be `NULL` to create a new empty frozenset. Return the new set on success or `NULL` on failure. Raise **`TypeError`** if *iterable* is not actually iterable.

The following functions and macros are available for instances of **`set`** or **`frozenset`** or instances of their subtypes.

Py_ssize_t PySet_Size(PyObject *anyset)

Part of the Stable ABI.
Return the length of a **`set`** or **`frozenset`** object. Equivalent to `len(anyset)`. Raises a **`SystemError`** if *anyset* is not a **`set`**, **`frozenset`**, or an instance of a subtype.

Py_ssize_t PySet_GET_SIZE(PyObject *anyset)

Macro form of **`PySet_Size()`** without error checking.

int PySet_Contains(PyObject *anyset, PyObject *key)

Part of the Stable ABI.
Return `1` if found, `0` if not found, and `-1` if an error is encountered. Unlike the Python **`__contains__()`** method, this function does not automatically convert unhashable sets into temporary frozensets. Raise a **`TypeError`** if the *key* is unhashable. Raise **`SystemError`** if *anyset* is not a **`set`**, **`frozenset`**, or an instance of a subtype.

int PySet_Add(PyObject *set, PyObject *key)

Part of the Stable ABI.

Add *key* to a **`set`** instance. Also works with **`frozenset`** instances (like **`PyTuple_SetItem()`** it can be used to fill in the values of brand new frozensets before they are exposed to other code). Return `0` on success or `-1` on failure. Raise a **`TypeError`** if the *key* is unhashable. Raise a **`MemoryError`** if there is no room to grow. Raise a **`SystemError`** if *set* is not an instance of **`set`** or its subtype.

The following functions are available for instances of **`set`** or its subtypes but not for instances of **`frozenset`** or its subtypes.

int PySet_Discard(PyObject *set, PyObject *key)

Part of the Stable ABI.

Return `1` if found and removed, `0` if not found (no action taken), and `-1` if an error is encountered. Does not raise **`KeyError`** for missing keys. Raise a **`TypeError`** if the *key* is unhashable. Unlike the Python **`discard()`** method, this function does not automatically convert unhashable sets into temporary frozensets. Raise **`SystemError`** if *set* is not an instance of **`set`** or its subtype.

PyObject *PySet_Pop(PyObject *set)

Return value: New reference. Part of the Stable ABI.

Return a new reference to an arbitrary object in the *set*, and removes the object from the *set*. Return `NULL` on failure. Raise **`KeyError`** if the set is empty. Raise a **`SystemError`** if *set* is not an instance of **`set`** or its subtype.

int PySet_Clear(PyObject *set)

Part of the Stable ABI.

Empty an existing set of all elements. Return `0` on success. Return `-1` and raise **`SystemError`** if *set* is not an instance of **`set`** or its subtype.

Deprecated API

PySet_MINSIZE

A soft deprecated constant representing the size of an internal preallocated table inside **`PySetObject`** instances.

This is documented solely for completeness, as there are no guarantees that a given version of CPython uses preallocated tables with a fixed size. In code that does not deal with unstable set internals, **`PySet_MINSIZE`** can be replaced with a small constant like `8`.

If looking for the size of a set, use **`PySet_Size()`** instead.

Function Objects

There are a few functions specific to Python functions.

type PyFunctionObject

The C structure used for functions.

PyTypeObject PyFunction_Type

This is an instance of **`PyTypeObject`** and represents the Python function type. It is exposed to Python programmers as `types.FunctionType`.

int PyFunction_Check(PyObject *o)

Return true if *o* is a function object (has type **`PyFunction_Type`**). The parameter must not be `NULL`. This function always succeeds.

PyObject *PyFunction_New(PyObject *code, PyObject *globals)

Return value: New reference.
Return a new function object associated with the code object *code*. *globals* must be a dictionary with the global variables accessible to the function.

The function's docstring and name are retrieved from the code object. **`__module__`** is retrieved from *globals*. The argument defaults, annotations and closure are set to `NULL`. **`__qualname__`** is set to the same value as the code object's **`co_qualname`** field.

PyObject *PyFunction_NewWithQualName(PyObject *code, PyObject *globals, PyObject *qualname)

Return value: New reference.

As `PyFunction_New()`, but also allows setting the function object's `__qualname__` attribute. *qualname* should be a unicode object or `NULL`; if `NULL`, the **`__qualname__`** attribute is set to the same value as the code object's `co_qualname` field.

Added in version 3.3.

PyObject *PyFunction_GetCode(PyObject *op)

Return value: Borrowed reference.
Return the code object associated with the function object *op*.

PyObject *PyFunction_GetGlobals(PyObject *op)

Return value: Borrowed reference.
Return the globals dictionary associated with the function object *op*.

PyObject *PyFunction_GetModule(PyObject *op)

Return value: Borrowed reference.
Return a borrowed reference to the `__module__` attribute of the function object *op*. It can be *NULL*.

This is normally a `string` containing the module name, but can be set to any other object by Python code.

PyObject *PyFunction_GetDefaults(PyObject *op)

Return value: Borrowed reference.
Return the argument default values of the function object *op*. This can be a tuple of arguments or `NULL`.

int PyFunction_SetDefaults(PyObject *op, PyObject *defaults)

Set the argument default values for the function object *op*. *defaults* must be `Py_None` or a tuple.

Raises **`SystemError`** and returns `-1` on failure.

void PyFunction_SetVectorcall(PyFunctionObject *func, vectorcallfunc vectorcall)

Set the vectorcall field of a given function object *func*.

Warning: extensions using this API must preserve the behavior of the unaltered (default) vectorcall function!

Added in version 3.12.

PyObject *PyFunction_GetKwDefaults(PyObject *op)

Return value: Borrowed reference.
Return the keyword-only argument default values of the function object *op*. This can be a dictionary of arguments or `NULL`.

int PyFunction_SetKwDefaults(PyObject *op, PyObject *defaults)

Set the keyword-only argument default values of the function object *op*. *defaults* must be a dictionary of keyword-only arguments or `Py_None`.

This function returns `0` on success, and returns `-1` with an exception set on failure.

PyObject *PyFunction_GetClosure(PyObject *op)

Return value: Borrowed reference.
Return the closure associated with the function object *op*. This can be `NULL` or a tuple of cell objects.

int PyFunction_SetClosure(PyObject *op, PyObject *closure)

Set the closure associated with the function object *op*. *closure* must be `Py_None` or a tuple of cell objects.

Raises **`SystemError`** and returns `-1` on failure.

PyObject *PyFunction_GetAnnotations(PyObject *op)

Return value: Borrowed reference.
Return the annotations of the function object *op*. This can be a mutable dictionary or `NULL`.

int PyFunction_SetAnnotations(PyObject *op, PyObject *annotations)

Set the annotations for the function object *op*. *annotations* must be a dictionary or `Py_None`.

Raises **`SystemError`** and returns `-1` on failure.

PyObject *PyFunction_GET_CODE(PyObject *op)
PyObject *PyFunction_GET_GLOBALS(PyObject *op)
PyObject *PyFunction_GET_MODULE(PyObject *op)
PyObject *PyFunction_GET_DEFAULTS(PyObject *op)
PyObject *PyFunction_GET_KW_DEFAULTS(PyObject *op)
PyObject *PyFunction_GET_CLOSURE(PyObject *op)
PyObject *PyFunction_GET_ANNOTATIONS(PyObject *op)

Return value: Borrowed reference.
These functions are similar to their `PyFunction_Get*` counterparts, but do not do type checking. Passing anything other than an instance of **`PyFunction_Type`** is undefined behavior.

int PyFunction_AddWatcher(PyFunction_WatchCallback callback)

Register *callback* as a function watcher for the current interpreter. Return an ID which may be passed to **`PyFunction_ClearWatcher()`**. In case of error (e.g. no more watcher IDs available), return `-1` and set an exception.

Added in version 3.12.

int PyFunction_ClearWatcher(int watcher_id)

Clear watcher identified by *watcher_id* previously returned from **`PyFunction_AddWatcher()`** for the current interpreter. Return `0` on success, or `-1` and set an exception on error (e.g. if the given *watcher_id* was never registered.)

Added in version 3.12.

type PyFunction_WatchEvent

Enumeration of possible function watcher events:

- `PyFunction_EVENT_CREATE`
- `PyFunction_EVENT_DESTROY`
- `PyFunction_EVENT_MODIFY_CODE`
- `PyFunction_EVENT_MODIFY_DEFAULTS`
- `PyFunction_EVENT_MODIFY_KWDEFAULTS`

Added in version 3.12.

typedef int (*PyFunction_WatchCallback)(PyFunction_WatchEvent event, PyFunctionObject *func, PyObject *new_value)

Type of a function watcher callback function.

If *event* is `PyFunction_EVENT_CREATE` or `PyFunction_EVENT_DESTROY` then *new_value* will be `NULL`. Otherwise, *new_value* will hold a borrowed reference to the new value that is about to be stored in *func* for the attribute that is being modified.

The callback may inspect but must not modify *func*; doing so could have unpredictable effects, including infinite recursion.

If *event* is `PyFunction_EVENT_CREATE`, then the callback is invoked after *func* has been fully initialized. Otherwise, the callback is invoked before the modification to *func* takes place, so the prior state of *func* can be inspected. The runtime is permitted to optimize away the creation of function objects when possible. In such cases no event will be emitted. Although this creates the possibility of an observable difference of runtime behavior depending on optimization decisions, it does not change the semantics of the Python code being executed.

If *event* is `PyFunction_EVENT_DESTROY`, Taking a reference in the callback to the about-to-be-destroyed function will resurrect it, preventing it from being freed at this time. When the resurrected object is destroyed later, any watcher callbacks active at that time will be called again.

If the callback sets an exception, it must return `-1`; this exception will be printed as an unraisable exception using **`PyErr_WriteUnraisable()`**. Otherwise it should return `0`.

There may already be a pending exception set on entry to the callback. In this case, the callback should return `0` with the same exception still set. This means the callback may not call any other API that can set an exception unless it saves and clears the exception state first, and restores it before returning.

Added in version 3.12.

Instance Method Objects

An instance method is a wrapper for a **`PyCFunction`** and the new way to bind a **`PyCFunction`** to a class object. It replaces the former call `PyMethod_New(func, NULL, class)`.

PyTypeObject PyInstanceMethod_Type

This instance of **`PyTypeObject`** represents the Python instance method type. It is not exposed to Python programs.

int PyInstanceMethod_Check(PyObject *o)

Return true if *o* is an instance method object (has type **`PyInstanceMethod_Type`**). The parameter must not be `NULL`. This function always succeeds.

PyObject *PyInstanceMethod_New(PyObject *func)

Return value: New reference.
Return a new instance method object, with *func* being any callable object. *func* is the function that will be called when the instance method is called.

PyObject *PyInstanceMethod_Function(PyObject *im)

Return value: Borrowed reference.
Return the function object associated with the instance method *im*.

PyObject *PyInstanceMethod_GET_FUNCTION(PyObject *im)

Return value: Borrowed reference.
Macro version of **`PyInstanceMethod_Function()`** which avoids error checking.

Method Objects

Methods are bound function objects. Methods are always bound to an instance of a user-defined class. Unbound methods (methods bound to a class object) are no longer available.

PyTypeObject PyMethod_Type

This instance of **`PyTypeObject`** represents the Python method type. This is exposed to Python programs as `types.MethodType`.

int PyMethod_Check(PyObject *o)

Return true if *o* is a method object (has type **`PyMethod_Type`**). The parameter must not be `NULL`. This function always succeeds.

PyObject *PyMethod_New(PyObject *func, PyObject *self)

Return value: New reference.
Return a new method object, with *func* being any callable object and *self* the instance the method should be bound. *func* is the function that will be called when the method is called. *self* must not be `NULL`.

PyObject *PyMethod_Function(PyObject *meth)

Return value: Borrowed reference.
Return the function object associated with the method *meth*.

PyObject *PyMethod_GET_FUNCTION(PyObject *meth)

Return value: Borrowed reference.
Macro version of **`PyMethod_Function()`** which avoids error checking.

PyObject *PyMethod_Self(PyObject *meth)

Return value: Borrowed reference.
Return the instance associated with the method *meth*.

PyObject *PyMethod_GET_SELF(PyObject *meth)

Return value: Borrowed reference.
Macro version of **`PyMethod_Self()`** which avoids error checking.

Cell Objects

“Cell” objects are used to implement variables referenced by multiple scopes. For each such variable, a cell object is created to store the value; the local variables of each stack frame that references the value contain a reference to the cells from outer scopes which also use that variable. When the value is accessed, the value contained in the cell is used instead of the cell object itself. This de-referencing of the cell object requires support from the generated byte-code; these are not automatically de-referenced when accessed. Cell objects are not likely to be useful elsewhere.

type PyCellObject

The C structure used for cell objects.

PyTypeObject PyCell_Type

The type object corresponding to cell objects.

int PyCell_Check(PyObject *ob)

Return true if *ob* is a cell object; *ob* must not be `NULL`. This function always succeeds.

PyObject *PyCell_New(PyObject *ob)

Return value: New reference.
Create and return a new cell object containing the value *ob*. The parameter may be `NULL`.

PyObject *PyCell_Get(PyObject *cell)

Return value: New reference.
Return the contents of the cell *cell*, which can be `NULL`. If *cell* is not a cell object, returns `NULL` with an exception set.

PyObject *PyCell_GET(PyObject *cell)

Return value: Borrowed reference.
Return the contents of the cell *cell*, but without checking that *cell* is non-`NULL` and a cell object.

int PyCell_Set(PyObject *cell, PyObject *value)

Set the contents of the cell object *cell* to *value*. This releases the reference to any current content of the cell. *value* may be `NULL`. *cell* must be non-`NULL`.

On success, return `0`. If *cell* is not a cell object, set an exception and return `-1`.

void PyCell_SET(PyObject *cell, PyObject *value)

Sets the value of the cell object *cell* to *value*. No reference counts are adjusted, and no checks are made for safety; *cell* must be non-`NULL` and must be a cell object.

Code Objects

Code objects are a low-level detail of the CPython implementation. Each one represents a chunk of executable code that hasn’t yet been bound into a function.

type PyCodeObject

The C structure of the objects used to describe code objects. The fields of this type are subject to change at any time.

PyTypeObject PyCode_Type

This is an instance of **`PyTypeObject`** representing the Python code object.

int PyCode_Check(PyObject *co)

Return true if *co* is a code object. This function always succeeds.

Py_ssize_t PyCode_GetNumFree(PyCodeObject *co)

Return the number of free (closure) variables in a code object.

int PyUnstable_Code_GetFirstFree(PyCodeObject *co)

This is Unstable API. It may change without warning in minor releases.

Return the position of the first free (closure) variable in a code object.

Changed in version 3.13: Renamed from `PyCode_GetFirstFree` as part of Unstable C API. The old name is deprecated, but will remain available until the signature changes again.

PyCodeObject *PyUnstable_Code_New(int argcount, int kwonlyargcount, int nlocals, int stacksize, int flags, PyObject *code, PyObject *consts, PyObject *names, PyObject *varnames, PyObject *freevars, PyObject *cellvars, PyObject *filename, PyObject *name, PyObject *qualname, int firstlineno, PyObject *linetable, PyObject *exceptiontable)

> *This is Unstable API. It may change without warning in minor releases.*

> Return a new code object. If you need a dummy code object to create a frame, use **`PyCode_NewEmpty()`** instead.
>
> Since the definition of the bytecode changes often, calling **`PyUnstable_Code_New()`** directly can bind you to a precise Python version.
>
> The many arguments of this function are inter-dependent in complex ways, meaning that subtle changes to values are likely to result in incorrect execution or VM crashes. Use this function only with extreme care.
>
> *Changed in version 3.11:* Added `qualname` and `exceptiontable` parameters.
>
> *Changed in version 3.12:* Renamed from `PyCode_New` as part of Unstable C API. The old name is deprecated, but will remain available until the signature changes again.

PyCodeObject *PyUnstable_Code_NewWithPosOnlyArgs(int argcount, int posonlyargcount, int kwonlyargcount, int nlocals, int stacksize, int flags, PyObject *code, PyObject *consts, PyObject *names, PyObject *varnames, PyObject *freevars, PyObject *cellvars, PyObject *filename, PyObject *name, PyObject *qualname, int firstlineno, PyObject *linetable, PyObject *exceptiontable)

This is Unstable API. It may change without warning in minor releases.

Similar to `PyUnstable_Code_New()`, but with an extra "posonlyargcount" for positional-only arguments. The same caveats that apply to `PyUnstable_Code_New` also apply to this function.

Added in version 3.8: as `PyCode_NewWithPosOnlyArgs`

Changed in version 3.11: Added `qualname` and `exceptiontable` parameters.

Changed in version 3.12: Renamed to `PyUnstable_Code_NewWithPosOnlyArgs`. The old name is deprecated, but will remain available until the signature changes again.

PyCodeObject *PyCode_NewEmpty(const char *filename, const char *funcname, int firstlineno)

Return value: New reference.
Return a new empty code object with the specified filename, function name, and first line number. The resulting code object will raise an `Exception` if executed.

int PyCode_Addr2Line(PyCodeObject *co, int byte_offset)

Return the line number of the instruction that occurs on or before `byte_offset` and ends after it. If you just need the line number of a frame, use `PyFrame_GetLineNumber()` instead.

For efficiently iterating over the line numbers in a code object, use **the API described in PEP 626** [https://peps.python.org/pep-0626/#out-of-process-debuggers-and-profilers].

int PyCode_Addr2Location(PyObject *co, int byte_offset, int *start_line, int *start_column, int *end_line, int *end_column)

Sets the passed `int` pointers to the source code line and column numbers for the instruction at `byte_offset`. Sets the value to `0` when information is not available for any particular element.

Returns `1` if the function succeeds and 0 otherwise.

Added in version 3.11.

PyObject *PyCode_GetCode(PyCodeObject *co)

Equivalent to the Python code `getattr(co, 'co_code')`. Returns a strong reference to a **`PyBytesObject`** representing the bytecode in a code object. On error, `NULL` is returned and an exception is raised.

This `PyBytesObject` may be created on-demand by the interpreter and does not necessarily represent the bytecode actually executed by CPython. The primary use case for this function is debuggers and profilers.

Added in version 3.11.

PyObject *PyCode_GetVarnames(PyCodeObject *co)

Equivalent to the Python code `getattr(co, 'co_varnames')`. Returns a new reference to a **`PyTupleObject`** containing the names of the local variables. On error, `NULL` is returned and an exception is raised.

Added in version 3.11.

PyObject *PyCode_GetCellvars(PyCodeObject *co)

Equivalent to the Python code `getattr(co, 'co_cellvars')`. Returns a new reference to a **`PyTupleObject`** containing the names of the local variables that are referenced by nested functions. On error, `NULL` is returned and an exception is raised.

Added in version 3.11.

PyObject *PyCode_GetFreevars(PyCodeObject *co)

Equivalent to the Python code `getattr(co, 'co_freevars')`. Returns a new reference to a **`PyTupleObject`** containing the names of the free (closure) variables. On error, `NULL` is returned and an exception is raised.

Added in version 3.11.

int PyCode_AddWatcher(PyCode_WatchCallback callback)

Register *callback* as a code object watcher for the current interpreter. Return an ID which may be passed to **`PyCode_ClearWatcher()`**. In case of error (e.g. no more watcher IDs available), return `-1` and set an exception.

Added in version 3.12.

int PyCode_ClearWatcher(int watcher_id)

Clear watcher identified by *watcher_id* previously returned from **`PyCode_AddWatcher()`** for the current interpreter. Return `0` on success, or `-1` and set an exception on error (e.g. if the given *watcher_id* was never registered.)

Added in version 3.12.

type PyCodeEvent

Enumeration of possible code object watcher events: - `PY_CODE_EVENT_CREATE` - `PY_CODE_EVENT_DESTROY`

Added in version 3.12.

typedef int (*PyCode_WatchCallback)(PyCodeEvent event, PyCodeObject *co)

Type of a code object watcher callback function.

If *event* is `PY_CODE_EVENT_CREATE`, then the callback is invoked after *co* has been fully initialized. Otherwise, the callback is invoked before the destruction of *co* takes place, so the prior state of *co* can be inspected.

If *event* is `PY_CODE_EVENT_DESTROY`, taking a reference in the callback to the about-to-be-destroyed code object will resurrect it and prevent it from being freed at this time. When the resurrected object is destroyed later, any watcher callbacks active at that time will be called again.

Users of this API should not rely on internal runtime implementation details. Such details may include, but are not limited to, the exact order and timing of creation and destruction of code objects. While changes in these details may result in differences observable by watchers (including whether a callback is invoked or not), it does not change the semantics of the Python code being executed.

If the callback sets an exception, it must return `-1`; this exception will be printed as an unraisable exception using **`PyErr_WriteUnraisable()`**. Otherwise it should return `0`.

There may already be a pending exception set on entry to the callback. In this case, the callback should return `0` with the same exception still set. This means the callback may not call any other API that can set an exception unless it saves and clears the exception state first, and restores it before returning.

Added in version 3.12.

PyObject *PyCode_Optimize(PyObject *code, PyObject *consts, PyObject *names, PyObject *lnotab_obj)

This is a soft deprecated function that does nothing.

Prior to Python 3.10, this function would perform basic optimizations to a code object.

Changed in version 3.10: This function now does nothing.

Code Object Flags

Code objects contain a bit-field of flags, which can be retrieved as the `co_flags` Python attribute (for example using `PyObject_GetAttrString()`), and set using a *flags* argument to `PyUnstable_Code_New()` and similar functions.

Flags whose names start with `CO_FUTURE_` correspond to features normally selectable by future statements. These flags can be used in `PyCompilerFlags.cf_flags`. Note that many `CO_FUTURE_` flags are mandatory in current versions of Python, and setting them has no effect.

The following flags are available. For their meaning, see the linked documentation of their Python equivalents.

Flag	**Meaning**
CO_OPTIMIZED	`inspect.CO_OPTIMIZED`
CO_NEWLOCALS	`inspect.CO_NEWLOCALS`
CO_VARARGS	`inspect.CO_VARARGS`
CO_VARKEYWORDS	`inspect.CO_VARKEYWORDS`

Flag	Meaning
CO_NESTED	`inspect.CO_NESTED`
CO_GENERATOR	`inspect.CO_GENERATOR`
CO_COROUTINE	`inspect.CO_COROUTINE`
CO_ITERABLE_COROUTINE	`inspect.CO_ITERABLE_COROUTINE`
CO_ASYNC_GENERATOR	`inspect.CO_ASYNC_GENERATOR`
CO_HAS_DOCSTRING	`inspect.CO_HAS_DOCSTRING`
CO_METHOD	`inspect.CO_METHOD`
CO_FUTURE_DIVISION	no effect (`__future__.division`)
CO_FUTURE_ABSOLUTE_IMPORT	no effect (`__future__.absolute_import`)
CO_FUTURE_WITH_STATEMENT	no effect (`__future__.with_statement`)
CO_FUTURE_PRINT_FUNCTION	no effect (`__future__.print_function`)

Flag	Meaning
CO_FUTURE_UNICODE_LITERALS	no effect (`__future__.unicode_literals`)
CO_FUTURE_GENERATOR_STOP	no effect (`__future__.generator_stop`)
CO_FUTURE_ANNOTATIONS	`__future__.annotations`

Extra information

To support low-level extensions to frame evaluation, such as external just-in-time compilers, it is possible to attach arbitrary extra data to code objects.

These functions are part of the unstable C API tier: this functionality is a CPython implementation detail, and the API may change without deprecation warnings.

Py_ssize_t PyUnstable_Eval_RequestCodeExtraIndex(freefunc free)

> *This is Unstable API. It may change without warning in minor releases.*

> Return a new opaque index value used to adding data to code objects.
>
> You generally call this function once (per interpreter) and use the result with `PyCode_GetExtra` and `PyCode_SetExtra` to

manipulate data on individual code objects.

If *free* is not `NULL`: when a code object is deallocated, *free* will be called on non-`NULL` data stored under the new index. Use **`Py_DecRef()`** when storing **`PyObject`**.

Added in version 3.6: as `_PyEval_RequestCodeExtraIndex`

Changed in version 3.12: Renamed to `PyUnstable_Eval_RequestCodeExtraIndex`. The old private name is deprecated, but will be available until the API changes.

int PyUnstable_Code_GetExtra(PyObject *code, Py_ssize_t index, void **extra)

This is Unstable API. It may change without warning in minor releases.

Set *extra* to the extra data stored under the given index. Return 0 on success. Set an exception and return -1 on failure.

If no data was set under the index, set *extra* to `NULL` and return 0 without setting an exception.

Added in version 3.6: as `_PyCode_GetExtra`

Changed in version 3.12: Renamed to `PyUnstable_Code_GetExtra`. The old private name is deprecated, but will be available until the API changes.

int PyUnstable_Code_SetExtra(PyObject *code, Py_ssize_t index, void *extra)

This is Unstable API. It may change without warning in minor releases.

Set the extra data stored under the given index to *extra*. Return 0 on success. Set an exception and return -1 on failure.

Added in version 3.6: as `_PyCode_SetExtra`

Changed in version 3.12: Renamed to `PyUnstable_Code_SetExtra`. The old private name is deprecated, but will be available until the API changes.

File Objects

These APIs are a minimal emulation of the Python 2 C API for built-in file objects, which used to rely on the buffered I/O (FILE*) support from the C standard library. In Python 3, files and streams use the new `io` module, which defines several layers over the low-level unbuffered I/O of the operating system. The functions described below are convenience C wrappers over these new APIs, and meant mostly for internal error reporting in the interpreter; third-party code is advised to access the `io` APIs instead.

PyObject *PyFile_FromFd(int fd, const char *name, const char *mode, int buffering, const char *encoding, const char *errors, const char *newline, int closefd)

Return value: New reference. Part of the Stable ABI. Create a Python file object from the file descriptor of an already opened file *fd*. The arguments *name*, *encoding*, *errors* and *newline* can be `NULL` to use the defaults; *buffering* can be *-1* to use the default. *name* is ignored and kept for backward compatibility. Return `NULL` on failure. For a more comprehensive description of the arguments, please refer to the `io.open()` function documentation.

Warning

Since Python streams have their own buffering layer, mixing them with OS-level file descriptors can produce various issues (such as unexpected ordering of data).

Changed in version 3.2: Ignore *name* attribute.

int PyObject_AsFileDescriptor(PyObject *p)

Part of the Stable ABI.

Return the file descriptor associated with *p* as an int. If the object is an integer, its value is returned. If not, the object’s **`fileno()`** method is called if it exists; the method must return an integer, which is returned as the file descriptor value. Sets an exception and returns `-1` on failure.

PyObject *PyFile_GetLine(PyObject *p, int n)

Return value: New reference. Part of the Stable ABI.

Equivalent to `p.readline([n])`, this function reads one line from the object *p*. *p* may be a file object or any object with a **`readline()`** method. If *n* is `0`, exactly one line is read, regardless of the length of the line. If *n* is greater than `0`, no more than *n* bytes will be read from the file; a partial line can be returned. In both cases, an empty string is returned if the end of the file is reached immediately. If *n* is less than `0`, however, one line is read regardless of length, but **`EOFError`** is raised if the end of the file is reached immediately.

int PyFile_SetOpenCodeHook(Py_OpenCodeHookFunction handler)

Overrides the normal behavior of **`io.open_code()`** to pass its parameter through the provided handler.

The *handler* is a function of type:

typedef PyObject *(*Py_OpenCodeHookFunction)(PyObject*, void*)

Equivalent of PyObject *(*)(PyObject *path, void *userData), where *path* is guaranteed to be **`PyUnicodeObject`**.

The *userData* pointer is passed into the hook function. Since hook functions may be called from different runtimes, this pointer should not refer directly to Python state.

As this hook is intentionally used during import, avoid importing new modules during its execution unless they are known to be frozen or available in `sys.modules`.

Once a hook has been set, it cannot be removed or replaced, and later calls to **`PyFile_SetOpenCodeHook()`** will fail. On failure, the function returns -1 and sets an exception if the interpreter has been initialized.

This function is safe to call before **`Py_Initialize()`**.

Raises an auditing event `setopencodehook` with no arguments.

Added in version 3.8.

PyObject *PyFile_OpenCodeObject(PyObject *path)

Open *path* with the mode `'rb'`. *path* must be a Python **`str`** object. The behavior of this function may be overridden by **`PyFile_SetOpenCodeHook()`** to allow for some preprocessing of the text.

This is analogous to **`io.open_code()`** in Python.

On success, this function returns a strong reference to a Python file object. On failure, this function returns `NULL` with an exception set.

Added in version 3.8.

PyObject *PyFile_OpenCode(const char *path)

Similar to **`PyFile_OpenCodeObject()`**, but *path* is a UTF-8 encoded const char*.

Added in version 3.8.

int PyFile_WriteObject(PyObject *obj, PyObject *p, int flags)

Part of the Stable ABI.

Write object *obj* to file object *p*. The only supported flag for *flags* is **`Py_PRINT_RAW`**; if given, the **`str()`** of the object is written instead of the **`repr()`**. Return `0` on success or `-1` on failure; the appropriate exception will be set.

int PyFile_WriteString(const char *s, PyObject *p)

Part of the Stable ABI.

Write string *s* to file object *p*. Return `0` on success or `-1` on failure; the appropriate exception will be set.

Deprecated API

These are soft deprecated APIs that were included in Python's C API by mistake. They are documented solely for completeness; use other `PyFile*` APIs instead.

PyObject *PyFile_NewStdPrinter(int fd)

Use **`PyFile_FromFd()`** with defaults (`fd, NULL, "w", -1, NULL, NULL, NULL, 0`) instead.

PyTypeObject PyStdPrinter_Type

Type of file-like objects used internally at Python startup when **`io`** is not yet available. Use Python **`open()`** or **`PyFile_FromFd()`** to create file objects instead.

Module Objects

PyTypeObject PyModule_Type

Part of the Stable ABI.

This instance of `PyTypeObject` represents the Python module type. This is exposed to Python programs as `types.ModuleType`.

int PyModule_Check(PyObject *p)

Return true if *p* is a module object, or a subtype of a module object. This function always succeeds.

int PyModule_CheckExact(PyObject *p)

Return true if *p* is a module object, but not a subtype of `PyModule_Type`. This function always succeeds.

PyObject *PyModule_NewObject(PyObject *name)

Return value: New reference. Part of the Stable ABI since version 3.7.

Return a new module object with `module.__name__` set to *name*. The module's `__name__`, `__doc__`, `__package__` and `__loader__` attributes are filled in (all but `__name__` are set to `None`). The caller is responsible for setting a `__file__` attribute.

Return `NULL` with an exception set on error.

Added in version 3.3.

Changed in version 3.4: `__package__` and `__loader__` are now set to `None`.

PyObject *PyModule_New(const char *name)

Return value: New reference. Part of the Stable ABI.
Similar to `PyModule_NewObject()`, but the name is a UTF-8 encoded string instead of a Unicode object.

PyObject *PyModule_GetDict(PyObject *module)

Return value: Borrowed reference. Part of the Stable ABI.
Return the dictionary object that implements *module*'s namespace; this object is the same as the `__dict__` attribute of the module object. If *module* is not a module object (or a subtype of a module object), `SystemError` is raised and `NULL` is returned.

It is recommended extensions use other `PyModule_*` and `PyObject_*` functions rather than directly manipulate a module's `__dict__`.

The returned reference is borrowed from the module; it is valid until the module is destroyed.

PyObject *PyModule_GetNameObject(PyObject *module)

Return value: New reference. Part of the Stable ABI since version 3.7.
Return *module*'s `__name__` value. If the module does not provide one, or if it is not a string, `SystemError` is raised and `NULL` is returned.

Added in version 3.3.

const char *PyModule_GetName(PyObject *module)

Part of the Stable ABI.
Similar to `PyModule_GetNameObject()` but return the name encoded to `'utf-8'`.

The returned buffer is only valid until the module is renamed or destroyed. Note that Python code may rename a module by setting its `__name__` attribute.

void *PyModule_GetState(PyObject *module)

Part of the Stable ABI.
Return the “state” of the module, that is, a pointer to the block of memory allocated at module creation time, or `NULL`. See **`PyModuleDef.m_size`**.

PyModuleDef *PyModule_GetDef(PyObject *module)

Part of the Stable ABI.
Return a pointer to the **`PyModuleDef`** struct from which the module was created, or `NULL` if the module wasn’t created from a definition.

On error, return `NULL` with an exception set. Use **`PyErr_Occurred()`** to tell this case apart from a missing **`PyModuleDef`**.

PyObject *PyModule_GetFilenameObject(PyObject *module)

Return value: New reference. Part of the Stable ABI.
Return the name of the file from which *module* was loaded using *module*’s **`__file__`** attribute. If this is not defined, or if it is not a string, raise **`SystemError`** and return `NULL`; otherwise return a reference to a Unicode object.

Added in version 3.2.

const char *PyModule_GetFilename(PyObject *module)

Part of the Stable ABI.
Similar to **`PyModule_GetFilenameObject()`** but return the filename encoded to ‘utf-8’.

The returned buffer is only valid until the module’s **`__file__`** attribute is reassigned or the module is destroyed.

Deprecated since version 3.2: **`PyModule_GetFilename()`** raises **`UnicodeEncodeError`** on unencodable filenames, use

`PyModule_GetFilenameObject()` instead.

Module definitions

The functions in the previous section work on any module object, including modules imported from Python code.

Modules defined using the C API typically use a *module definition*, `PyModuleDef` – a statically allocated, constant “description” of how a module should be created.

The definition is usually used to define an extension’s “main” module object (see Defining extension modules for details). It is also used to create extension modules dynamically.

Unlike `PyModule_New()`, the definition allows management of *module state* – a piece of memory that is allocated and cleared together with the module object. Unlike the module’s Python attributes, Python code cannot replace or delete data stored in module state.

type PyModuleDef

Part of the Stable ABI (including all members).
The module definition struct, which holds all information needed to create a module object. This structure must be statically allocated (or be otherwise guaranteed to be valid while any modules created from it exist). Usually, there is only one variable of this type for each extension module.

PyModuleDef_Base m_base

Always initialize this member to **`PyModuleDef_HEAD_INIT`**.

const char *m_name

Name for the new module.

const char *m_doc

Docstring for the module; usually a docstring variable created with **`PyDoc_STRVAR`** is used.

Py_ssize_t m_size

Module state may be kept in a per-module memory area that can be retrieved with **`PyModule_GetState()`**, rather than in static globals. This makes modules safe for use in multiple sub-interpreters.

This memory area is allocated based on *m_size* on module creation, and freed when the module object is deallocated, after the **`m_free`** function has been called, if present.

Setting it to a non-negative value means that the module can be re-initialized and specifies the additional amount of memory it requires for its state.

Setting `m_size` to `-1` means that the module does not support sub-interpreters, because it has global state. Negative `m_size` is only allowed when using legacy single-phase initialization or when creating modules dynamically.

See **PEP 3121** [https://peps.python.org/pep-3121/] for more details.

PyMethodDef *m_methods

A pointer to a table of module-level functions, described by **`PyMethodDef`** values. Can be `NULL` if no functions are present.

PyModuleDef_Slot *m_slots

An array of slot definitions for multi-phase initialization, terminated by a `{0, NULL}` entry. When using legacy single-phase initialization, *m_slots* must be `NULL`.

Changed in version 3.5: Prior to version 3.5, this member was always set to `NULL`, and was defined as:

inquiry m_reload

traverseproc m_traverse

A traversal function to call during GC traversal of the module object, or `NULL` if not needed.

This function is not called if the module state was requested but is not allocated yet. This is the case immediately after the module is created and before the module is executed (**`Py_mod_exec`** function). More precisely, this function is not called if **`m_size`** is greater than 0 and the module state (as returned by **`PyModule_GetState()`**) is `NULL`.

Changed in version 3.9: No longer called before the module state is allocated.

inquiry m_clear

A clear function to call during GC clearing of the module object, or `NULL` if not needed.

This function is not called if the module state was requested but is not allocated yet. This is the case immediately after the module is created and before the module is executed (**`Py_mod_exec`** function). More precisely, this function is not called if **`m_size`** is greater than 0 and the module state (as returned by **`PyModule_GetState()`**) is `NULL`.

Like `PyTypeObject.tp_clear`, this function is not *always* called before a module is deallocated. For example, when reference counting is enough to determine that an object is no longer used, the cyclic garbage collector is not involved and `m_free` is called directly.

Changed in version 3.9: No longer called before the module state is allocated.

freefunc m_free

A function to call during deallocation of the module object, or `NULL` if not needed.

This function is not called if the module state was requested but is not allocated yet. This is the case immediately after the module is created and before the module is executed (`Py_mod_exec` function). More precisely, this function is not called if `m_size` is greater than 0 and the module state (as returned by `PyModule_GetState()`) is `NULL`.

Changed in version 3.9: No longer called before the module state is allocated.

Module slots

type PyModuleDef_Slot

Part of the Stable ABI (including all members) since version 3.5.

int slot

A slot ID, chosen from the available values explained below.

void *value

Value of the slot, whose meaning depends on the slot ID.

Added in version 3.5.

The available slot types are:

Py_mod_create

Part of the Stable ABI since version 3.5.

Specifies a function that is called to create the module object itself. The *value* pointer of this slot must point to a function of the signature:

PyObject *create_module(PyObject *spec, PyModuleDef *def)

The function receives a **`ModuleSpec`** instance, as defined in **PEP 451** [https://peps.python.org/pep-0451/], and the module definition. It should return a new module object, or set an error and return `NULL`.

This function should be kept minimal. In particular, it should not call arbitrary Python code, as trying to import the same module again may result in an infinite loop.

Multiple `Py_mod_create` slots may not be specified in one module definition.

If `Py_mod_create` is not specified, the import machinery will create a normal module object using **`PyModule_New()`**. The name is taken from *spec*, not the definition, to allow extension modules to dynamically adjust to their place in the module hierarchy and be imported under different names through symlinks, all while sharing a single module definition.

There is no requirement for the returned object to be an instance of **`PyModule_Type`**. Any type can be used, as long as it supports setting and getting import-related attributes. However, only `PyModule_Type` instances may be returned if the `PyModuleDef` has non-`NULL` `m_traverse`, `m_clear`, `m_free`; non-zero `m_size`; or slots other than `Py_mod_create`.

Added in version 3.5.

Py_mod_exec

Part of the Stable ABI since version 3.5.

Specifies a function that is called to *execute* the module. This is equivalent to executing the code of a Python module: typically, this function adds classes and constants to the module. The signature of the function is:

int exec_module(PyObject *module)

If multiple `Py_mod_exec` slots are specified, they are processed in the order they appear in the *m_slots* array.

Added in version 3.5.

Py_mod_multiple_interpreters

Part of the Stable ABI since version 3.12.

Specifies one of the following values:

Py_MOD_MULTIPLE_INTERPRETERS_NOT_SUPPORTED

The module does not support being imported in subinterpreters.

Py_MOD_MULTIPLE_INTERPRETERS_SUPPORTED

The module supports being imported in subinterpreters, but only when they share the main interpreter’s GIL. (See Isolating Extension Modules.)

Py_MOD_PER_INTERPRETER_GIL_SUPPORTED

The module supports being imported in subinterpreters, even when they have their own GIL. (See Isolating Extension Modules.)

This slot determines whether or not importing this module in a subinterpreter will fail.

Multiple `Py_mod_multiple_interpreters` slots may not be specified in one module definition.

If `Py_mod_multiple_interpreters` is not specified, the import machinery defaults to `Py_MOD_MULTIPLE_INTERPRETERS_SUPPORTED`.

Added in version 3.12.

Py_mod_gil

Part of the Stable ABI since version 3.13.
Specifies one of the following values:

Py_MOD_GIL_USED

The module depends on the presence of the global interpreter lock (GIL), and may access global state without synchronization.

Py_MOD_GIL_NOT_USED

The module is safe to run without an active GIL.

This slot is ignored by Python builds not configured with **`--disable-gil`**. Otherwise, it determines whether or not importing this module will cause the GIL to be automatically enabled. See Free-threaded CPython for more detail.

Multiple `Py_mod_gil` slots may not be specified in one module definition.

If `Py_mod_gil` is not specified, the import machinery defaults to `Py_MOD_GIL_USED`.

Added in version 3.13.

Creating extension modules dynamically

The following functions may be used to create a module outside of an extension's initialization function. They are also used in single-phase initialization.

PyObject *PyModule_Create(PyModuleDef *def)

Return value: New reference.
Create a new module object, given the definition in *def*. This is a macro that calls **`PyModule_Create2()`** with *module_api_version* set to **`PYTHON_API_VERSION`**, or to **`PYTHON_ABI_VERSION`** if using the limited API.

PyObject *PyModule_Create2(PyModuleDef *def, int module_api_version)

Return value: New reference. Part of the Stable ABI.
Create a new module object, given the definition in *def*, assuming the API version *module_api_version*. If that version does not match the version of the running interpreter, a **`RuntimeWarning`** is emitted.

Return `NULL` with an exception set on error.

This function does not support slots. The **`m_slots`** member of *def* must be `NULL`.

Note

Most uses of this function should be using **`PyModule_Create()`** instead; only use this if you are sure you need it.

PyObject *PyModule_FromDefAndSpec(PyModuleDef *def, PyObject *spec)

Return value: New reference.
This macro calls `PyModule_FromDefAndSpec2()` with *module_api_version* set to `PYTHON_API_VERSION`, or to `PYTHON_ABI_VERSION` if using the limited API.

Added in version 3.5.

PyObject *PyModule_FromDefAndSpec2(PyModuleDef *def, PyObject *spec, int module_api_version)

Return value: New reference. Part of the Stable ABI since version 3.7.
Create a new module object, given the definition in *def* and the ModuleSpec *spec*, assuming the API version *module_api_version*. If that version does not match the version of the running interpreter, a `RuntimeWarning` is emitted.

Return `NULL` with an exception set on error.

Note that this does not process execution slots (`Py_mod_exec`). Both `PyModule_FromDefAndSpec` and `PyModule_ExecDef` must be called to fully initialize a module.

Note

Most uses of this function should be using `PyModule_FromDefAndSpec()` instead; only use this if you are sure you need it.

Added in version 3.5.

int PyModule_ExecDef(PyObject *module, PyModuleDef *def)

Part of the Stable ABI since version 3.7.
Process any execution slots (`Py_mod_exec`) given in *def*.

Added in version 3.5.

PYTHON_API_VERSION

The C API version. Defined for backwards compatibility.

Currently, this constant is not updated in new Python versions, and is not useful for versioning. This may change in the future.

PYTHON_ABI_VERSION

Defined as `3` for backwards compatibility.

Currently, this constant is not updated in new Python versions, and is not useful for versioning. This may change in the future.

Support functions

The following functions are provided to help initialize a module state. They are intended for a module's execution slots (`Py_mod_exec`), the initialization function for legacy single-phase initialization, or code that creates modules dynamically.

int PyModule_AddObjectRef(PyObject *module, const char *name, PyObject *value)

Part of the Stable ABI since version 3.10.
Add an object to *module* as *name*. This is a convenience function which can be used from the module's initialization function.

On success, return `0`. On error, raise an exception and return `-1`.

Example usage:

```
static int
add_spam(PyObject *module, int value)
{
    PyObject *obj = PyLong_FromLong(value);
    if (obj == NULL) {
        return -1;
    }
    int res = PyModule_AddObjectRef(module, "spam", obj);
    Py_DECREF(obj);
    return res;
 }
```

To be convenient, the function accepts `NULL` *value* with an exception set. In this case, return `-1` and just leave the raised exception unchanged.

The example can also be written without checking explicitly if *obj* is `NULL`:

```
static int
add_spam(PyObject *module, int value)
{
    PyObject *obj = PyLong_FromLong(value);
    int res = PyModule_AddObjectRef(module, "spam", obj);
    Py_XDECREF(obj);
    return res;
 }
```

Note that `Py_XDECREF()` should be used instead of `Py_DECREF()` in this case, since *obj* can be `NULL`.

The number of different *name* strings passed to this function should be kept small, usually by only using statically allocated strings as *name*. For names that aren’t known at compile time, prefer calling

`PyUnicode_FromString()` and `PyObject_SetAttr()` directly. For more details, see `PyUnicode_InternFromString()`, which may be used internally to create a key object.

Added in version 3.10.

int PyModule_Add(PyObject *module, const char *name, PyObject *value)

Part of the Stable ABI since version 3.13.
Similar to `PyModule_AddObjectRef()`, but “steals” a reference to *value*. It can be called with a result of function that returns a new reference without bothering to check its result or even saving it to a variable.

Example usage:

```
if (PyModule_Add(module, "spam", PyBytes_FromString(value))
< 0) {
    goto error;
}
```

Added in version 3.13.

int PyModule_AddObject(PyObject *module, const char *name, PyObject *value)

Part of the Stable ABI.
Similar to `PyModule_AddObjectRef()`, but steals a reference to *value* on success (if it returns `0`).

The new `PyModule_Add()` or `PyModule_AddObjectRef()` functions are recommended, since it is easy to introduce reference leaks by misusing the `PyModule_AddObject()` function.

Note

Unlike other functions that steal references, `PyModule_AddObject()` only releases the reference to *value*

on success.

This means that its return value must be checked, and calling code must **`Py_XDECREF()`** *value* manually on error.

Example usage:

```
PyObject *obj = PyBytes_FromString(value);
if (PyModule_AddObject(module, "spam", obj) < 0) {
    // If 'obj' is not NULL and PyModule_AddObject() failed,
    // 'obj' strong reference must be deleted with
Py_XDECREF().
    // If 'obj' is NULL, Py_XDECREF() does nothing.
    Py_XDECREF(obj);
    goto error;
}
// PyModule_AddObject() stole a reference to obj:
// Py_XDECREF(obj) is not needed here.
```

Deprecated since version 3.13: **`PyModule_AddObject()`** is soft deprecated.

int PyModule_AddIntConstant(PyObject *module, const char *name, long value)

Part of the Stable ABI.
Add an integer constant to *module* as *name*. This convenience function can be used from the module’s initialization function. Return `-1` with an exception set on error, `0` on success.

This is a convenience function that calls **`PyLong_FromLong()`** and **`PyModule_AddObjectRef()`**; see their documentation for details.

int PyModule_AddStringConstant(PyObject *module, const char *name, const char *value)

Part of the Stable ABI.

Add a string constant to *module* as *name*. This convenience function can be used from the module's initialization function. The string *value* must be `NULL`-terminated. Return `-1` with an exception set on error, `0` on success.

This is a convenience function that calls **`PyUnicode_InternFromString()`** and **`PyModule_AddObjectRef()`**; see their documentation for details.

PyModule_AddIntMacro(module, macro)

Add an int constant to *module*. The name and the value are taken from *macro*. For example `PyModule_AddIntMacro(module, AF_INET)` adds the int constant *AF_INET* with the value of *AF_INET* to *module*. Return `-1` with an exception set on error, `0` on success.

PyModule_AddStringMacro(module, macro)

Add a string constant to *module*.

int PyModule_AddType(PyObject *module, PyTypeObject *type)

Part of the Stable ABI since version 3.10.
Add a type object to *module*. The type object is finalized by calling internally **`PyType_Ready()`**. The name of the type object is taken from the last component of **`tp_name`** after dot. Return `-1` with an exception set on error, `0` on success.

Added in version 3.9.

int PyModule_AddFunctions(PyObject *module, PyMethodDef *functions)

Part of the Stable ABI since version 3.7.

Add the functions from the `NULL` terminated *functions* array to *module*. Refer to the **`PyMethodDef`** documentation for details on individual entries (due to the lack of a shared module namespace, module level “functions” implemented in C typically receive the module as their first parameter, making them similar to instance methods on Python classes).

This function is called automatically when creating a module from `PyModuleDef` (such as when using Multi-phase initialization, `PyModule_Create`, or `PyModule_FromDefAndSpec`). Some module authors may prefer defining functions in multiple **`PyMethodDef`** arrays; in that case they should call this function directly.

The *functions* array must be statically allocated (or otherwise guaranteed to outlive the module object).

Added in version 3.5.

int PyModule_SetDocString(PyObject *module, const char *docstring)

Part of the Stable ABI since version 3.7.
Set the docstring for *module* to *docstring*. This function is called automatically when creating a module from `PyModuleDef` (such as when using Multi-phase initialization, `PyModule_Create`, or `PyModule_FromDefAndSpec`).

Added in version 3.5.

int PyUnstable_Module_SetGIL(PyObject *module, void *gil)

This is Unstable API. It may change without warning in minor releases.

Indicate that *module* does or does not support running without the global interpreter lock (GIL), using one of the values from **`Py_mod_gil`**. It must be called during *module*’s initialization function when using Legacy single-phase initialization. If this function is not called during module initialization, the import machinery assumes the module does not support running without the GIL. This function is only available in Python builds configured with **`--disable-gil`**. Return `-1` with an exception set on error, `0` on success.

Added in version 3.13.

Module lookup (single-phase initialization)

The legacy single-phase initialization initialization scheme creates singleton modules that can be looked up in the context of the current interpreter. This allows the module object to be retrieved later with only a reference to the module definition.

These functions will not work on modules created using multi-phase initialization, since multiple such modules can be created from a single definition.

PyObject *PyState_FindModule(PyModuleDef *def)

Return value: Borrowed reference. Part of the Stable ABI. Returns the module object that was created from *def* for the current interpreter. This method requires that the module object has been attached to the interpreter state with **`PyState_AddModule()`** beforehand. In case the corresponding module object is not found or has not been attached to the interpreter state yet, it returns `NULL`.

int PyState_AddModule(PyObject *module, PyModuleDef *def)

Part of the Stable ABI since version 3.3.
Attaches the module object passed to the function to the interpreter state. This allows the module object to be accessible via **`PyState_FindModule()`**.

Only effective on modules created using single-phase initialization.

Python calls `PyState_AddModule` automatically after importing a module that uses single-phase initialization, so it is unnecessary (but harmless) to call it from module initialization code. An explicit call is needed only if the module's own init code subsequently calls `PyState_FindModule`. The function is mainly intended for implementing alternative import mechanisms (either by calling it directly, or by referring to its implementation for details of the required state updates).

If a module was attached previously using the same *def*, it is replaced by the new *module*.

The caller must have an attached thread state.

Return `-1` with an exception set on error, `0` on success.

Added in version 3.3.

int PyState_RemoveModule(PyModuleDef *def)

Part of the Stable ABI since version 3.3.
Removes the module object created from *def* from the interpreter state. Return `-1` with an exception set on error, `0` on success.

The caller must have an attached thread state.

Added in version 3.3.

Iterator Objects

Python provides two general-purpose iterator objects. The first, a sequence iterator, works with an arbitrary sequence supporting the **`__getitem__()`** method. The second works with a callable object and a sentinel value, calling the callable for each item in the sequence, and ending the iteration when the sentinel value is returned.

PyTypeObject PySeqIter_Type

Part of the Stable ABI.
Type object for iterator objects returned by **`PySeqIter_New()`** and the one-argument form of the **`iter()`** built-in function for built-in sequence types.

int PySeqIter_Check(PyObject *op)

Return true if the type of *op* is **`PySeqIter_Type`**. This function always succeeds.

PyObject *PySeqIter_New(PyObject *seq)

Return value: New reference. Part of the Stable ABI.
Return an iterator that works with a general sequence object, *seq*. The iteration ends when the sequence raises **`IndexError`** for the subscripting operation.

PyTypeObject PyCallIter_Type

Part of the Stable ABI.
Type object for iterator objects returned by **`PyCallIter_New()`** and the two-argument form of the **`iter()`** built-in function.

int PyCallIter_Check(PyObject *op)

Return true if the type of *op* is `PyCallIter_Type`. This function always succeeds.

PyObject *PyCallIter_New(PyObject *callable, PyObject *sentinel)

Return value: New reference. Part of the Stable ABI.
Return a new iterator. The first parameter, *callable*, can be any Python callable object that can be called with no parameters; each call to it should return the next item in the iteration. When *callable* returns a value equal to *sentinel*, the iteration will be terminated.

Range Objects

PyTypeObject PyRange_Type

Part of the Stable ABI.
The type object for `range` objects.

int PyRange_Check(PyObject *o)

Return true if the object *o* is an instance of a `range` object. This function always succeeds.

Builtin Iterator Types

These are built-in iteration types that are included in Python’s C API, but provide no additional functions. They are here for completeness.

C type	**Python type**
PyTypeObject PyEnum_Type *Part of the Stable ABI.*	`enumerate`

C type	Python type
PyTypeObject PyFilter_Type *Part of the Stable ABI.*	`filter`
PyTypeObject PyMap_Type *Part of the Stable ABI.*	`map`
PyTypeObject PyReversed_Type *Part of the Stable ABI.*	`reversed`
PyTypeObject PyZip_Type *Part of the Stable ABI.*	`zip`

Other Iterator Objects

PyTypeObject PyByteArrayIter_Type
Part of the Stable ABI.

PyTypeObject PyBytesIter_Type
Part of the Stable ABI.

PyTypeObject PyListIter_Type
Part of the Stable ABI.

PyTypeObject PyListRevIter_Type
Part of the Stable ABI.

PyTypeObject PySetIter_Type
Part of the Stable ABI.

PyTypeObject PyTupleIter_Type

Part of the Stable ABI.

PyTypeObject PyRangeIter_Type

Part of the Stable ABI.

PyTypeObject PyLongRangeIter_Type

Part of the Stable ABI.

PyTypeObject PyDictIterKey_Type

Part of the Stable ABI.

PyTypeObject PyDictRevIterKey_Type

Part of the Stable ABI since version 3.8.

PyTypeObject PyDictIterValue_Type

Part of the Stable ABI.

PyTypeObject PyDictRevIterValue_Type

Part of the Stable ABI since version 3.8.

PyTypeObject PyDictIterItem_Type

Part of the Stable ABI.

PyTypeObject PyDictRevIterItem_Type

Part of the Stable ABI since version 3.8.

PyTypeObject PyODictIter_Type

Type objects for iterators of various built-in objects.

Do not create instances of these directly; prefer calling `PyObject_GetIter()` instead.

Note that there is no guarantee that a given built-in type uses a given iterator type. For example, iterating over `range` will use one of two iterator types depending on the size of the range. Other types may start using a similar scheme in the future, without warning.

Descriptor Objects

“Descriptors” are objects that describe some attribute of an object. They are found in the dictionary of type objects.

PyTypeObject PyProperty_Type

Part of the Stable ABI.

The type object for the built-in descriptor types.

PyObject *PyDescr_NewGetSet(PyTypeObject *type, struct PyGetSetDef *getset)

Return value: New reference. Part of the Stable ABI.

PyObject *PyDescr_NewMember(PyTypeObject *type, struct PyMemberDef *meth)

Return value: New reference. Part of the Stable ABI.

PyTypeObject PyMemberDescr_Type

Part of the Stable ABI.

The type object for member descriptor objects created from `PyMemberDef` structures. These descriptors expose fields of a C struct as attributes on a type, and correspond to `types.MemberDescriptorType` objects in Python.

PyTypeObject PyGetSetDescr_Type

Part of the Stable ABI.

The type object for get/set descriptor objects created from `PyGetSetDef` structures. These descriptors implement attributes whose value is computed by C getter and setter functions, and are used for many built-in type attributes.

PyObject *PyDescr_NewMethod(PyTypeObject *type, struct PyMethodDef *meth)

Return value: New reference. Part of the Stable ABI.

PyTypeObject PyMethodDescr_Type

Part of the Stable ABI.

The type object for method descriptor objects created from **`PyMethodDef`** structures. These descriptors expose C functions as methods on a type, and correspond to **`types.MemberDescriptorType`** objects in Python.

PyObject *PyDescr_NewWrapper(PyTypeObject *type, struct wrapperbase *wrapper, void *wrapped)

Return value: New reference.

PyTypeObject PyWrapperDescr_Type

Part of the Stable ABI.

The type object for wrapper descriptor objects created by **`PyDescr_NewWrapper()`** and **`PyWrapper_New()`**. Wrapper descriptors are used internally to expose special methods implemented via wrapper structures, and appear in Python as **`types.WrapperDescriptorType`** objects.

PyObject *PyDescr_NewClassMethod(PyTypeObject *type, PyMethodDef *method)

Return value: New reference. Part of the Stable ABI.

int PyDescr_IsData(PyObject *descr)

Return non-zero if the descriptor object *descr* describes a data attribute, or `0` if it describes a method. *descr* must be a descriptor object; there is no error checking.

PyObject *PyWrapper_New(PyObject*, PyObject*)

Return value: New reference. Part of the Stable ABI.

Built-in descriptors

PyTypeObject PySuper_Type

Part of the Stable ABI.

The type object for super objects. This is the same object as **`super`** in the Python layer.

PyTypeObject PyClassMethod_Type

The type of class method objects. This is the same object as **`classmethod`** in the Python layer.

PyTypeObject PyClassMethodDescr_Type

Part of the Stable ABI.

The type object for C-level class method descriptor objects. This is the type of the descriptors created for **`classmethod()`** defined in C extension types, and is the same object as **`classmethod`** in Python.

PyObject *PyClassMethod_New(PyObject *callable)

Create a new **`classmethod`** object wrapping *callable*. *callable* must be a callable object and must not be `NULL`.

On success, this function returns a strong reference to a new class method descriptor. On failure, this function returns `NULL` with an exception set.

PyTypeObject PyStaticMethod_Type

The type of static method objects. This is the same object as **`staticmethod`** in the Python layer.

PyObject *PyStaticMethod_New(PyObject *callable)

Create a new **`staticmethod`** object wrapping *callable*. *callable* must be a callable object and must not be `NULL`.

On success, this function returns a strong reference to a new static method descriptor. On failure, this function returns `NULL` with an exception set.

Slice Objects

PyTypeObject PySlice_Type

Part of the Stable ABI.

The type object for slice objects. This is the same as `slice` in the Python layer.

int PySlice_Check(PyObject *ob)

Return true if *ob* is a slice object; *ob* must not be `NULL`. This function always succeeds.

PyObject *PySlice_New(PyObject *start, PyObject *stop, PyObject *step)

Return value: New reference. Part of the Stable ABI.

Return a new slice object with the given values. The *start*, *stop*, and *step* parameters are used as the values of the slice object attributes of the same names. Any of the values may be `NULL`, in which case the `None` will be used for the corresponding attribute.

Return `NULL` with an exception set if the new object could not be allocated.

int PySlice_GetIndices(PyObject *slice, Py_ssize_t length, Py_ssize_t *start, Py_ssize_t *stop, Py_ssize_t *step)

Part of the Stable ABI.

Retrieve the start, stop and step indices from the slice object *slice*, assuming a sequence of length *length*. Treats indices greater than *length* as errors.

Returns `0` on success and `-1` on error with no exception set (unless one of the indices was not `None` and failed to be converted to an integer, in which case `-1` is returned with an exception set).

You probably do not want to use this function.

Changed in version 3.2: The parameter type for the *slice* parameter was `PySliceObject*` before.

int PySlice_GetIndicesEx(PyObject *slice, Py_ssize_t length, Py_ssize_t *start, Py_ssize_t *stop, Py_ssize_t *step, Py_ssize_t *slicelength)

Part of the Stable ABI.

Usable replacement for **`PySlice_GetIndices()`**. Retrieve the start, stop, and step indices from the slice object *slice* assuming a sequence of length *length*, and store the length of the slice in *slicelength*. Out of bounds indices are clipped in a manner consistent with the handling of normal slices.

Return `0` on success and `-1` on error with an exception set.

Note

This function is considered not safe for resizable sequences. Its invocation should be replaced by a combination of **`PySlice_Unpack()`** and **`PySlice_AdjustIndices()`** where

```
if (PySlice_GetIndicesEx(slice, length, &start, &stop,
&step, &slicelength) < 0) {
    // return error
}
```

is replaced by

```
if (PySlice_Unpack(slice, &start, &stop, &step) < 0) {
    // return error
}
slicelength = PySlice_AdjustIndices(length, &start, &stop,
step);
```

Changed in version 3.2: The parameter type for the *slice* parameter was `PySliceObject*` before.

Changed in version 3.6.1: If `Py_LIMITED_API` is not set or set to the value between `0x03050400` and `0x03060000` (not including) or `0x03060100` or higher **`PySlice_GetIndicesEx()`** is implemented as a macro using **`PySlice_Unpack()`** and **`PySlice_AdjustIndices()`**. Arguments *start*, *stop* and *step* are evaluated more than once.

Deprecated since version 3.6.1: If `Py_LIMITED_API` is set to the value less than `0x03050400` or between `0x03060000` and `0x03060100` (not including) **`PySlice_GetIndicesEx()`** is a deprecated function.

int PySlice_Unpack(PyObject *slice, Py_ssize_t *start, Py_ssize_t *stop, Py_ssize_t *step)

Part of the Stable ABI since version 3.7.
Extract the start, stop and step data members from a slice object as C integers. Silently reduce values larger than `PY_SSIZE_T_MAX` to `PY_SSIZE_T_MAX`, silently boost the start and stop values less than `PY_SSIZE_T_MIN` to `PY_SSIZE_T_MIN`, and silently boost the step values less than `-PY_SSIZE_T_MAX` to `-PY_SSIZE_T_MAX`.

Return `-1` with an exception set on error, `0` on success.

Added in version 3.6.1.

Py_ssize_t PySlice_AdjustIndices(Py_ssize_t length, Py_ssize_t *start, Py_ssize_t *stop, Py_ssize_t step)

Part of the Stable ABI since version 3.7.

Adjust start/end slice indices assuming a sequence of the specified length. Out of bounds indices are clipped in a manner consistent with the handling of normal slices.

Return the length of the slice. Always successful. Doesn't call Python code.

Added in version 3.6.1.

Ellipsis Object

PyTypeObject PyEllipsis_Type

Part of the Stable ABI.
The type of Python **`Ellipsis`** object. Same as **`types.EllipsisType`** in the Python layer.

PyObject *Py_Ellipsis

The Python `Ellipsis` object. This object has no methods. Like **`Py_None`**, it is an immortal singleton object.

Changed in version 3.12: **`Py_Ellipsis`** is immortal.

MemoryView objects

A `memoryview` object exposes the C level buffer interface as a Python object which can then be passed around like any other object.

PyTypeObject PyMemoryView_Type

Part of the Stable ABI.
This instance of `PyTypeObject` represents the Python memoryview type. This is the same object as `memoryview` in the Python layer.

PyObject *PyMemoryView_FromObject(PyObject *obj)

Return value: New reference. Part of the Stable ABI.
Create a memoryview object from an object that provides the buffer interface. If *obj* supports writable buffer exports, the memoryview object will be read/write, otherwise it may be either read-only or read/write at the discretion of the exporter.

PyBUF_READ

Part of the Stable ABI since version 3.11.
Flag to request a readonly buffer.

PyBUF_WRITE

Part of the Stable ABI since version 3.11.
Flag to request a writable buffer.

PyObject *PyMemoryView_FromMemory(char *mem, Py_ssize_t size, int flags)

Return value: New reference. Part of the Stable ABI since version 3.7.

Create a memoryview object using *mem* as the underlying buffer. *flags* can be one of **`PyBUF_READ`** or **`PyBUF_WRITE`**.

Added in version 3.3.

PyObject *PyMemoryView_FromBuffer(const Py_buffer *view)

Return value: New reference. Part of the Stable ABI since version 3.11.
Create a memoryview object wrapping the given buffer structure *view*. For simple byte buffers, **`PyMemoryView_FromMemory()`** is the preferred function.

PyObject *PyMemoryView_GetContiguous(PyObject *obj, int buffertype, char order)

Return value: New reference. Part of the Stable ABI.
Create a memoryview object to a contiguous chunk of memory (in either 'C' or 'F'ortran *order*) from an object that defines the buffer interface. If memory is contiguous, the memoryview object points to the original memory. Otherwise, a copy is made and the memoryview points to a new bytes object.

buffertype can be one of **`PyBUF_READ`** or **`PyBUF_WRITE`**.

int PyMemoryView_Check(PyObject *obj)

Return true if the object *obj* is a memoryview object. It is not currently allowed to create subclasses of **`memoryview`**. This function always succeeds.

Py_buffer *PyMemoryView_GET_BUFFER(PyObject *mview)

Return a pointer to the memoryview's private copy of the exporter's buffer. *mview* **must** be a memoryview instance; this macro doesn’t check its type, you must do it yourself or you will risk crashes.

PyObject *PyMemoryView_GET_BASE(PyObject *mview)

Return either a pointer to the exporting object that the memoryview is based on or `NULL` if the memoryview has been created by one of the functions `PyMemoryView_FromMemory()` or `PyMemoryView_FromBuffer()`. *mview* **must** be a memoryview instance.

Pickle buffer objects

Added in version 3.8.

A **`pickle.PickleBuffer`** object wraps a buffer-providing object for out-of-band data transfer with the **`pickle`** module.

PyTypeObject PyPickleBuffer_Type

This instance of **`PyTypeObject`** represents the Python pickle buffer type. This is the same object as **`pickle.PickleBuffer`** in the Python layer.

int PyPickleBuffer_Check(PyObject *op)

Return true if *op* is a pickle buffer instance. This function always succeeds.

PyObject *PyPickleBuffer_FromObject(PyObject *obj)

Create a pickle buffer from the object *obj*.

This function will fail if *obj* doesn’t support the buffer protocol.

On success, return a new pickle buffer instance. On failure, set an exception and return `NULL`.

Analogous to calling **`pickle.PickleBuffer`** with *obj* in Python.

const Py_buffer *PyPickleBuffer_GetBuffer(PyObject *picklebuf)

Get a pointer to the underlying **`Py_buffer`** that the pickle buffer wraps.

The returned pointer is valid as long as *picklebuf* is alive and has not been released. The caller must not modify or free the returned **`Py_buffer`**. If the pickle buffer has been released, raise **`ValueError`**.

On success, return a pointer to the buffer view. On failure, set an exception and return `NULL`.

int PyPickleBuffer_Release(PyObject *picklebuf)

Release the underlying buffer held by the pickle buffer.

Return `0` on success. On failure, set an exception and return `-1`.

Analogous to calling **`pickle.PickleBuffer.release()`** in Python.

Weak Reference Objects

Python supports *weak references* as first-class objects. There are two specific object types which directly implement weak references. The first is a simple reference object, and the second acts as a proxy for the original object as much as it can.

int PyWeakref_Check(PyObject *ob)

Return non-zero if *ob* is either a reference or proxy object. This function always succeeds.

int PyWeakref_CheckRef(PyObject *ob)

Return non-zero if *ob* is a reference object or a subclass of the reference type. This function always succeeds.

int PyWeakref_CheckRefExact(PyObject *ob)

Return non-zero if *ob* is a reference object, but not a subclass of the reference type. This function always succeeds.

int PyWeakref_CheckProxy(PyObject *ob)

Return non-zero if *ob* is a proxy object. This function always succeeds.

PyObject *PyWeakref_NewRef(PyObject *ob, PyObject *callback)

Return value: New reference. Part of the Stable ABI. Return a weak reference object for the object *ob*. This will always return a new reference, but is not guaranteed to create a new object; an existing reference object may be returned. The second parameter, *callback*, can be a callable object that receives notification when *ob* is garbage collected; it should accept a single parameter, which will be the weak reference object itself. *callback* may also be `None` or `NULL`. If *ob* is not a weakly referenceable object, or if *callback* is not callable, `None`, or `NULL`, this will return `NULL` and raise **`TypeError`**.

See also

`PyType_SUPPORTS_WEAKREFS()` for checking if *ob* is weakly referenceable.

PyObject *PyWeakref_NewProxy(PyObject *ob, PyObject *callback)

Return value: New reference. Part of the Stable ABI.
Return a weak reference proxy object for the object *ob*. This will always return a new reference, but is not guaranteed to create a new object; an existing proxy object may be returned. The second parameter, *callback*, can be a callable object that receives notification when *ob* is garbage collected; it should accept a single parameter, which will be the weak reference object itself. *callback* may also be `None` or `NULL`. If *ob* is not a weakly referenceable object, or if *callback* is not callable, `None`, or `NULL`, this will return `NULL` and raise **`TypeError`**.

See also

`PyType_SUPPORTS_WEAKREFS()` for checking if *ob* is weakly referenceable.

int PyWeakref_GetRef(PyObject *ref, PyObject **pobj)

Part of the Stable ABI since version 3.13.
Get a strong reference to the referenced object from a weak reference, *ref*, into **pobj*.

- On success, set **pobj* to a new strong reference to the referenced object and return 1.
- If the reference is dead, set **pobj* to `NULL` and return 0.
- On error, raise an exception and return -1.

Added in version 3.13.

PyObject *PyWeakref_GetObject(PyObject *ref)

Return value: Borrowed reference. Part of the Stable ABI.
Return a borrowed reference to the referenced object from a weak reference, *ref*. If the referent is no longer live, returns `Py_None`.

Note

This function returns a borrowed reference to the referenced object. This means that you should always call **`Py_INCREF()`** on the object except when it cannot be destroyed before the last usage of the borrowed reference.

Deprecated since version 3.13, will be removed in version 3.15: Use **`PyWeakref_GetRef()`** instead.

PyObject *PyWeakref_GET_OBJECT(PyObject *ref)

Return value: Borrowed reference.
Similar to **`PyWeakref_GetObject()`**, but does no error checking.

Deprecated since version 3.13, will be removed in version 3.15: Use **`PyWeakref_GetRef()`** instead.

int PyWeakref_IsDead(PyObject *ref)

Test if the weak reference *ref* is dead. Returns 1 if the reference is dead, 0 if it is alive, and -1 with an error set if *ref* is not a weak reference object.

Added in version 3.14.

void PyObject_ClearWeakRefs(PyObject *object)

Part of the Stable ABI.

This function is called by the **`tp_dealloc`** handler to clear weak references.

This iterates through the weak references for *object* and calls callbacks for those references which have one. It returns when all callbacks have been attempted.

void PyUnstable_Object_ClearWeakRefsNoCallbacks(PyObject *object)

> *This is Unstable API. It may change without warning in minor releases.*

Clears the weakrefs for *object* without calling the callbacks.

This function is called by the **`tp_dealloc`** handler for types with finalizers (i.e., **`__del__()`**). The handler for those objects first calls **`PyObject_ClearWeakRefs()`** to clear weakrefs and call their callbacks, then the finalizer, and finally this function to clear any weakrefs that may have been created by the finalizer.

In most circumstances, it’s more appropriate to use **`PyObject_ClearWeakRefs()`** to clear weakrefs instead of this function.

Added in version 3.13.

Capsules

Refer to Providing a C API for an Extension Module for more information on using these objects.

Added in version 3.1.

type PyCapsule

This subtype of **`PyObject`** represents an opaque value, useful for C extension modules which need to pass an opaque value (as a void* pointer) through Python code to other C code. It is often used to make a C function pointer defined in one module available to other modules, so the regular import mechanism can be used to access C APIs defined in dynamically loaded modules.

PyTypeObject PyCapsule_Type

Part of the Stable ABI.
The type object corresponding to capsule objects. This is the same object as **`types.CapsuleType`** in the Python layer.

type PyCapsule_Destructor

Part of the Stable ABI.
The type of a destructor callback for a capsule. Defined as:

```
typedef void (*PyCapsule_Destructor)(PyObject *);
```

See **`PyCapsule_New()`** for the semantics of PyCapsule_Destructor callbacks.

int PyCapsule_CheckExact(PyObject *p)

Return true if its argument is a **`PyCapsule`**. This function always succeeds.

PyObject *PyCapsule_New(void *pointer, const char *name, PyCapsule_Destructor destructor)

Return value: New reference. Part of the Stable ABI.
Create a **`PyCapsule`** encapsulating the *pointer*. The *pointer* argument may not be `NULL`.

On failure, set an exception and return `NULL`.

The *name* string may either be `NULL` or a pointer to a valid C string. If non-`NULL`, this string must outlive the capsule. (Though it is permitted to free it inside the *destructor*.)

If the *destructor* argument is not `NULL`, it will be called with the capsule as its argument when it is destroyed.

If this capsule will be stored as an attribute of a module, the *name* should be specified as `modulename.attributename`. This will enable other modules to import the capsule using **`PyCapsule_Import()`**.

void *PyCapsule_GetPointer(PyObject *capsule, const char *name)

Part of the Stable ABI.
Retrieve the *pointer* stored in the capsule. On failure, set an exception and return `NULL`.

The *name* parameter must compare exactly to the name stored in the capsule. If the name stored in the capsule is `NULL`, the *name* passed in must also be `NULL`. Python uses the C function **`strcmp()`** to compare capsule names.

PyCapsule_Destructor PyCapsule_GetDestructor(PyObject *capsule)

Part of the Stable ABI.
Return the current destructor stored in the capsule. On failure, set an exception and return `NULL`.

It is legal for a capsule to have a `NULL` destructor. This makes a `NULL` return code somewhat ambiguous; use **`PyCapsule_IsValid()`** or **`PyErr_Occurred()`** to disambiguate.

void *PyCapsule_GetContext(PyObject *capsule)

Part of the Stable ABI.
Return the current context stored in the capsule. On failure, set an exception and return `NULL`.

It is legal for a capsule to have a `NULL` context. This makes a `NULL` return code somewhat ambiguous; use **`PyCapsule_IsValid()`** or **`PyErr_Occurred()`** to disambiguate.

const char *PyCapsule_GetName(PyObject *capsule)

Part of the Stable ABI.
Return the current name stored in the capsule. On failure, set an exception and return `NULL`.

It is legal for a capsule to have a `NULL` name. This makes a `NULL` return code somewhat ambiguous; use **`PyCapsule_IsValid()`** or **`PyErr_Occurred()`** to disambiguate.

void *PyCapsule_Import(const char *name, int no_block)

Part of the Stable ABI.
Import a pointer to a C object from a capsule attribute in a module. The *name* parameter should specify the full name to the attribute, as in `module.attribute`. The *name* stored in the capsule must match this string exactly.

This function splits *name* on the `.` character, and imports the first element. It then processes further elements using attribute lookups.

Return the capsule's internal *pointer* on success. On failure, set an exception and return `NULL`.

Note

If *name* points to an attribute of some submodule or subpackage, this submodule or subpackage must be previously imported using other means (for example, by using **`PyImport_ImportModule()`**) for the attribute lookups to succeed.

Changed in version 3.3: no_block has no effect anymore.

int PyCapsule_IsValid(PyObject *capsule, const char *name)

Part of the Stable ABI.

Determines whether or not *capsule* is a valid capsule. A valid capsule is non-`NULL`, passes **`PyCapsule_CheckExact()`**, has a non-`NULL` pointer stored in it, and its internal name matches the *name* parameter. (See **`PyCapsule_GetPointer()`** for information on how capsule names are compared.)

In other words, if **`PyCapsule_IsValid()`** returns a true value, calls to any of the accessors (any function starting with `PyCapsule_Get`) are guaranteed to succeed.

Return a nonzero value if the object is valid and matches the name passed in. Return `0` otherwise. This function will not fail.

int PyCapsule_SetContext(PyObject *capsule, void *context)

Part of the Stable ABI.

Set the context pointer inside *capsule* to *context*.

Return `0` on success. Return nonzero and set an exception on failure.

int PyCapsule_SetDestructor(PyObject *capsule, PyCapsule_Destructor destructor)

Part of the Stable ABI.

Set the destructor inside *capsule* to *destructor*.

Return `0` on success. Return nonzero and set an exception on failure.

int PyCapsule_SetName(PyObject *capsule, const char *name)

Part of the Stable ABI.

Set the name inside *capsule* to *name*. If non-`NULL`, the name must outlive the capsule. If the previous *name* stored in the capsule was not `NULL`, no attempt is made to free it.

Return `0` on success. Return nonzero and set an exception on failure.

int PyCapsule_SetPointer(PyObject *capsule, void *pointer)

Part of the Stable ABI.

Set the void pointer inside *capsule* to *pointer*. The pointer may not be `NULL`.

Return `0` on success. Return nonzero and set an exception on failure.

Frame Objects

type PyFrameObject

Part of the Limited API (as an opaque struct).
The C structure of the objects used to describe frame objects.

There are no public members in this structure.

Changed in version 3.11: The members of this structure were removed from the public C API. Refer to the What’s New entry for details.

The **`PyEval_GetFrame()`** and **`PyThreadState_GetFrame()`** functions can be used to get a frame object.

See also Reflection.

PyTypeObject PyFrame_Type

The type of frame objects. It is the same object as **`types.FrameType`** in the Python layer.

Changed in version 3.11: Previously, this type was only available after including `<frameobject.h>`.

PyFrameObject *PyFrame_New(PyThreadState *tstate, PyCodeObject *code, PyObject *globals, PyObject *locals)

Create a new frame object. This function returns a strong reference to the new frame object on success, and returns `NULL` with an exception set on failure.

int PyFrame_Check(PyObject *obj)

Return non-zero if *obj* is a frame object.

Changed in version 3.11: Previously, this function was only available after including `<frameobject.h>`.

PyFrameObject *PyFrame_GetBack(PyFrameObject *frame)

Return value: New reference.
Get the *frame* next outer frame.

Return a strong reference, or `NULL` if *frame* has no outer frame.

Added in version 3.9.

PyObject *PyFrame_GetBuiltins(PyFrameObject *frame)

Return value: New reference.
Get the *frame*’s **`f_builtins`** attribute.

Return a strong reference. The result cannot be `NULL`.

Added in version 3.11.

PyCodeObject *PyFrame_GetCode(PyFrameObject *frame)

Return value: New reference. Part of the Stable ABI since version 3.10.
Get the *frame* code.

Return a strong reference.

The result (frame code) cannot be `NULL`.

Added in version 3.9.

PyObject *PyFrame_GetGenerator(PyFrameObject *frame)

Return value: New reference.
Get the generator, coroutine, or async generator that owns this frame, or `NULL` if this frame is not owned by a

generator. Does not raise an exception, even if the return value is `NULL`.

Return a strong reference, or `NULL`.

Added in version 3.11.

PyObject *PyFrame_GetGlobals(PyFrameObject *frame)

Return value: New reference.
Get the *frame*’s **`f_globals`** attribute.

Return a strong reference. The result cannot be `NULL`.

Added in version 3.11.

int PyFrame_GetLasti(PyFrameObject *frame)

Get the *frame*’s **`f_lasti`** attribute.

Returns -1 if `frame.f_lasti` is `None`.

Added in version 3.11.

PyObject *PyFrame_GetVar(PyFrameObject *frame, PyObject *name)

Return value: New reference.
Get the variable *name* of *frame*.

- Return a strong reference to the variable value on success.
- Raise **`NameError`** and return `NULL` if the variable does not exist.
- Raise an exception and return `NULL` on error.

name type must be a **`str`**.

Added in version 3.12.

PyObject *PyFrame_GetVarString(PyFrameObject *frame, const char *name)

Return value: New reference.
Similar to **`PyFrame_GetVar()`**, but the variable name is a C string encoded in UTF-8.

Added in version 3.12.

PyObject *PyFrame_GetLocals(PyFrameObject *frame)

Return value: New reference.
Get the *frame*’s **`f_locals`** attribute. If the frame refers to an optimized scope, this returns a write-through proxy object that allows modifying the locals. In all other cases (classes, modules, **`exec()`**, **`eval()`**) it returns the mapping representing the frame locals directly (as described for **`locals()`**).

Return a strong reference.

Added in version 3.11.

Changed in version 3.13: As part of **PEP 667** [https://peps.python.org/pep-0667/], return an instance of **`PyFrameLocalsProxy_Type`**.

int PyFrame_GetLineNumber(PyFrameObject *frame)

Part of the Stable ABI since version 3.10.
Return the line number that *frame* is currently executing.

Frame Locals Proxies

Added in version 3.13.

The **`f_locals`** attribute on a frame object is an instance of a “frame-locals proxy”. The proxy object exposes a write-through view of the underlying locals dictionary for the frame. This ensures that the variables exposed by `f_locals` are always up to date with the live local variables in the frame itself.

See **PEP 667** [https://peps.python.org/pep-0667/] for more information.

PyTypeObject PyFrameLocalsProxy_Type

The type of frame **`locals()`** proxy objects.

int PyFrameLocalsProxy_Check(PyObject *obj)

Return non-zero if *obj* is a frame **`locals()`** proxy.

Legacy Local Variable APIs

These APIs are soft deprecated. As of Python 3.13, they do nothing. They exist solely for backwards compatibility.

void PyFrame_LocalsToFast(PyFrameObject *f, int clear)

This function is soft deprecated and does nothing.

Prior to Python 3.13, this function would copy the **`f_locals`** attribute of *f* to the internal "fast" array of local variables, allowing changes in frame objects to be visible to the interpreter. If *clear* was true, this function would process variables that were unset in the locals dictionary.

Changed in version 3.13: This function now does nothing.

void PyFrame_FastToLocals(PyFrameObject *f)

This function is soft deprecated and does nothing.

Prior to Python 3.13, this function would copy the internal "fast" array of local variables (which is used by the interpreter) to the `f_locals` attribute of *f*, allowing changes in local variables to be visible to frame objects.

Changed in version 3.13: This function now does nothing.

int PyFrame_FastToLocalsWithError(PyFrameObject *f)

This function is soft deprecated and does nothing.

Prior to Python 3.13, this function was similar to `PyFrame_FastToLocals()`, but would return `0` on success, and `-1` with an exception set on failure.

Changed in version 3.13: This function now does nothing.

See also

PEP 667 [https://peps.python.org/pep-0667/]

Internal Frames

Unless using **PEP 523** [https://peps.python.org/pep-0523/], you will not need this.

struct _PyInterpreterFrame

The interpreter's internal frame representation.

Added in version 3.11.

PyObject *PyUnstable_InterpreterFrame_GetCode(struct _PyInterpreterFrame *frame);

This is Unstable API. It may change without warning in minor releases.

Return a strong reference to the code object for the frame.

Added in version 3.12.

int PyUnstable_InterpreterFrame_GetLasti(struct _PyInterpreterFrame *frame);

This is Unstable API. It may change without warning in minor releases.

Return the byte offset into the last executed instruction.

Added in version 3.12.

int PyUnstable_InterpreterFrame_GetLine(struct _PyInterpreterFrame *frame);

This is Unstable API. It may change without warning in minor releases.

Return the currently executing line number, or -1 if there is no line number.

Added in version 3.12.

Generator Objects

Generator objects are what Python uses to implement generator iterators. They are normally created by iterating over a function that yields values, rather than explicitly calling **`PyGen_New()`** or **`PyGen_NewWithQualName()`**.

type PyGenObject

The C structure used for generator objects.

PyTypeObject PyGen_Type

The type object corresponding to generator objects.

int PyGen_Check(PyObject *ob)

Return true if *ob* is a generator object; *ob* must not be `NULL`. This function always succeeds.

int PyGen_CheckExact(PyObject *ob)

Return true if *ob*’s type is **`PyGen_Type`**; *ob* must not be `NULL`. This function always succeeds.

PyObject *PyGen_New(PyFrameObject *frame)

Return value: New reference.
Create and return a new generator object based on the *frame* object. A reference to *frame* is stolen by this function. The argument must not be `NULL`.

PyObject *PyGen_NewWithQualName(PyFrameObject *frame, PyObject *name, PyObject *qualname)

Return value: New reference.
Create and return a new generator object based on the *frame* object, with `__name__` and `__qualname__` set to *name*

and *qualname*. A reference to *frame* is stolen by this function. The *frame* argument must not be `NULL`.

PyCodeObject *PyGen_GetCode(PyGenObject *gen)

Return a new strong reference to the code object wrapped by *gen*. This function always succeeds.

Asynchronous Generator Objects

See also

PEP 525 [https://peps.python.org/pep-0525/]

PyTypeObject PyAsyncGen_Type

The type object corresponding to asynchronous generator objects. This is available as **`types.AsyncGeneratorType`** in the Python layer.

Added in version 3.6.

PyObject *PyAsyncGen_New(PyFrameObject *frame, PyObject *name, PyObject *qualname)

Create a new asynchronous generator wrapping *frame*, with `__name__` and `__qualname__` set to *name* and *qualname*. *frame* is stolen by this function and must not be `NULL`.

On success, this function returns a strong reference to the new asynchronous generator. On failure, this function returns `NULL` with an exception set.

Added in version 3.6.

int PyAsyncGen_CheckExact(PyObject *op)

Return true if *op* is an asynchronous generator object, false otherwise. This function always succeeds.

Added in version 3.6.

Deprecated API

PyAsyncGenASend_CheckExact(op)

This is a soft deprecated API that was included in Python’s C API by mistake.

It is solely here for completeness; do not use this API.

Coroutine Objects

Added in version 3.5.

Coroutine objects are what functions declared with an `async` keyword return.

type PyCoroObject

The C structure used for coroutine objects.

PyTypeObject PyCoro_Type

The type object corresponding to coroutine objects.

int PyCoro_CheckExact(PyObject *ob)

Return true if *ob*’s type is **`PyCoro_Type`**; *ob* must not be `NULL`. This function always succeeds.

PyObject *PyCoro_New(PyFrameObject *frame, PyObject *name, PyObject *qualname)

Return value: New reference.

Create and return a new coroutine object based on the *frame* object, with `__name__` and `__qualname__` set to *name* and *qualname*. A reference to *frame* is stolen by this function. The *frame* argument must not be `NULL`.

Context Variables Objects

Added in version 3.7.

Changed in version 3.7.1:

Note

In Python 3.7.1 the signatures of all context variables C APIs were **changed** to use `PyObject` pointers instead of `PyContext`, `PyContextVar`, and `PyContextToken`, e.g.:

```
// in 3.7.0:
PyContext *PyContext_New(void);

// in 3.7.1+:
PyObject *PyContext_New(void);
```

See bpo-34762 [https://bugs.python.org/issue?@action=redirect&bpo=34762] for more details.

This section details the public C API for the `contextvars` module.

type PyContext

The C structure used to represent a `contextvars.Context` object.

type PyContextVar

The C structure used to represent a `contextvars.ContextVar` object.

type PyContextToken

The C structure used to represent a `contextvars.Token` object.

PyTypeObject PyContext_Type

The type object representing the *context* type.

PyTypeObject PyContextVar_Type

The type object representing the *context variable* type.

PyTypeObject PyContextToken_Type

The type object representing the *context variable token* type.

Type-check macros:

int PyContext_CheckExact(PyObject *o)

Return true if *o* is of type `PyContext_Type`. *o* must not be `NULL`. This function always succeeds.

int PyContextVar_CheckExact(PyObject *o)

Return true if *o* is of type `PyContextVar_Type`. *o* must not be `NULL`. This function always succeeds.

int PyContextToken_CheckExact(PyObject *o)

Return true if *o* is of type `PyContextToken_Type`. *o* must not be `NULL`. This function always succeeds.

Context object management functions:

PyObject *PyContext_New(void)

Return value: New reference.
Create a new empty context object. Returns `NULL` if an error has occurred.

PyObject *PyContext_Copy(PyObject *ctx)

Return value: New reference.

Create a shallow copy of the passed *ctx* context object. Returns `NULL` if an error has occurred.

PyObject *PyContext_CopyCurrent(void)

Return value: New reference.
Create a shallow copy of the current thread context. Returns `NULL` if an error has occurred.

int PyContext_Enter(PyObject *ctx)

Set *ctx* as the current context for the current thread. Returns `0` on success, and `-1` on error.

int PyContext_Exit(PyObject *ctx)

Deactivate the *ctx* context and restore the previous context as the current context for the current thread. Returns `0` on success, and `-1` on error.

int PyContext_AddWatcher(PyContext_WatchCallback callback)

Register *callback* as a context object watcher for the current interpreter. Return an ID which may be passed to **`PyContext_ClearWatcher()`**. In case of error (e.g. no more watcher IDs available), return `-1` and set an exception.

Added in version 3.14.

int PyContext_ClearWatcher(int watcher_id)

Clear watcher identified by *watcher_id* previously returned from **`PyContext_AddWatcher()`** for the current interpreter. Return `0` on success, or `-1` and set an exception on error (e.g. if the given *watcher_id* was never registered.)

Added in version 3.14.

type PyContextEvent

Enumeration of possible context object watcher events:

- `Py_CONTEXT_SWITCHED`: The current context has switched to a different context. The object passed to the watch callback is the now-current **`contextvars.Context`** object, or None if no context is current.

Added in version 3.14.

typedef int (*PyContext_WatchCallback)(PyContextEvent event, PyObject *obj)

Context object watcher callback function. The object passed to the callback is event-specific; see **`PyContextEvent`** for details.

If the callback returns with an exception set, it must return `-1`; this exception will be printed as an unraisable exception using **`PyErr_FormatUnraisable()`**. Otherwise it should return `0`.

There may already be a pending exception set on entry to the callback. In this case, the callback should return `0` with the same exception still set. This means the callback may not call any other API that can set an exception unless it saves and clears the exception state first, and restores it before returning.

Added in version 3.14.

Context variable functions:

PyObject *PyContextVar_New(const char *name, PyObject *def)

Return value: New reference.
Create a new `ContextVar` object. The *name* parameter is used for introspection and debug purposes. The *def*

parameter specifies a default value for the context variable, or `NULL` for no default. If an error has occurred, this function returns `NULL`.

int PyContextVar_Get(PyObject *var, PyObject *default_value, PyObject **value)

Get the value of a context variable. Returns `-1` if an error has occurred during lookup, and `0` if no error occurred, whether or not a value was found.

If the context variable was found, *value* will be a pointer to it. If the context variable was *not* found, *value* will point to:

- *default_value*, if not `NULL`;
- the default value of *var*, if not `NULL`;
- `NULL`

Except for `NULL`, the function returns a new reference.

PyObject *PyContextVar_Set(PyObject *var, PyObject *value)

Return value: New reference.
Set the value of *var* to *value* in the current context. Returns a new token object for this change, or `NULL` if an error has occurred.

int PyContextVar_Reset(PyObject *var, PyObject *token)

Reset the state of the *var* context variable to that it was in before **`PyContextVar_Set()`** that returned the *token* was called. This function returns `0` on success and `-1` on error.

Objects for Type Hinting

Various built-in types for type hinting are provided. Currently, two types exist – GenericAlias and Union. Only `GenericAlias` is exposed to C.

PyObject *Py_GenericAlias(PyObject *origin, PyObject *args)

Part of the Stable ABI since version 3.9.
Create a GenericAlias object. Equivalent to calling the Python class **`types.GenericAlias`**. The *origin* and *args* arguments set the `GenericAlias`'s `__origin__` and `__args__` attributes respectively. *origin* should be a PyTypeObject*, and *args* can be a PyTupleObject* or any `PyObject*`. If *args* passed is not a tuple, a 1-tuple is automatically constructed and `__args__` is set to `(args,)`. Minimal checking is done for the arguments, so the function will succeed even if *origin* is not a type. The `GenericAlias`'s `__parameters__` attribute is constructed lazily from `__args__`. On failure, an exception is raised and `NULL` is returned.

Here's an example of how to make an extension type generic:

```
...
static PyMethodDef my_obj_methods[] = {
    // Other methods.
    ...
    {"__class_getitem__", Py_GenericAlias,
METH_O|METH_CLASS, "See PEP 585"}
    ...
}
```

See also

The data model method **`__class_getitem__()`**.

Added in version 3.9.

PyTypeObject Py_GenericAliasType

Part of the Stable ABI since version 3.9.

The C type of the object returned by **`Py_GenericAlias()`**. Equivalent to **`types.GenericAlias`** in Python.

Added in version 3.9.

Curses C API

`curses` exposes a small C interface for extension modules. Consumers must include the header file `py_curses.h` (which is not included by default by `Python.h`) and `import_curses()` must be invoked, usually as part of the module initialisation function, to populate `PyCurses_API`.

Warning

Neither the C API nor the pure Python `curses` module are compatible with subinterpreters.

import_curses()

Import the curses C API. The macro does not need a semi-colon to be called.

On success, populate the `PyCurses_API` pointer.

On failure, set `PyCurses_API` to NULL and set an exception. The caller must check if an error occurred via `PyErr_Occurred()`:

```
import_curses();  // semi-colon is optional but recommended
if (PyErr_Occurred()) { /* cleanup */ }
```

void **PyCurses_API

Dynamically allocated object containing the curses C API. This variable is only available once `import_curses` succeeds.

`PyCurses_API[0]` corresponds to `PyCursesWindow_Type`.

`PyCurses_API[1]`, `PyCurses_API[2]`, and `PyCurses_API[3]` are pointers to predicate functions of type `int (*)(void)`.

When called, these predicates return whether **`curses.setupterm()`**, **`curses.initscr()`**, and **`curses.start_color()`** have been called respectively.

See also the convenience macros **`PyCursesSetupTermCalled`**, **`PyCursesInitialised`**, and **`PyCursesInitialisedColor`**.

Note

The number of entries in this structure is subject to changes. Consider using **`PyCurses_API_pointers`** to check if new fields are available or not.

PyCurses_API_pointers

The number of accessible fields (`4`) in **`PyCurses_API`**. This number is incremented whenever new fields are added.

PyTypeObject PyCursesWindow_Type

The heap type corresponding to **`curses.window`**.

int PyCursesWindow_Check(PyObject *op)

Return true if *op* is a **`curses.window`** instance, false otherwise.

The following macros are convenience macros expanding into C statements. In particular, they can only be used as `macro;` or `macro`, but not `macro()` or `macro();`.

PyCursesSetupTermCalled

Macro checking if **`curses.setupterm()`** has been called.

The macro expansion is roughly equivalent to:

```
{
    typedef int (*predicate_t)(void);
    predicate_t was_setupterm_called =
(predicate_t)PyCurses_API[1];
    if (!was_setupterm_called()) {
        return NULL;
    }
}
```

PyCursesInitialised

Macro checking if `curses.initscr()` has been called.

The macro expansion is roughly equivalent to:

```
{
    typedef int (*predicate_t)(void);
    predicate_t was_initscr_called =
(predicate_t)PyCurses_API[2];
    if (!was_initscr_called()) {
        return NULL;
    }
}
```

PyCursesInitialisedColor

Macro checking if `curses.start_color()` has been called.

The macro expansion is roughly equivalent to:

```
{
    typedef int (*predicate_t)(void);
    predicate_t was_start_color_called =
(predicate_t)PyCurses_API[3];
    if (!was_start_color_called()) {
        return NULL;
    }
}
```

Internal data

The following objects are exposed by the C API but should be considered internal-only.

PyCurses_CAPSULE_NAME

Name of the curses capsule to pass to `PyCapsule_Import()`.

Internal usage only. Use `import_curses` instead.

DateTime Objects

Various date and time objects are supplied by the **`datetime`** module. Before using any of these functions, the header file `datetime.h` must be included in your source (note that this is not included by `Python.h`), and the macro **`PyDateTime_IMPORT`** must be invoked, usually as part of the module initialisation function. The macro puts a pointer to a C structure into a static variable, **`PyDateTimeAPI`**, that is used by the following macros.

PyDateTime_IMPORT()

Import the datetime C API.

On success, populate the **`PyDateTimeAPI`** pointer. On failure, set **`PyDateTimeAPI`** to `NULL` and set an exception. The caller must check if an error occurred via **`PyErr_Occurred()`**:

```
PyDateTime_IMPORT;
if (PyErr_Occurred()) { /* cleanup */ }
```

Warning

This is not compatible with subinterpreters.

type PyDateTime_CAPI

Structure containing the fields for the datetime C API.

The fields of this structure are private and subject to change.

Do not use this directly; prefer `PyDateTime_*` APIs instead.

PyDateTime_CAPI *PyDateTimeAPI

Dynamically allocated object containing the datetime C API.

This variable is only available once `PyDateTime_IMPORT` succeeds.

type PyDateTime_Date

This subtype of `PyObject` represents a Python date object.

type PyDateTime_DateTime

This subtype of `PyObject` represents a Python datetime object.

type PyDateTime_Time

This subtype of `PyObject` represents a Python time object.

type PyDateTime_Delta

This subtype of `PyObject` represents the difference between two datetime values.

PyTypeObject PyDateTime_DateType

This instance of `PyTypeObject` represents the Python date type; it is the same object as `datetime.date` in the Python layer.

PyTypeObject PyDateTime_DateTimeType

This instance of `PyTypeObject` represents the Python datetime type; it is the same object as `datetime.datetime` in the Python layer.

PyTypeObject PyDateTime_TimeType

This instance of `PyTypeObject` represents the Python time type; it is the same object as `datetime.time` in the Python layer.

PyTypeObject PyDateTime_DeltaType

This instance of `PyTypeObject` represents the Python type for the difference between two datetime values; it is the same object as `datetime.timedelta` in the Python layer.

PyTypeObject PyDateTime_TZInfoType

This instance of `PyTypeObject` represents the Python time zone info type; it is the same object as `datetime.tzinfo` in the Python layer.

Macro for access to the UTC singleton:

PyObject *PyDateTime_TimeZone_UTC

Returns the time zone singleton representing UTC, the same object as `datetime.timezone.utc`.

Added in version 3.7.

Type-check macros:

int PyDate_Check(PyObject *ob)

Return true if *ob* is of type `PyDateTime_DateType` or a subtype of **`PyDateTime_DateType`**. *ob* must not be `NULL`. This function always succeeds.

int PyDate_CheckExact(PyObject *ob)

Return true if *ob* is of type `PyDateTime_DateType`. *ob* must not be `NULL`. This function always succeeds.

int PyDateTime_Check(PyObject *ob)

Return true if *ob* is of type `PyDateTime_DateTimeType` or a subtype of **`PyDateTime_DateTimeType`**. *ob* must not be `NULL`. This function always succeeds.

int PyDateTime_CheckExact(PyObject *ob)

Return true if *ob* is of type `PyDateTime_DateTimeType`. *ob* must not be `NULL`. This function always succeeds.

int PyTime_Check(PyObject *ob)

Return true if *ob* is of type **`PyDateTime_TimeType`** or a subtype of **`PyDateTime_TimeType`**. *ob* must not be `NULL`. This function always succeeds.

int PyTime_CheckExact(PyObject *ob)

Return true if *ob* is of type **`PyDateTime_TimeType`**. *ob* must not be `NULL`. This function always succeeds.

int PyDelta_Check(PyObject *ob)

Return true if *ob* is of type **`PyDateTime_DeltaType`** or a subtype of **`PyDateTime_DeltaType`**. *ob* must not be `NULL`. This function always succeeds.

int PyDelta_CheckExact(PyObject *ob)

Return true if *ob* is of type **`PyDateTime_DeltaType`**. *ob* must not be `NULL`. This function always succeeds.

int PyTZInfo_Check(PyObject *ob)

Return true if *ob* is of type **`PyDateTime_TZInfoType`** or a subtype of **`PyDateTime_TZInfoType`**. *ob* must not be `NULL`. This function always succeeds.

int PyTZInfo_CheckExact(PyObject *ob)

Return true if *ob* is of type **`PyDateTime_TZInfoType`**. *ob* must not be `NULL`. This function always succeeds.

Macros to create objects:

PyObject *PyDate_FromDate(int year, int month, int day)

Return value: New reference.

Return a **`datetime.date`** object with the specified year, month and day.

PyObject *PyDateTime_FromDateAndTime(int year, int month, int day, int hour, int minute, int second, int usecond)

Return value: New reference.
Return a `datetime.datetime` object with the specified year, month, day, hour, minute, second and microsecond.

PyObject *PyDateTime_FromDateAndTimeAndFold(int year, int month, int day, int hour, int minute, int second, int usecond, int fold)

Return value: New reference.
Return a `datetime.datetime` object with the specified year, month, day, hour, minute, second, microsecond and fold.

Added in version 3.6.

PyObject *PyTime_FromTime(int hour, int minute, int second, int usecond)

Return value: New reference.
Return a `datetime.time` object with the specified hour, minute, second and microsecond.

PyObject *PyTime_FromTimeAndFold(int hour, int minute, int second, int usecond, int fold)

Return value: New reference.
Return a `datetime.time` object with the specified hour, minute, second, microsecond and fold.

Added in version 3.6.

PyObject *PyDelta_FromDSU(int days, int seconds, int useconds)

Return value: New reference.
Return a `datetime.timedelta` object representing the given number of days, seconds and microseconds. Normalization is performed so that the resulting number

of microseconds and seconds lie in the ranges documented for **`datetime.timedelta`** objects.

PyObject *PyTimeZone_FromOffset(PyObject *offset)

Return value: New reference.
Return a **`datetime.timezone`** object with an unnamed fixed offset represented by the *offset* argument.

Added in version 3.7.

PyObject *PyTimeZone_FromOffsetAndName(PyObject *offset, PyObject *name)

Return value: New reference.
Return a **`datetime.timezone`** object with a fixed offset represented by the *offset* argument and with tzname *name*.

Added in version 3.7.

Macros to extract fields from date objects. The argument must be an instance of **`PyDateTime_Date`**, including subclasses (such as **`PyDateTime_DateTime`**). The argument must not be `NULL`, and the type is not checked:

int PyDateTime_GET_YEAR(PyDateTime_Date *o)

Return the year, as a positive int.

int PyDateTime_GET_MONTH(PyDateTime_Date *o)

Return the month, as an int from 1 through 12.

int PyDateTime_GET_DAY(PyDateTime_Date *o)

Return the day, as an int from 1 through 31.

Macros to extract fields from datetime objects. The argument must be an instance of **`PyDateTime_DateTime`**, including subclasses. The argument must not be `NULL`, and the type is not checked:

int PyDateTime_DATE_GET_HOUR(PyDateTime_DateTime *o)

Return the hour, as an int from 0 through 23.

int PyDateTime_DATE_GET_MINUTE(PyDateTime_DateTime *o)

Return the minute, as an int from 0 through 59.

int PyDateTime_DATE_GET_SECOND(PyDateTime_DateTime *o)

Return the second, as an int from 0 through 59.

int PyDateTime_DATE_GET_MICROSECOND(PyDateTime_DateTime *o)

Return the microsecond, as an int from 0 through 999999.

int PyDateTime_DATE_GET_FOLD(PyDateTime_DateTime *o)

Return the fold, as an int from 0 through 1.

Added in version 3.6.

PyObject *PyDateTime_DATE_GET_TZINFO(PyDateTime_DateTime *o)

Return the tzinfo (which may be `None`).

Added in version 3.10.

Macros to extract fields from time objects. The argument must be an instance of **`PyDateTime_Time`**, including subclasses. The argument must not be `NULL`, and the type is not checked:

int PyDateTime_TIME_GET_HOUR(PyDateTime_Time *o)

Return the hour, as an int from 0 through 23.

int PyDateTime_TIME_GET_MINUTE(PyDateTime_Time *o)

Return the minute, as an int from 0 through 59.

int PyDateTime_TIME_GET_SECOND(PyDateTime_Time *o)

Return the second, as an int from 0 through 59.

int PyDateTime_TIME_GET_MICROSECOND(PyDateTime_Time *o)

Return the microsecond, as an int from 0 through 999999.

int PyDateTime_TIME_GET_FOLD(PyDateTime_Time *o)

Return the fold, as an int from 0 through 1.

Added in version 3.6.

PyObject *PyDateTime_TIME_GET_TZINFO(PyDateTime_Time *o)

Return the tzinfo (which may be `None`).

Added in version 3.10.

Macros to extract fields from time delta objects. The argument must be an instance of **`PyDateTime_Delta`**, including subclasses. The argument must not be `NULL`, and the type is not checked:

int PyDateTime_DELTA_GET_DAYS(PyDateTime_Delta *o)

Return the number of days, as an int from -999999999 to 999999999.

Added in version 3.3.

int PyDateTime_DELTA_GET_SECONDS(PyDateTime_Delta *o)

Return the number of seconds, as an int from 0 through 86399.

Added in version 3.3.

int PyDateTime_DELTA_GET_MICROSECONDS(PyDateTime_Delta *o)

Return the number of microseconds, as an int from 0 through 999999.

Added in version 3.3.

Macros for the convenience of modules implementing the DB API:

PyObject *PyDateTime_FromTimestamp(PyObject *args)

Return value: New reference.
Create and return a new **`datetime.datetime`** object given an argument tuple suitable for passing to **`datetime.datetime.fromtimestamp()`**.

PyObject *PyDate_FromTimestamp(PyObject *args)

Return value: New reference.
Create and return a new **`datetime.date`** object given an argument tuple suitable for passing to **`datetime.date.fromtimestamp()`**.

Internal data

The following symbols are exposed by the C API but should be considered internal-only.

PyDateTime_CAPSULE_NAME

Name of the datetime capsule to pass to `PyCapsule_Import()`.

Internal usage only. Use `PyDateTime_IMPORT` instead.

Initialization, Finalization, and Threads

See Python Initialization Configuration for details on how to configure the interpreter prior to initialization.

Before Python Initialization

In an application embedding Python, the **`Py_Initialize()`** function must be called before using any other Python/C API functions; with the exception of a few functions and the global configuration variables.

The following functions can be safely called before Python is initialized:

- Functions that initialize the interpreter:
  - **`Py_Initialize()`**
  - **`Py_InitializeEx()`**
  - **`Py_InitializeFromConfig()`**
  - **`Py_BytesMain()`**
  - **`Py_Main()`**
  - the runtime pre-initialization functions covered in Python Initialization Configuration
- Configuration functions:
  - **`PyImport_AppendInittab()`**
  - **`PyImport_ExtendInittab()`**
  - **`PyInitFrozenExtensions()`**
  - **`PyMem_SetAllocator()`**
  - **`PyMem_SetupDebugHooks()`**
  - **`PyObject_SetArenaAllocator()`**
  - **`Py_SetProgramName()`**

  - `Py_SetPythonHome()`
  - `PySys_ResetWarnOptions()`
  - the configuration functions covered in Python Initialization Configuration
- Informative functions:
  - `Py_IsInitialized()`
  - `PyMem_GetAllocator()`
  - `PyObject_GetArenaAllocator()`
  - `Py_GetBuildInfo()`
  - `Py_GetCompiler()`
  - `Py_GetCopyright()`
  - `Py_GetPlatform()`
  - `Py_GetVersion()`
  - `Py_IsInitialized()`
- Utilities:
  - `Py_DecodeLocale()`
  - the status reporting and utility functions covered in Python Initialization Configuration
- Memory allocators:
  - `PyMem_RawMalloc()`
  - `PyMem_RawRealloc()`
  - `PyMem_RawCalloc()`
  - `PyMem_RawFree()`
- Synchronization:
  - `PyMutex_Lock()`
  - `PyMutex_Unlock()`

Note

Despite their apparent similarity to some of the functions listed above, the following functions **should not be called** before the interpreter has been initialized: `Py_EncodeLocale()`, `Py_GetPath()`, `Py_GetPrefix()`, `Py_GetExecPrefix()`, `Py_GetProgramFullPath()`,

`Py_GetPythonHome()`, **`Py_GetProgramName()`**, **`PyEval_InitThreads()`**, and **`Py_RunMain()`**.

Global configuration variables

Python has variables for the global configuration to control different features and options. By default, these flags are controlled by command line options.

When a flag is set by an option, the value of the flag is the number of times that the option was set. For example, `-b` sets **`Py_BytesWarningFlag`** to 1 and `-bb` sets **`Py_BytesWarningFlag`** to 2.

int Py_BytesWarningFlag

This API is kept for backward compatibility: setting **`PyConfig.bytes_warning`** should be used instead, see Python Initialization Configuration.

Issue a warning when comparing **`bytes`** or **`bytearray`** with **`str`** or **`bytes`** with **`int`**. Issue an error if greater or equal to `2`.

Set by the **`-b`** option.

Deprecated since version 3.12, will be removed in version 3.15.

int Py_DebugFlag

This API is kept for backward compatibility: setting **`PyConfig.parser_debug`** should be used instead, see Python Initialization Configuration.

Turn on parser debugging output (for expert only, depending on compilation options).

Set by the `-d` option and the `PYTHONDEBUG` environment variable.

Deprecated since version 3.12, will be removed in version 3.15.

int Py_DontWriteBytecodeFlag

This API is kept for backward compatibility: setting `PyConfig.write_bytecode` should be used instead, see Python Initialization Configuration.

If set to non-zero, Python won't try to write `.pyc` files on the import of source modules.

Set by the `-B` option and the `PYTHONDONTWRITEBYTECODE` environment variable.

Deprecated since version 3.12, will be removed in version 3.15.

int Py_FrozenFlag

This API is kept for backward compatibility: setting `PyConfig.pathconfig_warnings` should be used instead, see Python Initialization Configuration.

Suppress error messages when calculating the module search path in `Py_GetPath()`.

Private flag used by `_freeze_module` and `frozenmain` programs.

Deprecated since version 3.12, will be removed in version 3.15.

int Py_HashRandomizationFlag

This API is kept for backward compatibility: setting `PyConfig.hash_seed` and `PyConfig.use_hash_seed` should be used instead, see Python Initialization Configuration.

Set to `1` if the **`PYTHONHASHSEED`** environment variable is set to a non-empty string.

If the flag is non-zero, read the **`PYTHONHASHSEED`** environment variable to initialize the secret hash seed.

Deprecated since version 3.12, will be removed in version 3.15.

int Py_IgnoreEnvironmentFlag

This API is kept for backward compatibility: setting **`PyConfig.use_environment`** should be used instead, see Python Initialization Configuration.

Ignore all **`PYTHON*`** environment variables, e.g. **`PYTHONPATH`** and **`PYTHONHOME`**, that might be set.

Set by the **`-E`** and **`-I`** options.

Deprecated since version 3.12, will be removed in version 3.15.

int Py_InspectFlag

This API is kept for backward compatibility: setting **`PyConfig.inspect`** should be used instead, see Python Initialization Configuration.

When a script is passed as first argument or the **`-c`** option is used, enter interactive mode after executing the script or the command, even when **`sys.stdin`** does not appear to be a terminal.

Set by the **`-i`** option and the **`PYTHONINSPECT`** environment variable.

Deprecated since version 3.12, will be removed in version 3.15.

int Py_InteractiveFlag

This API is kept for backward compatibility: setting `PyConfig.interactive` should be used instead, see Python Initialization Configuration.

Set by the `-i` option.

Deprecated since version 3.12, will be removed in version 3.15.

int Py_IsolatedFlag

This API is kept for backward compatibility: setting `PyConfig.isolated` should be used instead, see Python Initialization Configuration.

Run Python in isolated mode. In isolated mode `sys.path` contains neither the script's directory nor the user's site-packages directory.

Set by the `-I` option.

Added in version 3.4.

Deprecated since version 3.12, will be removed in version 3.15.

int Py_LegacyWindowsFSEncodingFlag

This API is kept for backward compatibility: setting `PyPreConfig.legacy_windows_fs_encoding` should be used instead, see Python Initialization Configuration.

If the flag is non-zero, use the `mbcs` encoding with `replace` error handler, instead of the UTF-8 encoding with `surrogatepass` error handler, for the filesystem encoding and error handler.

Set to `1` if the **`PYTHONLEGACYWINDOWSFSENCODING`** environment variable is set to a non-empty string.

See **PEP 529** [https://peps.python.org/pep-0529/] for more details.

Availability: Windows.

Deprecated since version 3.12, will be removed in version 3.15.

int Py_LegacyWindowsStdioFlag

This API is kept for backward compatibility: setting **`PyConfig.legacy_windows_stdio`** should be used instead, see Python Initialization Configuration.

If the flag is non-zero, use **`io.FileIO`** instead of **`io._WindowsConsoleIO`** for **`sys`** standard streams.

Set to `1` if the **`PYTHONLEGACYWINDOWSSTDIO`** environment variable is set to a non-empty string.

See **PEP 528** [https://peps.python.org/pep-0528/] for more details.

Availability: Windows.

Deprecated since version 3.12, will be removed in version 3.15.

int Py_NoSiteFlag

This API is kept for backward compatibility: setting **`PyConfig.site_import`** should be used instead, see Python Initialization Configuration.

Disable the import of the module `site` and the site-dependent manipulations of `sys.path` that it entails. Also disable these manipulations if `site` is explicitly imported later (call `site.main()` if you want them to be triggered).

Set by the `-S` option.

Deprecated since version 3.12, will be removed in version 3.15.

int Py_NoUserSiteDirectory

This API is kept for backward compatibility: setting `PyConfig.user_site_directory` should be used instead, see Python Initialization Configuration.

Don't add the `user site-packages directory` to `sys.path`.

Set by the `-s` and `-I` options, and the `PYTHONNOUSERSITE` environment variable.

Deprecated since version 3.12, will be removed in version 3.15.

int Py_OptimizeFlag

This API is kept for backward compatibility: setting `PyConfig.optimization_level` should be used instead, see Python Initialization Configuration.

Set by the `-O` option and the `PYTHONOPTIMIZE` environment variable.

Deprecated since version 3.12, will be removed in version 3.15.

int Py_QuietFlag

This API is kept for backward compatibility: setting `PyConfig.quiet` should be used instead, see Python

Initialization Configuration.

Don’t display the copyright and version messages even in interactive mode.

Set by the `-q` option.

Added in version 3.2.

Deprecated since version 3.12, will be removed in version 3.15.

int Py_UnbufferedStdioFlag

This API is kept for backward compatibility: setting `PyConfig.buffered_stdio` should be used instead, see Python Initialization Configuration.

Force the stdout and stderr streams to be unbuffered.

Set by the `-u` option and the `PYTHONUNBUFFERED` environment variable.

Deprecated since version 3.12, will be removed in version 3.15.

int Py_VerboseFlag

This API is kept for backward compatibility: setting `PyConfig.verbose` should be used instead, see Python Initialization Configuration.

Print a message each time a module is initialized, showing the place (filename or built-in module) from which it is loaded. If greater or equal to `2`, print a message for each file that is checked for when searching for a module. Also provides information on module cleanup at exit.

Set by the **`-v`** option and the **`PYTHONVERBOSE`** environment variable.

Deprecated since version 3.12, will be removed in version 3.15.

Initializing and finalizing the interpreter

void Py_Initialize()

Part of the Stable ABI.
Initialize the Python interpreter. In an application embedding Python, this should be called before using any other Python/C API functions; see Before Python Initialization for the few exceptions.

This initializes the table of loaded modules (`sys.modules`), and creates the fundamental modules **`builtins`**, **`__main__`** and **`sys`**. It also initializes the module search path (`sys.path`). It does not set `sys.argv`; use the Python Initialization Configuration API for that. This is a no-op when called for a second time (without calling **`Py_FinalizeEx()`** first). There is no return value; it is a fatal error if the initialization fails.

Use **`Py_InitializeFromConfig()`** to customize the Python Initialization Configuration.

Note

On Windows, changes the console mode from `O_TEXT` to `O_BINARY`, which will also affect non-Python uses of the console using the C Runtime.

void Py_InitializeEx(int initsigs)

Part of the Stable ABI.
This function works like **`Py_Initialize()`** if *initsigs* is `1`. If *initsigs* is `0`, it skips initialization registration of signal handlers, which may be useful when CPython is embedded as part of a larger application.

Use **`Py_InitializeFromConfig()`** to customize the Python Initialization Configuration.

PyStatus Py_InitializeFromConfig(const PyConfig *config)

Initialize Python from *config* configuration, as described in Initialization with PyConfig.

See the Python Initialization Configuration section for details on pre-initializing the interpreter, populating the runtime configuration structure, and querying the returned status structure.

int Py_IsInitialized()

Part of the Stable ABI.
Return true (nonzero) when the Python interpreter has been initialized, false (zero) if not. After **`Py_FinalizeEx()`** is called, this returns false until **`Py_Initialize()`** is called again.

int Py_IsFinalizing()

Part of the Stable ABI since version 3.13.
Return true (non-zero) if the main Python interpreter is shutting down. Return false (zero) otherwise.

Added in version 3.13.

int Py_FinalizeEx()

Part of the Stable ABI since version 3.6.
Undo all initializations made by **`Py_Initialize()`** and subsequent use of Python/C API functions, and destroy all

sub-interpreters (see `Py_NewInterpreter()` below) that were created and not yet destroyed since the last call to `Py_Initialize()`. This is a no-op when called for a second time (without calling `Py_Initialize()` again first).

Since this is the reverse of `Py_Initialize()`, it should be called in the same thread with the same interpreter active. That means the main thread and the main interpreter. This should never be called while `Py_RunMain()` is running.

Normally the return value is `0`. If there were errors during finalization (flushing buffered data), `-1` is returned.

Note that Python will do a best effort at freeing all memory allocated by the Python interpreter. Therefore, any C-Extension should make sure to correctly clean up all of the preveiously allocated PyObjects before using them in subsequent calls to `Py_Initialize()`. Otherwise it could introduce vulnerabilities and incorrect behavior.

This function is provided for a number of reasons. An embedding application might want to restart Python without having to restart the application itself. An application that has loaded the Python interpreter from a dynamically loadable library (or DLL) might want to free all memory allocated by Python before unloading the DLL. During a hunt for memory leaks in an application a developer might want to free all memory allocated by Python before exiting from the application.

Bugs and caveats: The destruction of modules and objects in modules is done in random order; this may cause destructors (`__del__()` methods) to fail when they depend on other objects (even functions) or modules. Dynamically loaded extension modules loaded by Python are not unloaded. Small amounts of memory allocated by the Python interpreter may not be freed (if you find a leak, please report it). Memory tied up in circular references between objects is not freed. Interned strings will all be deallocated regardless of their reference count. Some memory allocated by extension modules may not be freed. Some extensions may not work properly if their initialization routine is called more than once; this can happen if an application calls **`Py_Initialize()`** and **`Py_FinalizeEx()`** more than once. **`Py_FinalizeEx()`** must not be called recursively from within itself. Therefore, it must not be called by any code that may be run as part of the interpreter shutdown process, such as **`atexit`** handlers, object finalizers, or any code that may be run while flushing the stdout and stderr files.

Raises an auditing event `cpython._PySys_ClearAuditHooks` with no arguments.

Added in version 3.6.

void Py_Finalize()

Part of the Stable ABI.
This is a backwards-compatible version of **`Py_FinalizeEx()`** that disregards the return value.

int Py_BytesMain(int argc, char **argv)

Part of the Stable ABI since version 3.8.
Similar to **`Py_Main()`** but *argv* is an array of bytes strings, allowing the calling application to delegate the text decoding step to the CPython runtime.

Added in version 3.8.

int Py_Main(int argc, wchar_t **argv)

Part of the Stable ABI.

The main program for the standard interpreter, encapsulating a full initialization/finalization cycle, as well as additional behaviour to implement reading configurations settings from the environment and command line, and then executing `__main__` in accordance with Command line.

This is made available for programs which wish to support the full CPython command line interface, rather than just embedding a Python runtime in a larger application.

The *argc* and *argv* parameters are similar to those which are passed to a C program’s **`main()`** function, except that the *argv* entries are first converted to `wchar_t` using **`Py_DecodeLocale()`**. It is also important to note that the argument list entries may be modified to point to strings other than those passed in (however, the contents of the strings pointed to by the argument list are not modified).

The return value is `2` if the argument list does not represent a valid Python command line, and otherwise the same as **`Py_RunMain()`**.

In terms of the CPython runtime configuration APIs documented in the runtime configuration section (and without accounting for error handling), `Py_Main` is approximately equivalent to:

```
PyConfig config;
PyConfig_InitPythonConfig(&config);
PyConfig_SetArgv(&config, argc, argv);
Py_InitializeFromConfig(&config);
PyConfig_Clear(&config);

Py_RunMain();
```

In normal usage, an embedding application will call this function *instead* of calling `Py_Initialize()`, `Py_InitializeEx()` or `Py_InitializeFromConfig()` directly, and all settings will be applied as described elsewhere in this documentation. If this function is instead called *after* a preceding runtime initialization API call, then exactly which environmental and command line configuration settings will be updated is version dependent (as it depends on which settings correctly support being modified after they have already been set once when the runtime was first initialized).

int Py_RunMain(void)

Executes the main module in a fully configured CPython runtime.

Executes the command (`PyConfig.run_command`), the script (`PyConfig.run_filename`) or the module (`PyConfig.run_module`) specified on the command line or in the configuration. If none of these values are set, runs the interactive Python prompt (REPL) using the `__main__` module's global namespace.

If `PyConfig.inspect` is not set (the default), the return value will be `0` if the interpreter exits normally (that is, without raising an exception), the exit status of an unhandled `SystemExit`, or `1` for any other unhandled exception.

If `PyConfig.inspect` is set (such as when the `-i` option is used), rather than returning when the interpreter exits, execution will instead resume in an interactive Python prompt (REPL) using the `__main__` module's global namespace. If the interpreter exited with an exception, it is immediately raised in the REPL session. The function return value is then determined by the way the *REPL* *session* terminates: `0`, `1`, or the status of a **`SystemExit`**, as specified above.

This function always finalizes the Python interpreter before it returns.

See Python Configuration for an example of a customized Python that always runs in isolated mode using **`Py_RunMain()`**.

int PyUnstable_AtExit(PyInterpreterState *interp, void (*func)(void*), void *data)

This is Unstable API. It may change without warning in minor releases.

Register an **`atexit`** callback for the target interpreter *interp*. This is similar to **`Py_AtExit()`**, but takes an explicit interpreter and data pointer for the callback.

There must be an attached thread state for *interp*.

Added in version 3.13.

Process-wide parameters

void Py_SetProgramName(const wchar_t *name)

Part of the Stable ABI.
This API is kept for backward compatibility: setting **`PyConfig.program_name`** should be used instead, see Python Initialization Configuration.

This function should be called before **`Py_Initialize()`** is called for the first time, if it is called at all. It tells the interpreter the value of the `argv[0]` argument to the **`main()`** function of the program (converted to wide characters).

This is used by `Py_GetPath()` and some other functions below to find the Python run-time libraries relative to the interpreter executable. The default value is `'python'`. The argument should point to a zero-terminated wide character string in static storage whose contents will not change for the duration of the program's execution. No code in the Python interpreter will change the contents of this storage.

Use `Py_DecodeLocale()` to decode a bytes string to get a wchar_t* string.

Deprecated since version 3.11, will be removed in version 3.15.

wchar_t *Py_GetProgramName()

Part of the Stable ABI.
Return the program name set with `PyConfig.program_name`, or the default. The returned string points into static storage; the caller should not modify its value.

This function should not be called before `Py_Initialize()`, otherwise it returns `NULL`.

Changed in version 3.10: It now returns `NULL` if called before `Py_Initialize()`.

Deprecated since version 3.13, will be removed in version 3.15: Use `PyConfig_Get("executable")` (`sys.executable`) instead.

wchar_t *Py_GetPrefix()

Part of the Stable ABI.
Return the *prefix* for installed platform-independent files. This is derived through a number of complicated rules from the program name set with `PyConfig.program_name` and

some environment variables; for example, if the program name is `'/usr/local/bin/python'`, the prefix is `'/usr/local'`. The returned string points into static storage; the caller should not modify its value. This corresponds to the **prefix** variable in the top-level `Makefile` and the `--prefix` argument to the **configure** script at build time. The value is available to Python code as `sys.base_prefix`. It is only useful on Unix. See also the next function.

This function should not be called before `Py_Initialize()`, otherwise it returns `NULL`.

Changed in version 3.10: It now returns `NULL` if called before `Py_Initialize()`.

Deprecated since version 3.13, will be removed in version 3.15: Use `PyConfig_Get("base_prefix")` (`sys.base_prefix`) instead. Use `PyConfig_Get("prefix")` (`sys.prefix`) if virtual environments need to be handled.

wchar_t *Py_GetExecPrefix()

Part of the Stable ABI.
Return the *exec-prefix* for installed platform-*dependent* files. This is derived through a number of complicated rules from the program name set with `PyConfig.program_name` and some environment variables; for example, if the program name is `'/usr/local/bin/python'`, the exec-prefix is `'/usr/local'`. The returned string points into static storage; the caller should not modify its value. This corresponds to the **exec_prefix** variable in the top-level `Makefile` and the `--exec-prefix` argument to the **configure** script at build time. The value is available to Python code as `sys.base_exec_prefix`. It is only useful on Unix.

Background: The exec-prefix differs from the prefix when platform dependent files (such as executables and shared libraries) are installed in a different directory tree. In a typical installation, platform dependent files may be installed in the `/usr/local/plat` subtree while platform independent may be installed in `/usr/local`.

Generally speaking, a platform is a combination of hardware and software families, e.g. Sparc machines running the Solaris 2.x operating system are considered the same platform, but Intel machines running Solaris 2.x are another platform, and Intel machines running Linux are yet another platform. Different major revisions of the same operating system generally also form different platforms. Non-Unix operating systems are a different story; the installation strategies on those systems are so different that the prefix and exec-prefix are meaningless, and set to the empty string. Note that compiled Python bytecode files are platform independent (but not independent from the Python version by which they were compiled!).

System administrators will know how to configure the **mount** or **automount** programs to share `/usr/local` between platforms while having `/usr/local/plat` be a different filesystem for each platform.

This function should not be called before `Py_Initialize()`, otherwise it returns `NULL`.

Changed in version 3.10: It now returns `NULL` if called before `Py_Initialize()`.

Deprecated since version 3.13, will be removed in version 3.15: Use `PyConfig_Get("base_exec_prefix")` (`sys.base_exec_prefix`) instead. Use

`PyConfig_Get("exec_prefix")` (`sys.exec_prefix`) if virtual environments need to be handled.

wchar_t *Py_GetProgramFullPath()

Part of the Stable ABI.
Return the full program name of the Python executable; this is computed as a side-effect of deriving the default module search path from the program name (set by `PyConfig.program_name`). The returned string points into static storage; the caller should not modify its value. The value is available to Python code as `sys.executable`.

This function should not be called before `Py_Initialize()`, otherwise it returns `NULL`.

Changed in version 3.10: It now returns `NULL` if called before `Py_Initialize()`.

Deprecated since version 3.13, will be removed in version 3.15: Use `PyConfig_Get("executable")` (`sys.executable`) instead.

wchar_t *Py_GetPath()

Part of the Stable ABI.
Return the default module search path; this is computed from the program name (set by `PyConfig.program_name`) and some environment variables. The returned string consists of a series of directory names separated by a platform dependent delimiter character. The delimiter character is `':'` on Unix and macOS, `';'` on Windows. The returned string points into static storage; the caller should not modify its value. The list `sys.path` is initialized with this value on interpreter startup; it can be (and usually is) modified later to change the search path for loading modules.

This function should not be called before **`Py_Initialize()`**, otherwise it returns `NULL`.

Changed in version 3.10: It now returns `NULL` if called before **`Py_Initialize()`**.

Deprecated since version 3.13, will be removed in version 3.15: Use **`PyConfig_Get("module_search_paths")`** (**`sys.path`**) instead.

const char *Py_GetVersion()

Part of the Stable ABI.

Return the version of this Python interpreter. This is a string that looks something like

```
"3.0a5+ (py3k:63103M, May 12 2008, 00:53:55) \n[GCC 4.2.3]"
```

The first word (up to the first space character) is the current Python version; the first characters are the major and minor version separated by a period. The returned string points into static storage; the caller should not modify its value. The value is available to Python code as **`sys.version`**.

See also the **`Py_Version`** constant.

const char *Py_GetPlatform()

Part of the Stable ABI.

Return the platform identifier for the current platform. On Unix, this is formed from the "official" name of the operating system, converted to lower case, followed by the major revision number; e.g., for Solaris 2.x, which is also known as SunOS 5.x, the value is `'sunos5'`. On macOS, it is `'darwin'`. On Windows, it is `'win'`. The returned string points into static storage; the caller should not modify its value. The value is available to Python code as `sys.platform`.

const char *Py_GetCopyright()

Part of the Stable ABI.

Return the official copyright string for the current Python version, for example

```
'Copyright 1991-1995 Stichting Mathematisch Centrum,
Amsterdam'
```

The returned string points into static storage; the caller should not modify its value. The value is available to Python code as `sys.copyright`.

const char *Py_GetCompiler()

Part of the Stable ABI.

Return an indication of the compiler used to build the current Python version, in square brackets, for example:

```
"[GCC 2.7.2.2]"
```

The returned string points into static storage; the caller should not modify its value. The value is available to Python code as part of the variable `sys.version`.

const char *Py_GetBuildInfo()

Part of the Stable ABI.

Return information about the sequence number and build date and time of the current Python interpreter instance, for example

```
"#67, Aug  1 1997, 22:34:28"
```

The returned string points into static storage; the caller should not modify its value. The value is available to Python code as part of the variable `sys.version`.

void PySys_SetArgvEx(int argc, wchar_t **argv, int updatepath)

Part of the Stable ABI.
This API is kept for backward compatibility: setting **`PyConfig.argv`**, **`PyConfig.parse_argv`** and **`PyConfig.safe_path`** should be used instead, see Python Initialization Configuration.

Set **`sys.argv`** based on *argc* and *argv*. These parameters are similar to those passed to the program's **`main()`** function with the difference that the first entry should refer to the script file to be executed rather than the executable hosting the Python interpreter. If there isn't a script that will be run, the first entry in *argv* can be an empty string. If this function fails to initialize **`sys.argv`**, a fatal condition is signalled using **`Py_FatalError()`**.

If *updatepath* is zero, this is all the function does. If *updatepath* is non-zero, the function also modifies **`sys.path`** according to the following algorithm:

- If the name of an existing script is passed in `argv[0]`, the absolute path of the directory where the script is located is prepended to **`sys.path`**.
- Otherwise (that is, if *argc* is `0` or `argv[0]` doesn't point to an existing file name), an empty string is prepended to **`sys.path`**, which is the same as prepending the current working directory (`"."`).

Use **`Py_DecodeLocale()`** to decode a bytes string to get a wchar_t* string.

See also **`PyConfig.orig_argv`** and **`PyConfig.argv`** members of the Python Initialization Configuration.

Note

It is recommended that applications embedding the Python interpreter for purposes other than executing a single script pass `0` as *updatepath*, and update `sys.path` themselves if desired. See **CVE 2008-5983** [https://www.cve.org/CVERecord?id=CVE-2008-5983].

On versions before 3.1.3, you can achieve the same effect by manually popping the first `sys.path` element after having called `PySys_SetArgv()`, for example using:

```
PyRun_SimpleString("import sys; sys.path.pop(0)\n");
```

Added in version 3.1.3.

Deprecated since version 3.11, will be removed in version 3.15.

void PySys_SetArgv(int argc, wchar_t **argv)

Part of the Stable ABI.

This API is kept for backward compatibility: setting `PyConfig.argv` and `PyConfig.parse_argv` should be used instead, see Python Initialization Configuration.

This function works like `PySys_SetArgvEx()` with *updatepath* set to `1` unless the **python** interpreter was started with the `-I`.

Use `Py_DecodeLocale()` to decode a bytes string to get a wchar_t* string.

See also `PyConfig.orig_argv` and `PyConfig.argv` members of the Python Initialization Configuration.

Changed in version 3.4: The *updatepath* value depends on `-I`.

Deprecated since version 3.11, will be removed in version 3.15.

void Py_SetPythonHome(const wchar_t *home)

Part of the Stable ABI.

This API is kept for backward compatibility: setting `PyConfig.home` should be used instead, see Python Initialization Configuration.

Set the default “home” directory, that is, the location of the standard Python libraries. See `PYTHONHOME` for the meaning of the argument string.

The argument should point to a zero-terminated character string in static storage whose contents will not change for the duration of the program’s execution. No code in the Python interpreter will change the contents of this storage.

Use `Py_DecodeLocale()` to decode a bytes string to get a wchar_t* string.

Deprecated since version 3.11, will be removed in version 3.15.

wchar_t *Py_GetPythonHome()

Part of the Stable ABI.

Return the default “home”, that is, the value set by `PyConfig.home`, or the value of the `PYTHONHOME` environment variable if it is set.

This function should not be called before `Py_Initialize()`, otherwise it returns `NULL`.

Changed in version 3.10: It now returns `NULL` if called before `Py_Initialize()`.

Deprecated since version 3.13, will be removed in version 3.15: Use `PyConfig_Get("home")` or the `PYTHONHOME` environment variable instead.

Thread State and the Global Interpreter Lock

Unless on a free-threaded build of CPython, the Python interpreter is not fully thread-safe. In order to support multi-threaded Python programs, there’s a global lock, called the global interpreter lock or GIL, that must be held by the current thread before it can safely access Python objects. Without the lock, even the simplest operations could cause problems in a multi-threaded program: for example, when two threads simultaneously increment the reference count of the same object, the reference count could end up being incremented only once instead of twice.

Therefore, the rule exists that only the thread that has acquired the GIL may operate on Python objects or call Python/C API functions. In order to emulate concurrency of execution, the interpreter regularly tries to switch threads (see **`sys.setswitchinterval()`**). The lock is also released around potentially blocking I/O operations like reading or writing a file, so that other Python threads can run in the meantime.

The Python interpreter keeps some thread-specific bookkeeping information inside a data structure called **`PyThreadState`**, known as a thread state. Each OS thread has a thread-local pointer to a **`PyThreadState`**; a thread state referenced by this pointer is considered to be attached.

A thread can only have one attached thread state at a time. An attached thread state is typically analogous with holding the GIL, except on free-threaded builds. On builds with the GIL enabled, attaching a thread state will block until the GIL can be acquired. However, even on builds with the GIL disabled, it is still required to have an attached thread state to call most of the C API.

In general, there will always be an attached thread state when using Python's C API. Only in some specific cases (such as in a **`Py_BEGIN_ALLOW_THREADS`** block) will the thread not have an attached thread state. If uncertain, check if **`PyThreadState_GetUnchecked()`** returns `NULL`.

Detaching the thread state from extension code

Most extension code manipulating the thread state has the following simple structure:

```
Save the thread state in a local variable.
... Do some blocking I/O operation ...
Restore the thread state from the local variable.
```

This is so common that a pair of macros exists to simplify it:

```
Py_BEGIN_ALLOW_THREADS
... Do some blocking I/O operation ...
Py_END_ALLOW_THREADS
```

The **`Py_BEGIN_ALLOW_THREADS`** macro opens a new block and declares a hidden local variable; the **`Py_END_ALLOW_THREADS`** macro closes the block.

The block above expands to the following code:

```
PyThreadState *_save;

_save = PyEval_SaveThread();
... Do some blocking I/O operation ...
PyEval_RestoreThread(_save);
```

Here is how these functions work:

The attached thread state holds the GIL for the entire interpreter. When detaching the attached thread state, the GIL is released, allowing other threads to attach a thread state to their own thread, thus getting the GIL and can start executing. The pointer to the prior attached thread state is stored as a local variable. Upon reaching `Py_END_ALLOW_THREADS`, the thread state that was previously attached is passed to `PyEval_RestoreThread()`. This function will block until another releases its thread state, thus allowing the old thread state to get re-attached and the C API can be called again.

For free-threaded builds, the GIL is normally out of the question, but detaching the thread state is still required for blocking I/O and long operations. The difference is that threads don’t have to wait for the GIL to be released to attach their thread state, allowing true multi-core parallelism.

Note

Calling system I/O functions is the most common use case for detaching the thread state, but it can also be useful before calling long-running computations which don’t need access to Python objects, such as compression or cryptographic functions operating over memory buffers. For example, the standard `zlib` and `hashlib` modules detach the thread state when compressing or hashing data.

Non-Python created threads

When threads are created using the dedicated Python APIs (such as the `threading` module), a thread state is automatically associated to them and the code showed above is therefore correct. However, when threads are created from C (for example by a third-party library with its own thread management), they don’t hold the GIL, because they don’t have an attached thread state.

If you need to call Python code from these threads (often this will be part of a callback API provided by the aforementioned third-party library), you must first register these threads with the interpreter by creating an attached thread state before you can start using the Python/C API. When you are done, you should detach the thread state, and finally free it.

The **`PyGILState_Ensure()`** and **`PyGILState_Release()`** functions do all of the above automatically. The typical idiom for calling into Python from a C thread is:

```
PyGILState_STATE gstate;
gstate = PyGILState_Ensure();

/* Perform Python actions here. */
result = CallSomeFunction();
/* evaluate result or handle exception */

/* Release the thread. No Python API allowed beyond this point.
*/
PyGILState_Release(gstate);
```

Note that the `PyGILState_*` functions assume there is only one global interpreter (created automatically by **`Py_Initialize()`**). Python supports the creation of additional interpreters (using **`Py_NewInterpreter()`**), but mixing multiple interpreters and the `PyGILState_*` API is unsupported. This is because **`PyGILState_Ensure()`** and similar functions default to attaching a thread state for the main interpreter, meaning that the thread can’t safely interact with the calling subinterpreter.

Supporting subinterpreters in non-Python threads

If you would like to support subinterpreters with non-Python created threads, you must use the `PyThreadState_*` API instead of the traditional `PyGILState_*` API.

In particular, you must store the interpreter state from the calling function and pass it to **`PyThreadState_New()`**, which will ensure that the thread state is targeting the correct interpreter:

```
/* The return value of PyInterpreterState_Get() from the
   function that created this thread. */
PyInterpreterState *interp = ThreadData->interp;
PyThreadState *tstate = PyThreadState_New(interp);
PyThreadState_Swap(tstate);

/* GIL of the subinterpreter is now held.
   Perform Python actions here. */
result = CallSomeFunction();
/* evaluate result or handle exception */

/* Destroy the thread state. No Python API allowed beyond this
point. */
PyThreadState_Clear(tstate);
PyThreadState_DeleteCurrent();
```

Cautions about fork()

Another important thing to note about threads is their behaviour in the face of the C **`fork()`** call. On most systems with **`fork()`**, after a process forks only the thread that issued the fork will exist. This has a concrete impact both on how locks must be handled and on all stored state in CPython’s runtime.

The fact that only the “current” thread remains means any locks held by other threads will never be released. Python solves this for `os.fork()` by acquiring the locks it uses internally before the fork, and releasing them afterwards. In addition, it resets any Lock objects in the child. When extending or embedding Python, there is no way to inform Python of additional (non-Python) locks that need to be acquired before or reset after a fork. OS facilities such as `pthread_atfork()` would need to be used to accomplish the same thing. Additionally, when extending or embedding Python, calling `fork()` directly rather than through `os.fork()` (and returning to or calling into Python) may result in a deadlock by one of Python’s internal locks being held by a thread that is defunct after the fork. `PyOS_AfterFork_Child()` tries to reset the necessary locks, but is not always able to.

The fact that all other threads go away also means that CPython’s runtime state there must be cleaned up properly, which `os.fork()` does. This means finalizing all other `PyThreadState` objects belonging to the current interpreter and all other `PyInterpreterState` objects. Due to this and the special nature of the “main” interpreter, `fork()` should only be called in that interpreter’s “main” thread, where the CPython global runtime was originally initialized. The only exception is if `exec()` will be called immediately after.

Cautions regarding runtime finalization

In the late stage of interpreter shutdown, after attempting to wait for non-daemon threads to exit (though this can be interrupted by `KeyboardInterrupt`) and running the `atexit` functions, the runtime is marked as *finalizing*: `Py_IsFinalizing()` and `sys.is_finalizing()` return true. At this point, only the *finalization thread* that initiated finalization (typically the main thread) is allowed to acquire the GIL.

If any thread, other than the finalization thread, attempts to attach a thread state during finalization, either explicitly or implicitly, the thread enters **a permanently blocked state** where it remains until the program exits. In most cases this is harmless, but this can result in deadlock if a later stage of finalization attempts to acquire a lock owned by the blocked thread, or otherwise waits on the blocked thread.

Gross? Yes. This prevents random crashes and/or unexpectedly skipped C++ finalizations further up the call stack when such threads were forcibly exited here in CPython 3.13 and earlier. The CPython runtime thread state C APIs have never had any error reporting or handling expectations at thread state attachment time that would've allowed for graceful exit from this situation. Changing that would require new stable C APIs and rewriting the majority of C code in the CPython ecosystem to use those with error handling.

High-level API

These are the most commonly used types and functions when writing C extension code, or when embedding the Python interpreter:

type PyInterpreterState

Part of the Limited API (as an opaque struct).
This data structure represents the state shared by a number of cooperating threads. Threads belonging to the same interpreter share their module administration and a few other internal items. There are no public members in this structure.

Threads belonging to different interpreters initially share nothing, except process state like available memory, open file descriptors and such. The global interpreter lock is also shared by all threads, regardless of to which interpreter they belong.

Changed in version 3.12: **PEP 684** [https://peps.python.org/pep-0684/] introduced the possibility of a per-interpreter GIL. See **`Py_NewInterpreterFromConfig()`**.

type PyThreadState

Part of the Limited API (as an opaque struct).

This data structure represents the state of a single thread. The only public data member is:

PyInterpreterState *interp

This thread's interpreter state.

void PyEval_InitThreads()

Part of the Stable ABI.

Deprecated function which does nothing.

In Python 3.6 and older, this function created the GIL if it didn't exist.

Changed in version 3.9: The function now does nothing.

Changed in version 3.7: This function is now called by **`Py_Initialize()`**, so you don't have to call it yourself anymore.

Changed in version 3.2: This function cannot be called before **`Py_Initialize()`** anymore.

Deprecated since version 3.9.

PyThreadState *PyEval_SaveThread()

Part of the Stable ABI.

Detach the attached thread state and return it. The thread will have no thread state upon returning.

void PyEval_RestoreThread(PyThreadState *tstate)

Part of the Stable ABI.

Set the attached thread state to *tstate*. The passed thread state **should not** be attached, otherwise deadlock ensues. *tstate* will be attached upon returning.

Note

Calling this function from a thread when the runtime is finalizing will hang the thread until the program exits, even if the thread was not created by Python. Refer to Cautions regarding runtime finalization for more details.

Changed in version 3.14: Hangs the current thread, rather than terminating it, if called while the interpreter is finalizing.

PyThreadState *PyThreadState_Get()

Part of the Stable ABI.

Return the attached thread state. If the thread has no attached thread state, (such as when inside of **`Py_BEGIN_ALLOW_THREADS`** block), then this issues a fatal error (so that the caller needn't check for `NULL`).

See also **`PyThreadState_GetUnchecked()`**.

PyThreadState *PyThreadState_GetUnchecked()

Similar to **`PyThreadState_Get()`**, but don't kill the process with a fatal error if it is NULL. The caller is responsible to check if the result is NULL.

Added in version 3.13: In Python 3.5 to 3.12, the function was private and known as `_PyThreadState_UncheckedGet()`.

PyThreadState *PyThreadState_Swap(PyThreadState *tstate)

Part of the Stable ABI.

Set the attached thread state to *tstate*, and return the thread state that was attached prior to calling.

This function is safe to call without an attached thread state; it will simply return `NULL` indicating that there was no prior thread state.

See also

`PyEval_ReleaseThread()`

Note

Similar to **`PyGILState_Ensure()`**, this function will hang the thread if the runtime is finalizing.

The following functions use thread-local storage, and are not compatible with sub-interpreters:

type PyGILState_STATE

Part of the Stable ABI.

The type of the value returned by **`PyGILState_Ensure()`** and passed to **`PyGILState_Release()`**.

enumerator PyGILState_LOCKED

The GIL was already held when **`PyGILState_Ensure()`** was called.

enumerator PyGILState_UNLOCKED

The GIL was not held when **`PyGILState_Ensure()`** was called.

PyGILState_STATE PyGILState_Ensure()

Part of the Stable ABI.

Ensure that the current thread is ready to call the Python C API regardless of the current state of Python, or of the attached thread state. This may be called as many times as desired by a thread as long as each call is matched with a call to **`PyGILState_Release()`**. In general, other thread-related APIs may be used between **`PyGILState_Ensure()`** and **`PyGILState_Release()`** calls as long as the thread state is restored to its previous state before the Release(). For example, normal usage of the **`Py_BEGIN_ALLOW_THREADS`** and **`Py_END_ALLOW_THREADS`** macros is acceptable.

The return value is an opaque “handle” to the attached thread state when **`PyGILState_Ensure()`** was called, and must be passed to **`PyGILState_Release()`** to ensure Python is left in the same state. Even though recursive calls are allowed, these handles *cannot* be shared - each unique call to **`PyGILState_Ensure()`** must save the handle for its call to **`PyGILState_Release()`**.

When the function returns, there will be an attached thread state and the thread will be able to call arbitrary Python code. Failure is a fatal error.

Warning

Calling this function when the runtime is finalizing is unsafe. Doing so will either hang the thread until the program ends, or fully crash the interpreter in rare cases. Refer to Cautions regarding runtime finalization for more details.

Changed in version 3.14: Hangs the current thread, rather than terminating it, if called while the interpreter is finalizing.

void PyGILState_Release(PyGILState_STATE)

Part of the Stable ABI.

Release any resources previously acquired. After this call, Python’s state will be the same as it was prior to the corresponding **`PyGILState_Ensure()`** call (but generally this state will be unknown to the caller, hence the use of the GILState API).

Every call to **`PyGILState_Ensure()`** must be matched by a call to **`PyGILState_Release()`** on the same thread.

PyThreadState *PyGILState_GetThisThreadState()

Part of the Stable ABI.

Get the attached thread state for this thread. May return `NULL` if no GILState API has been used on the current thread. Note that the main thread always has such a thread-state, even if no auto-thread-state call has been made on the main thread. This is mainly a helper/diagnostic function.

Note

This function may return non-`NULL` even when the thread state is detached. Prefer **`PyThreadState_Get()`** or **`PyThreadState_GetUnchecked()`** for most cases.

See also

`PyThreadState_Get()`

int PyGILState_Check()

Return `1` if the current thread is holding the GIL and `0` otherwise. This function can be called from any thread at any time. Only if it has had its thread state initialized via `PyGILState_Ensure()` will it return `1`. This is mainly a helper/diagnostic function. It can be useful for example in callback contexts or memory allocation functions when knowing that the GIL is locked can allow the caller to perform sensitive actions or otherwise behave differently.

Note

If the current Python process has ever created a subinterpreter, this function will *always* return `1`. Prefer `PyThreadState_GetUnchecked()` for most cases.

Added in version 3.4.

The following macros are normally used without a trailing semicolon; look for example usage in the Python source distribution.

Py_BEGIN_ALLOW_THREADS

Part of the Stable ABI.

This macro expands to `{ PyThreadState *_save; _save = PyEval_SaveThread();`. Note that it contains an opening brace; it must be matched with a following `Py_END_ALLOW_THREADS` macro. See above for further discussion of this macro.

Py_END_ALLOW_THREADS

Part of the Stable ABI.

This macro expands to `PyEval_RestoreThread(_save); }`. Note that it contains a closing brace; it must be matched with an earlier `Py_BEGIN_ALLOW_THREADS` macro. See above for further discussion of this macro.

Py_BLOCK_THREADS

Part of the Stable ABI.

This macro expands to `PyEval_RestoreThread(_save);`: it is equivalent to **`Py_END_ALLOW_THREADS`** without the closing brace.

Py_UNBLOCK_THREADS

Part of the Stable ABI.

This macro expands to `_save = PyEval_SaveThread();`: it is equivalent to **`Py_BEGIN_ALLOW_THREADS`** without the opening brace and variable declaration.

Low-level API

All of the following functions must be called after **`Py_Initialize()`**.

Changed in version 3.7: **`Py_Initialize()`** now initializes the GIL and sets an attached thread state.

PyInterpreterState *PyInterpreterState_New()

Part of the Stable ABI.

Create a new interpreter state object. An attached thread state is not needed, but may optionally exist if it is necessary to serialize calls to this function.

Raises an auditing event `cpython.PyInterpreterState_New` with no arguments.

void PyInterpreterState_Clear(PyInterpreterState *interp)

Part of the Stable ABI.

Reset all information in an interpreter state object. There must be an attached thread state for the interpreter.

Raises an auditing event `cpython.PyInterpreterState_Clear` with no arguments.

void PyInterpreterState_Delete(PyInterpreterState *interp)

Part of the Stable ABI.
Destroy an interpreter state object. There **should not** be an attached thread state for the target interpreter. The interpreter state must have been reset with a previous call to `PyInterpreterState_Clear()`.

PyThreadState *PyThreadState_New(PyInterpreterState *interp)

Part of the Stable ABI.
Create a new thread state object belonging to the given interpreter object. An attached thread state is not needed.

void PyThreadState_Clear(PyThreadState *tstate)

Part of the Stable ABI.
Reset all information in a thread state object. *tstate* must be attached

Changed in version 3.9: This function now calls the `PyThreadState.on_delete` callback. Previously, that happened in `PyThreadState_Delete()`.

Changed in version 3.13: The `PyThreadState.on_delete` callback was removed.

void PyThreadState_Delete(PyThreadState *tstate)

Part of the Stable ABI.
Destroy a thread state object. *tstate* should not be attached to any thread. *tstate* must have been reset with a previous call to `PyThreadState_Clear()`.

void PyThreadState_DeleteCurrent(void)

Detach the attached thread state (which must have been reset with a previous call to `PyThreadState_Clear()`) and then destroy it.

No thread state will be attached upon returning.

PyFrameObject *PyThreadState_GetFrame(PyThreadState *tstate)

Part of the Stable ABI since version 3.10.
Get the current frame of the Python thread state *tstate*.

Return a strong reference. Return `NULL` if no frame is currently executing.

See also **`PyEval_GetFrame()`**.

tstate must not be `NULL`, and must be attached.

Added in version 3.9.

uint64_t PyThreadState_GetID(PyThreadState *tstate)

Part of the Stable ABI since version 3.10.
Get the unique thread state identifier of the Python thread state *tstate*.

tstate must not be `NULL`, and must be attached.

Added in version 3.9.

PyInterpreterState *PyThreadState_GetInterpreter(PyThreadState *tstate)

Part of the Stable ABI since version 3.10.
Get the interpreter of the Python thread state *tstate*.

tstate must not be `NULL`, and must be attached.

Added in version 3.9.

void PyThreadState_EnterTracing(PyThreadState *tstate)

Suspend tracing and profiling in the Python thread state *tstate*.

Resume them using the **`PyThreadState_LeaveTracing()`** function.

Added in version 3.11.

void PyThreadState_LeaveTracing(PyThreadState *tstate)

Resume tracing and profiling in the Python thread state *tstate* suspended by the **`PyThreadState_EnterTracing()`** function.

See also **`PyEval_SetTrace()`** and **`PyEval_SetProfile()`** functions.

Added in version 3.11.

int PyUnstable_ThreadState_SetStackProtection(PyThreadState *tstate, void *stack_start_addr, size_t stack_size)

This is Unstable API. It may change without warning in minor releases.

Set the stack protection start address and stack protection size of a Python thread state.

On success, return `0`. On failure, set an exception and return `-1`.

CPython implements recursion control for C code by raising **`RecursionError`** when it notices that the machine execution stack is close to overflow. See for example the **`Py_EnterRecursiveCall()`** function. For this, it needs to know the location of the current thread’s stack, which it normally gets from the operating system. When the stack is changed, for example using context switching techniques like the Boost library’s `boost::context`, you must call **`PyUnstable_ThreadState_SetStackProtection()`** to inform CPython of the change.

Call **`PyUnstable_ThreadState_SetStackProtection()`** either before or after changing the stack. Do not call any other Python C API between the call and the stack change.

See **`PyUnstable_ThreadState_ResetStackProtection()`** for undoing this operation.

Added in version 3.14.1:

Warning

This function was added in a bugfix release, and extensions that use it will be incompatible with Python 3.14.0. Most packaging tools for Python are not able to handle this incompatibility automatically, and will need explicit configuration. When using PyPA standards (wheels and source distributions), specify `Requires-Python: != 3.14.0.*` in core metadata [https://packaging.python.org/en/latest/specifications/core-metadata/#requires-python].

void PyUnstable_ThreadState_ResetStackProtection(PyThreadState *tstate)

This is Unstable API. It may change without warning in minor releases.

Reset the stack protection start address and stack protection size of a Python thread state to the operating system defaults.

See `PyUnstable_ThreadState_SetStackProtection()` for an explanation.

Added in version 3.14.1:

Warning

This function was added in a bugfix release, and extensions that use it will be incompatible with Python 3.14.0. Most packaging tools for Python are not able to handle this incompatibility automatically, and will need explicit configuration. When using PyPA standards (wheels and source distributions), specify `Requires-Python: != 3.14.0.*` in core metadata [https://packaging.python.org/en/latest/specifications/core-metadata/#requires-python].

PyInterpreterState *PyInterpreterState_Get(void)

Part of the Stable ABI since version 3.9.
Get the current interpreter.

Issue a fatal error if there no attached thread state. It cannot return NULL.

Added in version 3.9.

int64_t PyInterpreterState_GetID(PyInterpreterState *interp)

Part of the Stable ABI since version 3.7.
Return the interpreter’s unique ID. If there was any error in doing so then `-1` is returned and an error is set.

The caller must have an attached thread state.

Added in version 3.7.

PyObject *PyInterpreterState_GetDict(PyInterpreterState *interp)

Return value: Borrowed reference. Part of the Stable ABI since version 3.8.
Return a dictionary in which interpreter-specific data may be stored. If this function returns `NULL` then no exception has been raised and the caller should assume no interpreter-specific dict is available.

This is not a replacement for **`PyModule_GetState()`**, which extensions should use to store interpreter-specific state information.

The returned dictionary is borrowed from the interpreter and is valid until interpreter shutdown.

Added in version 3.8.

typedef PyObject *(*_PyFrameEvalFunction)(PyThreadState *tstate, _PyInterpreterFrame *frame, int throwflag)

Type of a frame evaluation function.

The *throwflag* parameter is used by the `throw()` method of generators: if non-zero, handle the current exception.

Changed in version 3.9: The function now takes a *tstate* parameter.

Changed in version 3.11: The *frame* parameter changed from `PyFrameObject*` to `_PyInterpreterFrame*`.

_PyFrameEvalFunction _PyInterpreterState_GetEvalFrameFunc(PyInterpreterState *interp)

Get the frame evaluation function.

See the **PEP 523** [https://peps.python.org/pep-0523/] “Adding a frame evaluation API to CPython”.

Added in version 3.9.

void _PyInterpreterState_SetEvalFrameFunc(PyInterpreterState *interp, _PyFrameEvalFunction eval_frame)

Set the frame evaluation function.

See the **PEP 523** [https://peps.python.org/pep-0523/] “Adding a frame evaluation API to CPython”.

Added in version 3.9.

PyObject *PyThreadState_GetDict()

Return value: Borrowed reference. Part of the Stable ABI.
Return a dictionary in which extensions can store thread-specific state information. Each extension should use a unique key to use to store state in the dictionary. It is okay to call this function when no thread state is attached. If this function returns `NULL`, no exception has been raised and the caller should assume no thread state is attached.

int PyThreadState_SetAsyncExc(unsigned long id, PyObject *exc)

Part of the Stable ABI.
Asynchronously raise an exception in a thread. The *id* argument is the thread id of the target thread; *exc* is the exception object to be raised. This function does not steal any references to *exc*. To prevent naive misuse, you must write your own C extension to call this. Must be called with an attached thread state. Returns the number of thread states modified; this is normally one, but will be zero if the thread id isn’t found. If *exc* is `NULL`, the pending

exception (if any) for the thread is cleared. This raises no exceptions.

Changed in version 3.7: The type of the *id* parameter changed from long to unsigned long.

void PyEval_AcquireThread(PyThreadState *tstate)

Part of the Stable ABI.
Attach *tstate* to the current thread, which must not be `NULL` or already attached.

The calling thread must not already have an attached thread state.

Note

Calling this function from a thread when the runtime is finalizing will hang the thread until the program exits, even if the thread was not created by Python. Refer to Cautions regarding runtime finalization for more details.

Changed in version 3.8: Updated to be consistent with `PyEval_RestoreThread()`, `Py_END_ALLOW_THREADS()`, and `PyGILState_Ensure()`, and terminate the current thread if called while the interpreter is finalizing.

Changed in version 3.14: Hangs the current thread, rather than terminating it, if called while the interpreter is finalizing.

`PyEval_RestoreThread()` is a higher-level function which is always available (even when threads have not been initialized).

void PyEval_ReleaseThread(PyThreadState *tstate)

Part of the Stable ABI.

Detach the attached thread state. The *tstate* argument, which must not be `NULL`, is only used to check that it represents the attached thread state — if it isn’t, a fatal error is reported.

`PyEval_SaveThread()` is a higher-level function which is always available (even when threads have not been initialized).

Sub-interpreter support

While in most uses, you will only embed a single Python interpreter, there are cases where you need to create several independent interpreters in the same process and perhaps even in the same thread. Sub-interpreters allow you to do that.

The “main” interpreter is the first one created when the runtime initializes. It is usually the only Python interpreter in a process. Unlike sub-interpreters, the main interpreter has unique process-global responsibilities like signal handling. It is also responsible for execution during runtime initialization and is usually the active interpreter during runtime finalization. The `PyInterpreterState_Main()` function returns a pointer to its state.

You can switch between sub-interpreters using the `PyThreadState_Swap()` function. You can create and destroy them using the following functions:

type PyInterpreterConfig

Structure containing most parameters to configure a sub-interpreter. Its values are used only in `Py_NewInterpreterFromConfig()` and never modified by the runtime.

Added in version 3.12.

Structure fields:

int use_main_obmalloc

If this is `0` then the sub-interpreter will use its own "object" allocator state. Otherwise it will use (share) the main interpreter's.

If this is `0` then `check_multi_interp_extensions` must be `1` (non-zero). If this is `1` then `gil` must not be `PyInterpreterConfig_OWN_GIL`.

int allow_fork

If this is `0` then the runtime will not support forking the process in any thread where the sub-interpreter is currently active. Otherwise fork is unrestricted.

Note that the `subprocess` module still works when fork is disallowed.

int allow_exec

If this is `0` then the runtime will not support replacing the current process via exec (e.g. `os.execv()`) in any thread where the sub-interpreter is currently active. Otherwise exec is unrestricted.

Note that the `subprocess` module still works when exec is disallowed.

int allow_threads

If this is `0` then the sub-interpreter's `threading` module won't create threads. Otherwise threads are allowed.

int allow_daemon_threads

If this is `0` then the sub-interpreter’s `threading` module won’t create daemon threads. Otherwise daemon threads are allowed (as long as `allow_threads` is non-zero).

int check_multi_interp_extensions

If this is `0` then all extension modules may be imported, including legacy (single-phase init) modules, in any thread where the sub-interpreter is currently active. Otherwise only multi-phase init extension modules (see **PEP 489** [https://peps.python.org/pep-0489/]) may be imported. (Also see `Py_mod_multiple_interpreters`.)

This must be `1` (non-zero) if `use_main_obmalloc` is `0`.

int gil

This determines the operation of the GIL for the sub-interpreter. It may be one of the following:

PyInterpreterConfig_DEFAULT_GIL

Use the default selection (`PyInterpreterConfig_SHARED_GIL`).

PyInterpreterConfig_SHARED_GIL

Use (share) the main interpreter’s GIL.

PyInterpreterConfig_OWN_GIL

Use the sub-interpreter’s own GIL.

If this is `PyInterpreterConfig_OWN_GIL` then `PyInterpreterConfig.use_main_obmalloc` must be `0`.

PyStatus Py_NewInterpreterFromConfig(PyThreadState **tstate_p, const PyInterpreterConfig *config)

Create a new sub-interpreter. This is an (almost) totally separate environment for the execution of Python code. In particular, the new interpreter has separate, independent versions of all imported modules, including the fundamental modules **`builtins`**, **`__main__`** and **`sys`**. The table of loaded modules (`sys.modules`) and the module search path (`sys.path`) are also separate. The new environment has no `sys.argv` variable. It has new standard I/O stream file objects `sys.stdin`, `sys.stdout` and `sys.stderr` (however these refer to the same underlying file descriptors).

The given *config* controls the options with which the interpreter is initialized.

Upon success, *tstate_p* will be set to the first thread state created in the new sub-interpreter. This thread state is attached. Note that no actual thread is created; see the discussion of thread states below. If creation of the new interpreter is unsuccessful, *tstate_p* is set to `NULL`; no exception is set since the exception state is stored in the attached thread state, which might not exist.

Like all other Python/C API functions, an attached thread state must be present before calling this function, but it might be detached upon returning. On success, the returned thread state will be attached. If the sub-interpreter is created with its own GIL then the attached thread state of the calling interpreter will be detached. When the function returns, the new interpreter's thread state will be attached to the current thread and the previous interpreter's attached thread state will remain detached.

Added in version 3.12.

Sub-interpreters are most effective when isolated from each other, with certain functionality restricted:

```
PyInterpreterConfig config = {
    .use_main_obmalloc = 0,
    .allow_fork = 0,
    .allow_exec = 0,
    .allow_threads = 1,
    .allow_daemon_threads = 0,
    .check_multi_interp_extensions = 1,
    .gil = PyInterpreterConfig_OWN_GIL,
};
PyThreadState *tstate = NULL;
PyStatus status = Py_NewInterpreterFromConfig(&tstate,
&config);
if (PyStatus_Exception(status)) {
    Py_ExitStatusException(status);
}
```

Note that the config is used only briefly and does not get modified. During initialization the config's values are converted into various `PyInterpreterState` values. A read-only copy of the config may be stored internally on the `PyInterpreterState`.

Extension modules are shared between (sub-)interpreters as follows:

- For modules using multi-phase initialization, e.g. `PyModule_FromDefAndSpec()`, a separate module object is created and initialized for each interpreter. Only C-level static and global variables are shared between these module objects.

- For modules using single-phase initialization, e.g. `PyModule_Create()`, the first time a particular extension is imported, it is initialized normally, and a (shallow) copy of its module's dictionary is squirreled away. When the same extension is imported by another (sub-)interpreter, a new module is initialized and filled with the contents of this copy; the extension's `init` function is not called. Objects in the module's dictionary thus end up shared across (sub-)interpreters, which might cause unwanted behavior (see Bugs and caveats below).

Note that this is different from what happens when an extension is imported after the interpreter has been completely re-initialized by calling `Py_FinalizeEx()` and `Py_Initialize()`; in that case, the extension's `initmodule` function *is* called again. As with multi-phase initialization, this means that only C-level static and global variables are shared between these modules.

PyThreadState *Py_NewInterpreter(void)

Part of the Stable ABI.
Create a new sub-interpreter. This is essentially just a wrapper around `Py_NewInterpreterFromConfig()` with a config that preserves the existing behavior. The result is an unisolated sub-interpreter that shares the main interpreter's GIL, allows fork/exec, allows daemon threads, and allows single-phase init modules.

void Py_EndInterpreter(PyThreadState *tstate)

Part of the Stable ABI.
Destroy the (sub-)interpreter represented by the given thread state. The given thread state must be attached. When the call returns, there will be no attached thread state. All thread states associated with this interpreter are destroyed.

`Py_FinalizeEx()` will destroy all sub-interpreters that haven't been explicitly destroyed at that point.

A Per-Interpreter GIL

Using `Py_NewInterpreterFromConfig()` you can create a sub-interpreter that is completely isolated from other interpreters, including having its own GIL. The most important benefit of this isolation is that such an interpreter can execute Python code without being blocked by other interpreters or blocking any others. Thus a single Python process can truly take advantage of multiple CPU cores when running Python code. The isolation also encourages a different approach to concurrency than that of just using threads. (See **PEP 554** [https://peps.python.org/pep-0554/] and **PEP 684** [https://peps.python.org/pep-0684/].)

Using an isolated interpreter requires vigilance in preserving that isolation. That especially means not sharing any objects or mutable state without guarantees about thread-safety. Even objects that are otherwise immutable (e.g. `None`, `(1, 5)`) can't normally be shared because of the refcount. One simple but less-efficient approach around this is to use a global lock around all use of some state (or object). Alternately, effectively immutable objects (like integers or strings) can be made safe in spite of their refcounts by making them immortal. In fact, this has been done for the builtin singletons, small integers, and a number of other builtin objects.

If you preserve isolation then you will have access to proper multi-core computing without the complications that come with free-threading. Failure to preserve isolation will expose you to the full consequences of free-threading, including races and hard-to-debug crashes.

Aside from that, one of the main challenges of using multiple isolated interpreters is how to communicate between them safely (not break isolation) and efficiently.

The runtime and stdlib do not provide any standard approach to this yet. A future stdlib module would help mitigate the effort of preserving isolation and expose effective tools for communicating (and sharing) data between interpreters.

Added in version 3.12.

Bugs and caveats

Because sub-interpreters (and the main interpreter) are part of the same process, the insulation between them isn't perfect — for example, using low-level file operations like `os.close()` they can (accidentally or maliciously) affect each other's open files. Because of the way extensions are shared between (sub-)interpreters, some extensions may not work properly; this is especially likely when using single-phase initialization or (static) global variables. It is possible to insert objects created in one sub-interpreter into a namespace of another (sub-)interpreter; this should be avoided if possible.

Special care should be taken to avoid sharing user-defined functions, methods, instances or classes between sub-interpreters, since import operations executed by such objects may affect the wrong (sub-)interpreter's dictionary of loaded modules. It is equally important to avoid sharing objects from which the above are reachable.

Also note that combining this functionality with `PyGILState_*` APIs is delicate, because these APIs assume a bijection between Python thread states and OS-level threads, an assumption broken by the presence of sub-interpreters. It is highly recommended that you don't switch sub-interpreters between a pair of matching `PyGILState_Ensure()` and `PyGILState_Release()` calls. Furthermore, extensions (such as `ctypes`) using these APIs to allow calling of Python code from non-Python created threads will probably be broken when using sub-interpreters.

Asynchronous Notifications

A mechanism is provided to make asynchronous notifications to the main interpreter thread. These notifications take the form of a function pointer and a void pointer argument.

int Py_AddPendingCall(int (*func)(void*), void *arg)

Part of the Stable ABI.

Schedule a function to be called from the main interpreter thread. On success, `0` is returned and *func* is queued for being called in the main thread. On failure, `-1` is returned without setting any exception.

When successfully queued, *func* will be *eventually* called from the main interpreter thread with the argument *arg*. It will be called asynchronously with respect to normally running Python code, but with both these conditions met:

- on a bytecode boundary;
- with the main thread holding an attached thread state (*func* can therefore use the full C API).

func must return `0` on success, or `-1` on failure with an exception set. *func* won’t be interrupted to perform another asynchronous notification recursively, but it can still be interrupted to switch threads if the thread state is detached.

This function doesn’t need an attached thread state. However, to call this function in a subinterpreter, the caller must have an attached thread state. Otherwise, the function *func* can be scheduled to be called from the wrong interpreter.

Warning

This is a low-level function, only useful for very special cases. There is no guarantee that *func* will be called as quick as possible. If the main thread is busy executing a system call, *func* won’t be called before the system call returns. This function is generally **not** suitable for calling Python code from arbitrary C threads. Instead, use the PyGILState API.

Added in version 3.1.

Changed in version 3.9: If this function is called in a subinterpreter, the function *func* is now scheduled to be called from the subinterpreter, rather than being called from the main interpreter. Each subinterpreter now has its own list of scheduled calls.

Changed in version 3.12: This function now always schedules *func* to be run in the main interpreter.

int Py_MakePendingCalls(void)

Part of the Stable ABI.

Execute all pending calls. This is usually executed automatically by the interpreter.

This function returns `0` on success, and returns `-1` with an exception set on failure.

If this is not called in the main thread of the main interpreter, this function does nothing and returns `0`. The caller must hold an attached thread state.

Added in version 3.1.

Changed in version 3.12: This function only runs pending calls in the main interpreter.

Profiling and Tracing

The Python interpreter provides some low-level support for attaching profiling and execution tracing facilities. These are used for profiling, debugging, and coverage analysis tools.

This C interface allows the profiling or tracing code to avoid the overhead of calling through Python-level callable objects, making a direct C function call instead. The essential attributes of the facility have not changed; the interface allows trace functions to be installed per-thread, and the basic events reported to the trace function are the same as had been reported to the Python-level trace functions in previous versions.

typedef int (*Py_tracefunc)(PyObject *obj, PyFrameObject *frame, int what, PyObject *arg)

The type of the trace function registered using `PyEval_SetProfile()` and `PyEval_SetTrace()`. The first parameter is the object passed to the registration function as *obj*, *frame* is the frame object to which the event pertains, *what* is one of the constants `PyTrace_CALL`, `PyTrace_EXCEPTION`, `PyTrace_LINE`, `PyTrace_RETURN`, `PyTrace_C_CALL`, `PyTrace_C_EXCEPTION`, `PyTrace_C_RETURN`, or `PyTrace_OPCODE`, and *arg* depends on the value of *what*:

Value of *what*	**Meaning of *arg***
`PyTrace_CALL`	Always `Py_None`.

Value of *what*	**Meaning of *arg***
`PyTrace_EXCEPTION`	Exception information as returned by `sys.exc_info()`.
`PyTrace_LINE`	Always `Py_None`.
`PyTrace_RETURN`	Value being returned to the caller, or `NULL` if caused by an exception.
`PyTrace_C_CALL`	Function object being called.
`PyTrace_C_EXCEPTION`	Function object being called.
`PyTrace_C_RETURN`	Function object being called.
`PyTrace_OPCODE`	Always `Py_None`.

int PyTrace_CALL

The value of the *what* parameter to a `Py_tracefunc` function when a new call to a function or method is being reported, or a new entry into a generator. Note that the creation of the iterator for a generator function is not reported as there is no control transfer to the Python bytecode in the corresponding frame.

int PyTrace_EXCEPTION

The value of the *what* parameter to a `Py_tracefunc` function when an exception has been raised. The callback function is called with this value for *what* when after any bytecode is processed after which the exception becomes set within the frame being executed. The effect of this is that as exception propagation causes the Python stack to unwind, the callback is called upon return to each frame as the exception propagates. Only trace functions receives these events; they are not needed by the profiler.

int PyTrace_LINE

The value passed as the *what* parameter to a `Py_tracefunc` function (but not a profiling function) when a line-number event is being reported. It may be disabled for a frame by setting `f_trace_lines` to *0* on that frame.

int PyTrace_RETURN

The value for the *what* parameter to `Py_tracefunc` functions when a call is about to return.

int PyTrace_C_CALL

The value for the *what* parameter to `Py_tracefunc` functions when a C function is about to be called.

int PyTrace_C_EXCEPTION

The value for the *what* parameter to `Py_tracefunc` functions when a C function has raised an exception.

int PyTrace_C_RETURN

The value for the *what* parameter to `Py_tracefunc` functions when a C function has returned.

int PyTrace_OPCODE

The value for the *what* parameter to `Py_tracefunc` functions (but not profiling functions) when a new opcode is about to be executed. This event is not emitted by default: it must be explicitly requested by setting `f_trace_opcodes` to *1* on the frame.

void PyEval_SetProfile(Py_tracefunc func, PyObject *obj)

Set the profiler function to *func*. The *obj* parameter is passed to the function as its first parameter, and may be any Python object, or `NULL`. If the profile function needs to maintain state, using a different value for *obj* for each thread provides a convenient and thread-safe place to store it. The profile function is called for all monitored events except `PyTrace_LINE` `PyTrace_OPCODE` and `PyTrace_EXCEPTION`.

See also the `sys.setprofile()` function.

The caller must have an attached thread state.

void PyEval_SetProfileAllThreads(Py_tracefunc func, PyObject *obj)

Like `PyEval_SetProfile()` but sets the profile function in all running threads belonging to the current interpreter instead of the setting it only on the current thread.

The caller must have an attached thread state.

As `PyEval_SetProfile()`, this function ignores any exceptions raised while setting the profile functions in all threads.

Added in version 3.12.

void PyEval_SetTrace(Py_tracefunc func, PyObject *obj)

Set the tracing function to *func*. This is similar to `PyEval_SetProfile()`, except the tracing function does receive line-number events and per-opcode events, but does not receive any event related to C function objects being called. Any trace function registered using `PyEval_SetTrace()` will not receive `PyTrace_C_CALL`, `PyTrace_C_EXCEPTION` or `PyTrace_C_RETURN` as a value for the *what* parameter.

See also the `sys.settrace()` function.

The caller must have an attached thread state.

void PyEval_SetTraceAllThreads(Py_tracefunc func, PyObject *obj)

Like **`PyEval_SetTrace()`** but sets the tracing function in all running threads belonging to the current interpreter instead of the setting it only on the current thread.

The caller must have an attached thread state.

As **`PyEval_SetTrace()`**, this function ignores any exceptions raised while setting the trace functions in all threads.

Added in version 3.12.

Reference tracing

Added in version 3.13.

typedef int (*PyRefTracer)(PyObject*, int event, void *data)

The type of the trace function registered using **`PyRefTracer_SetTracer()`**. The first parameter is a Python object that has been just created (when **event** is set to **`PyRefTracer_CREATE`**) or about to be destroyed (when **event** is set to **`PyRefTracer_DESTROY`**). The **data** argument is the opaque pointer that was provided when **`PyRefTracer_SetTracer()`** was called.

Added in version 3.13.

int PyRefTracer_CREATE

The value for the *event* parameter to **`PyRefTracer`** functions when a Python object has been created.

int PyRefTracer_DESTROY

The value for the *event* parameter to **`PyRefTracer`** functions when a Python object has been destroyed.

int PyRefTracer_SetTracer(PyRefTracer tracer, void *data)

Register a reference tracer function. The function will be called when a new Python has been created or when an object is going to be destroyed. If **data** is provided it must be an opaque pointer that will be provided when the tracer function is called. Return `0` on success. Set an exception and return `-1` on error.

Not that tracer functions **must not** create Python objects inside or otherwise the call will be re-entrant. The tracer also **must not** clear any existing exception or set an exception. A thread state will be active every time the tracer function is called.

There must be an attached thread state when calling this function.

Added in version 3.13.

PyRefTracer PyRefTracer_GetTracer(void **data)

Get the registered reference tracer function and the value of the opaque data pointer that was registered when **`PyRefTracer_SetTracer()`** was called. If no tracer was registered this function will return NULL and will set the **data** pointer to NULL.

There must be an attached thread state when calling this function.

Added in version 3.13.

Advanced Debugger Support

These functions are only intended to be used by advanced debugging tools.

PyInterpreterState *PyInterpreterState_Head()

Return the interpreter state object at the head of the list of all such objects.

PyInterpreterState *PyInterpreterState_Main()

Return the main interpreter state object.

PyInterpreterState *PyInterpreterState_Next(PyInterpreterState *interp)

Return the next interpreter state object after *interp* from the list of all such objects.

PyThreadState *PyInterpreterState_ThreadHead(PyInterpreterState *interp)

Return the pointer to the first **`PyThreadState`** object in the list of threads associated with the interpreter *interp*.

PyThreadState *PyThreadState_Next(PyThreadState *tstate)

Return the next thread state object after *tstate* from the list of all such objects belonging to the same **`PyInterpreterState`** object.

Thread Local Storage Support

The Python interpreter provides low-level support for thread-local storage (TLS) which wraps the underlying native TLS implementation to support the Python-level thread local storage API (**`threading.local`**). The CPython C level APIs are similar to those offered by pthreads and Windows: use a thread key and functions to associate a void* value per thread.

A thread state does *not* need to be attached when calling these functions; they suppl their own locking.

Note that `Python.h` does not include the declaration of the TLS APIs, you need to include `pythread.h` to use thread-local storage.

Note

None of these API functions handle memory management on behalf of the void* values. You need to allocate and deallocate them yourself. If the void* values happen to be PyObject*, these functions don't do refcount operations on them either.

Thread Specific Storage (TSS) API

TSS API is introduced to supersede the use of the existing TLS API within the CPython interpreter. This API uses a new type **`Py_tss_t`** instead of int to represent thread keys.

Added in version 3.7.

See also

"A New C-API for Thread-Local Storage in CPython" (**PEP 539** [https://peps.python.org/pep-0539/])

type Py_tss_t

This data structure represents the state of a thread key, the definition of which may depend on the underlying TLS implementation, and it has an internal field representing the key's initialization state. There are no public members in this structure.

When Py_LIMITED_API is not defined, static allocation of this type by `Py_tss_NEEDS_INIT` is allowed.

Py_tss_NEEDS_INIT

This macro expands to the initializer for `Py_tss_t` variables. Note that this macro won’t be defined with Py_LIMITED_API.

Dynamic Allocation

Dynamic allocation of the `Py_tss_t`, required in extension modules built with Py_LIMITED_API, where static allocation of this type is not possible due to its implementation being opaque at build time.

Py_tss_t *PyThread_tss_alloc()

Part of the Stable ABI since version 3.7.
Return a value which is the same state as a value initialized with `Py_tss_NEEDS_INIT`, or `NULL` in the case of dynamic allocation failure.

void PyThread_tss_free(Py_tss_t *key)

Part of the Stable ABI since version 3.7.
Free the given *key* allocated by `PyThread_tss_alloc()`, after first calling `PyThread_tss_delete()` to ensure any associated thread locals have been unassigned. This is a no-op if the *key* argument is `NULL`.

Note

A freed key becomes a dangling pointer. You should reset the key to `NULL`.

Methods

The parameter *key* of these functions must not be `NULL`. Moreover, the behaviors of **`PyThread_tss_set()`** and **`PyThread_tss_get()`** are undefined if the given **`Py_tss_t`** has not been initialized by **`PyThread_tss_create()`**.

int PyThread_tss_is_created(Py_tss_t *key)

Part of the Stable ABI since version 3.7.
Return a non-zero value if the given **`Py_tss_t`** has been initialized by **`PyThread_tss_create()`**.

int PyThread_tss_create(Py_tss_t *key)

Part of the Stable ABI since version 3.7.
Return a zero value on successful initialization of a TSS key. The behavior is undefined if the value pointed to by the *key* argument is not initialized by **`Py_tss_NEEDS_INIT`**. This function can be called repeatedly on the same key – calling it on an already initialized key is a no-op and immediately returns success.

void PyThread_tss_delete(Py_tss_t *key)

Part of the Stable ABI since version 3.7.
Destroy a TSS key to forget the values associated with the key across all threads, and change the key's initialization state to uninitialized. A destroyed key is able to be initialized again by **`PyThread_tss_create()`**. This function can be called repeatedly on the same key – calling it on an already destroyed key is a no-op.

int PyThread_tss_set(Py_tss_t *key, void *value)

Part of the Stable ABI since version 3.7.
Return a zero value to indicate successfully associating a void* value with a TSS key in the current thread. Each thread has a distinct mapping of the key to a void* value.

void *PyThread_tss_get(Py_tss_t *key)

Part of the Stable ABI since version 3.7.
Return the void* value associated with a TSS key in the current thread. This returns `NULL` if no value is associated with the key in the current thread.

Thread Local Storage (TLS) API

Deprecated since version 3.7: This API is superseded by Thread Specific Storage (TSS) API.

Note

This version of the API does not support platforms where the native TLS key is defined in a way that cannot be safely cast to `int`. On such platforms, **`PyThread_create_key()`** will return immediately with a failure status, and the other TLS functions will all be no-ops on such platforms.

Due to the compatibility problem noted above, this version of the API should not be used in new code.

int PyThread_create_key()
Part of the Stable ABI.

void PyThread_delete_key(int key)
Part of the Stable ABI.

int PyThread_set_key_value(int key, void *value)
Part of the Stable ABI.

void *PyThread_get_key_value(int key)
Part of the Stable ABI.

void PyThread_delete_key_value(int key)

Part of the Stable ABI.

void PyThread_ReInitTLS()

Part of the Stable ABI.

Synchronization Primitives

The C-API provides a basic mutual exclusion lock.

type PyMutex

A mutual exclusion lock. The **`PyMutex`** should be initialized to zero to represent the unlocked state. For example:

```
PyMutex mutex = {0};
```

Instances of **`PyMutex`** should not be copied or moved. Both the contents and address of a **`PyMutex`** are meaningful, and it must remain at a fixed, writable location in memory.

Note

A **`PyMutex`** currently occupies one byte, but the size should be considered unstable. The size may change in future Python releases without a deprecation period.

Added in version 3.13.

void PyMutex_Lock(PyMutex *m)

Lock mutex *m*. If another thread has already locked it, the calling thread will block until the mutex is unlocked. While blocked, the thread will temporarily detach the thread state if one exists.

Added in version 3.13.

void PyMutex_Unlock(PyMutex *m)

Unlock mutex *m*. The mutex must be locked — otherwise, the function will issue a fatal error.

Added in version 3.13.

int PyMutex_IsLocked(PyMutex *m)

Returns non-zero if the mutex *m* is currently locked, zero otherwise.

Note

This function is intended for use in assertions and debugging only and should not be used to make concurrency control decisions, as the lock state may change immediately after the check.

Added in version 3.14.

Python Critical Section API

The critical section API provides a deadlock avoidance layer on top of per-object locks for free-threaded CPython. They are intended to replace reliance on the global interpreter lock, and are no-ops in versions of Python with the global interpreter lock.

Critical sections are intended to be used for custom types implemented in C-API extensions. They should generally not be used with built-in types like `list` and `dict` because their public C-APIs already use critical sections internally, with the notable exception of `PyDict_Next()`, which requires critical section to be acquired externally.

Critical sections avoid deadlocks by implicitly suspending active critical sections, hence, they do not provide exclusive access such as provided by traditional locks like `PyMutex`. When a critical section is started, the per-object lock for the object is acquired. If the code executed inside the critical section calls C-API functions then it can suspend the critical section thereby releasing the per-object lock, so other threads can acquire the per-object lock for the same object.

Variants that accept `PyMutex` pointers rather than Python objects are also available. Use these variants to start a critical section in a situation where there is no `PyObject` – for example, when working with a C type that does not extend or wrap `PyObject` but still needs to call into the C API in a manner that might lead to deadlocks.

The functions and structs used by the macros are exposed for cases where C macros are not available. They should only be used as in the given macro expansions. Note that the sizes and contents of the structures may change in future Python versions.

Note

Operations that need to lock two objects at once must use `Py_BEGIN_CRITICAL_SECTION2`. You *cannot* use nested critical sections to lock more than one object at once, because the inner critical section may suspend the outer critical sections. This API does not provide a way to lock more than two objects at once.

Example usage:

```
static PyObject *
set_field(MyObject *self, PyObject *value)
{
   Py_BEGIN_CRITICAL_SECTION(self);
   Py_SETREF(self->field, Py_XNewRef(value));
```

```
    Py_END_CRITICAL_SECTION();
    Py_RETURN_NONE;
}
```

In the above example, **`Py_SETREF`** calls **`Py_DECREF`**, which can call arbitrary code through an object's deallocation function. The critical section API avoids potential deadlocks due to reentrancy and lock ordering by allowing the runtime to temporarily suspend the critical section if the code triggered by the finalizer blocks and calls **`PyEval_SaveThread()`**.

Py_BEGIN_CRITICAL_SECTION(op)

Acquires the per-object lock for the object *op* and begins a critical section.

In the free-threaded build, this macro expands to:

```
{
    PyCriticalSection _py_cs;
    PyCriticalSection_Begin(&_py_cs, (PyObject*)(op))
```

In the default build, this macro expands to `{`.

Added in version 3.13.

Py_BEGIN_CRITICAL_SECTION_MUTEX(m)

Locks the mutex *m* and begins a critical section.

In the free-threaded build, this macro expands to:

```
{
     PyCriticalSection _py_cs;
     PyCriticalSection_BeginMutex(&_py_cs, m)
```

Note that unlike **`Py_BEGIN_CRITICAL_SECTION`**, there is no cast for the argument of the macro - it must be a **`PyMutex`** pointer.

On the default build, this macro expands to `{`.

Added in version 3.14.

Py_END_CRITICAL_SECTION()

Ends the critical section and releases the per-object lock.

In the free-threaded build, this macro expands to:

```
    PyCriticalSection_End(&_py_cs);
}
```

In the default build, this macro expands to `}`.

Added in version 3.13.

Py_BEGIN_CRITICAL_SECTION2(a, b)

Acquires the per-objects locks for the objects *a* and *b* and begins a critical section. The locks are acquired in a consistent order (lowest address first) to avoid lock ordering deadlocks.

In the free-threaded build, this macro expands to:

```
{
    PyCriticalSection2 _py_cs2;
    PyCriticalSection2_Begin(&_py_cs2, (PyObject*)(a), 
(PyObject*)(b))
```

In the default build, this macro expands to `{`.

Added in version 3.13.

Py_BEGIN_CRITICAL_SECTION2_MUTEX(m1, m2)

Locks the mutexes *m1* and *m2* and begins a critical section.

In the free-threaded build, this macro expands to:

```
{
     PyCriticalSection2 _py_cs2;
```

```
    PyCriticalSection2_BeginMutex(&_py_cs2, m1, m2)
```

Note that unlike `Py_BEGIN_CRITICAL_SECTION2`, there is no cast for the arguments of the macro - they must be `PyMutex` pointers.

On the default build, this macro expands to `{`.

Added in version 3.14.

Py_END_CRITICAL_SECTION2()

Ends the critical section and releases the per-object locks.

In the free-threaded build, this macro expands to:

```
    PyCriticalSection2_End(&_py_cs2);
}
```

In the default build, this macro expands to `}`.

Added in version 3.13.

Legacy Locking APIs

These APIs are obsolete since Python 3.13 with the introduction of `PyMutex`.

Changed in version 3.15: These APIs are now a simple wrapper around `PyMutex`.

type PyThread_type_lock

A pointer to a mutual exclusion lock.

type PyLockStatus

The result of acquiring a lock with a timeout.

enumerator PY_LOCK_FAILURE

Failed to acquire the lock.

enumerator PY_LOCK_ACQUIRED

The lock was successfully acquired.

enumerator PY_LOCK_INTR

The lock was interrupted by a signal.

PyThread_type_lock PyThread_allocate_lock(void)

Part of the Stable ABI.

Allocate a new lock.

On success, this function returns a lock; on failure, this function returns `0` without an exception set.

The caller does not need to hold an attached thread state.

Changed in version 3.15: This function now always uses **`PyMutex`**. In prior versions, this would use a lock provided by the operating system.

void PyThread_free_lock(PyThread_type_lock lock)

Part of the Stable ABI.

Destroy *lock*. The lock should not be held by any thread when calling this.

The caller does not need to hold an attached thread state.

PyLockStatus PyThread_acquire_lock_timed(PyThread_type_lock lock, long long microseconds, int intr_flag)

Part of the Stable ABI.

Acquire *lock* with a timeout.

This will wait for *microseconds* microseconds to acquire the lock. If the timeout expires, this function returns **`PY_LOCK_FAILURE`**. If *microseconds* is `-1`, this will wait indefinitely until the lock has been released.

If *intr_flag* is `1`, acquiring the lock may be interrupted by a signal, in which case this function returns **`PY_LOCK_INTR`**. Upon interruption, it's generally expected that the caller makes a call to **`Py_MakePendingCalls()`** to propagate an exception to Python code.

If the lock is successfully acquired, this function returns **`PY_LOCK_ACQUIRED`**.

The caller does not need to hold an attached thread state.

int PyThread_acquire_lock(PyThread_type_lock lock, int waitflag)

Part of the Stable ABI.
Acquire *lock*.

If *waitflag* is `1` and another thread currently holds the lock, this function will wait until the lock can be acquired and will always return `1`.

If *waitflag* is `0` and another thread holds the lock, this function will not wait and instead return `0`. If the lock is not held by any other thread, then this function will acquire it and return `1`.

Unlike **`PyThread_acquire_lock_timed()`**, acquiring the lock cannot be interrupted by a signal.

The caller does not need to hold an attached thread state.

int PyThread_release_lock(PyThread_type_lock lock)

Part of the Stable ABI.

Release *lock*. If *lock* is not held, then this function issues a fatal error.

The caller does not need to hold an attached thread state.

Operating System Thread APIs

PYTHREAD_INVALID_THREAD_ID

Sentinel value for an invalid thread ID.

This is currently equivalent to `(unsigned long)-1`.

unsigned long PyThread_start_new_thread(void (*func)(void*), void *arg)

Part of the Stable ABI.

Start function *func* in a new thread with argument *arg*. The resulting thread is not intended to be joined.

func must not be `NULL`, but *arg* may be `NULL`.

On success, this function returns the identifier of the new thread; on failure, this returns **`PYTHREAD_INVALID_THREAD_ID`**.

The caller does not need to hold an attached thread state.

unsigned long PyThread_get_thread_ident(void)

Part of the Stable ABI.

Return the identifier of the current thread, which will never be zero.

This function cannot fail, and the caller does not need to hold an attached thread state.

See also

`threading.get_ident()`

PyObject *PyThread_GetInfo(void)

Part of the Stable ABI since version 3.3.
Get general information about the current thread in the form of a struct sequence object. This information is accessible as `sys.thread_info` in Python.

On success, this returns a new strong reference to the thread information; on failure, this returns `NULL` with an exception set.

The caller must hold an attached thread state.

PY_HAVE_THREAD_NATIVE_ID

This macro is defined when the system supports native thread IDs.

unsigned long PyThread_get_thread_native_id(void)

Part of the Stable ABI on platforms with native thread IDs.
Get the native identifier of the current thread as it was assigned by the operating system’s kernel, which will never be less than zero.

This function is only available when `PY_HAVE_THREAD_NATIVE_ID` is defined.

This function cannot fail, and the caller does not need to hold an attached thread state.

See also

`threading.get_native_id()`

void PyThread_exit_thread(void)

Part of the Stable ABI.

Terminate the current thread. This function is generally considered unsafe and should be avoided. It is kept solely for backwards compatibility.

This function is only safe to call if all functions in the full call stack are written to safely allow it.

Warning

If the current system uses POSIX threads (also known as “pthreads”), this calls *pthread_exit(3)* *[https://manpages.debian.org/pthread_exit(3)]*, which attempts to unwind the stack and call C++ destructors on some libc implementations. However, if a `noexcept` function is reached, it may terminate the process. Other systems, such as macOS, do unwinding.

On Windows, this function calls `_endthreadex()`, which kills the thread without calling C++ destructors.

In any case, there is a risk of corruption on the thread’s stack.

Deprecated since version 3.14.

void PyThread_init_thread(void)

Part of the Stable ABI.

Initialize `PyThread*` APIs. Python executes this function automatically, so there’s little need to call it from an extension module.

int PyThread_set_stacksize(size_t size)

Part of the Stable ABI.

Set the stack size of the current thread to *size* bytes.

This function returns `0` on success, `-1` if *size* is invalid, or `-2` if the system does not support changing the stack size. This function does not set exceptions.

The caller does not need to hold an attached thread state.

size_t PyThread_get_stacksize(void)

Part of the Stable ABI.

Return the stack size of the current thread in bytes, or `0` if the system’s default stack size is in use.

The caller does not need to hold an attached thread state.

Python Initialization Configuration

PyInitConfig C API

Added in version 3.14.

Python can be initialized with `Py_InitializeFromInitConfig()`.

The `Py_RunMain()` function can be used to write a customized Python program.

See also Initialization, Finalization, and Threads.

See also

PEP 741 [https://peps.python.org/pep-0741/] “Python Configuration C API”.

Example

Example of customized Python always running with the Python Development Mode enabled; return `-1` on error:

```
int init_python(void)
{
    PyInitConfig *config = PyInitConfig_Create();
    if (config == NULL) {
        printf("PYTHON INIT ERROR: memory allocation failed\n");
        return -1;
    }

    // Enable the Python Development Mode
    if (PyInitConfig_SetInt(config, "dev_mode", 1) < 0) {
        goto error;
    }

    // Initialize Python with the configuration
    if (Py_InitializeFromInitConfig(config) < 0) {
        goto error;
    }
    PyInitConfig_Free(config);
    return 0;
error:
    {
        // Display the error message.
        //
        // This uncommon braces style is used, because you cannot make
        // goto targets point to variable declarations.
        const char *err_msg;
        (void)PyInitConfig_GetError(config, &err_msg);
        printf("PYTHON INIT ERROR: %s\n", err_msg);
        PyInitConfig_Free(config);
        return -1;
    }
}
```

Create Config

struct PyInitConfig

Opaque structure to configure the Python initialization.

PyInitConfig *PyInitConfig_Create(void)

Create a new initialization configuration using Isolated Configuration default values.

It must be freed by **`PyInitConfig_Free()`**.

Return `NULL` on memory allocation failure.

void PyInitConfig_Free(PyInitConfig *config)

Free memory of the initialization configuration *config*.

If *config* is `NULL`, no operation is performed.

Error Handling

int PyInitConfig_GetError(PyInitConfig *config, const char **err_msg)

Get the *config* error message.

- Set **err_msg* and return `1` if an error is set.
- Set **err_msg* to `NULL` and return `0` otherwise.

An error message is a UTF-8 encoded string.

If *config* has an exit code, format the exit code as an error message.

The error message remains valid until another `PyInitConfig` function is called with *config*. The caller doesn’t have to free the error message.

int PyInitConfig_GetExitCode(PyInitConfig *config, int *exitcode)

Get the *config* exit code.

- Set **exitcode* and return `1` if *config* has an exit code set.
- Return `0` if *config* has no exit code set.

Only the `Py_InitializeFromInitConfig()` function can set an exit code if the `parse_argv` option is non-zero.

An exit code can be set when parsing the command line failed (exit code `2`) or when a command line option asks to display the command line help (exit code `0`).

Get Options

The configuration option *name* parameter must be a non-NULL null-terminated UTF-8 encoded string. See Configuration Options.

int PyInitConfig_HasOption(PyInitConfig *config, const char *name)

Test if the configuration has an option called *name*.

Return `1` if the option exists, or return `0` otherwise.

int PyInitConfig_GetInt(PyInitConfig *config, const char *name, int64_t *value)

Get an integer configuration option.

- Set **value*, and return `0` on success.
- Set an error in *config* and return `-1` on error.

int PyInitConfig_GetStr(PyInitConfig *config, const char *name, char **value)

Get a string configuration option as a null-terminated UTF-8 encoded string.

- Set **value*, and return `0` on success.
- Set an error in *config* and return `-1` on error.

**value* can be set to `NULL` if the option is an optional string and the option is unset.

On success, the string must be released with `free(value)` if it’s not `NULL`.

int PyInitConfig_GetStrList(PyInitConfig *config, const char *name, size_t *length, char ***items)

Get a string list configuration option as an array of null-terminated UTF-8 encoded strings.

- Set **length* and **value*, and return `0` on success.
- Set an error in *config* and return `-1` on error.

On success, the string list must be released with `PyInitConfig_FreeStrList(length, items)`.

void PyInitConfig_FreeStrList(size_t length, char **items)

Free memory of a string list created by `PyInitConfig_GetStrList()`.

Set Options

The configuration option *name* parameter must be a non-NULL null-terminated UTF-8 encoded string. See Configuration Options.

Some configuration options have side effects on other options. This logic is only implemented when `Py_InitializeFromInitConfig()` is called, not by the “Set” functions below. For example, setting `dev_mode` to `1` does not set `faulthandler` to `1`.

int PyInitConfig_SetInt(PyInitConfig *config, const char *name, int64_t value)

Set an integer configuration option.

- Return `0` on success.
- Set an error in *config* and return `-1` on error.

int PyInitConfig_SetStr(PyInitConfig *config, const char *name, const char *value)

Set a string configuration option from a null-terminated UTF-8 encoded string. The string is copied.

- Return `0` on success.
- Set an error in *config* and return `-1` on error.

int PyInitConfig_SetStrList(PyInitConfig *config, const char *name, size_t length, char *const *items)

Set a string list configuration option from an array of null-terminated UTF-8 encoded strings. The string list is copied.

- Return `0` on success.
- Set an error in *config* and return `-1` on error.

Module

int PyInitConfig_AddModule(PyInitConfig *config, const char *name, PyObject *(*initfunc)(void))

Add a built-in extension module to the table of built-in modules.

The new module can be imported by the name *name*, and uses the function *initfunc* as the initialization function called on the first attempted import.

- Return `0` on success.
- Set an error in *config* and return `-1` on error.

If Python is initialized multiple times, `PyInitConfig_AddModule()` must be called at each Python initialization.

Similar to the **`PyImport_AppendInittab()`** function.

Initialize Python

int Py_InitializeFromInitConfig(PyInitConfig *config)

Initialize Python from the initialization configuration.

- Return `0` on success.
- Set an error in *config* and return `-1` on error.
- Set an exit code in *config* and return `-1` if Python wants to exit.

See `PyInitConfig_GetExitcode()` for the exit code case.

Configuration Options

Option	PyConfig/PyPreConfig member	Type	Visibility
`"allocator"`	**`allocator`**	`int`	Read-only

`"user_site_directory"`	`user_site_directory`	`bool`	Read-only
`"utf8_mode"`	`utf8_mode`	`bool`	Read-only
`"verbose"`	`verbose`	`int`	Public
`"warn_default_encoding"`	`warn_default_encoding`	`bool`	Read-only
`"warnoptions"`	`warnoptions`	`list[str]`	Public
`"write_bytecode"`	`write_bytecode`	`bool`	Public
`"xoptions"`	`xoptions`	`dict[str, str]`	Public
`"_pystats"`	`_pystats`	`bool`	Read-only

Visibility:

- Public: Can by get by `PyConfig_Get()` and set by `PyConfig_Set()`.
- Read-only: Can by get by `PyConfig_Get()`, but cannot be set by `PyConfig_Set()`.

Runtime Python configuration API

At runtime, it’s possible to get and set configuration options using **`PyConfig_Get()`** and **`PyConfig_Set()`** functions.

The configuration option *name* parameter must be a non-NULL null-terminated UTF-8 encoded string. See Configuration Options.

Some options are read from the **`sys`** attributes. For example, the option `"argv"` is read from **`sys.argv`**.

PyObject *PyConfig_Get(const char *name)

Get the current runtime value of a configuration option as a Python object.

- Return a new reference on success.
- Set an exception and return `NULL` on error.

The object type depends on the configuration option. It can be:

- `bool`
- `int`
- `str`
- `list[str]`
- `dict[str, str]`

The caller must have an attached thread state. The function cannot be called before Python initialization nor after Python finalization.

Added in version 3.14.

int PyConfig_GetInt(const char *name, int *value)

Similar to **`PyConfig_Get()`**, but get the value as a C int.

- Return `0` on success.
- Set an exception and return `-1` on error.

Added in version 3.14.

PyObject *PyConfig_Names(void)

Get all configuration option names as a `frozenset`.

- Return a new reference on success.
- Set an exception and return `NULL` on error.

The caller must have an attached thread state. The function cannot be called before Python initialization nor after Python finalization.

Added in version 3.14.

int PyConfig_Set(const char *name, PyObject *value)

Set the current runtime value of a configuration option.

- Raise a `ValueError` if there is no option *name*.
- Raise a `ValueError` if *value* is an invalid value.
- Raise a `ValueError` if the option is read-only (cannot be set).
- Raise a `TypeError` if *value* has not the proper type.

The caller must have an attached thread state. The function cannot be called before Python initialization nor after Python finalization.

Raises an auditing event `cpython.PyConfig_Set` with arguments `name`, `value`.

Added in version 3.14.

PyConfig C API

Added in version 3.8.

Python can be initialized with `Py_InitializeFromConfig()` and the `PyConfig` structure. It can be preinitialized with `Py_PreInitialize()` and the `PyPreConfig` structure.

There are two kinds of configuration:

- The Python Configuration can be used to build a customized Python which behaves as the regular Python. For example, environment variables and command line arguments are used to configure Python.
- The Isolated Configuration can be used to embed Python into an application. It isolates Python from the system. For example, environment variables are ignored, the LC_CTYPE locale is left unchanged and no signal handler is registered.

The `Py_RunMain()` function can be used to write a customized Python program.

See also Initialization, Finalization, and Threads.

See also

PEP 587 [https://peps.python.org/pep-0587/] “Python Initialization Configuration”.

Example

Example of customized Python always running in isolated mode:

```
int main(int argc, char **argv)
{
    PyStatus status;

    PyConfig config;
    PyConfig_InitPythonConfig(&config);
    config.isolated = 1;

    /* Decode command line arguments.
       Implicitly preinitialize Python (in isolated mode). */
    status = PyConfig_SetBytesArgv(&config, argc, argv);
    if (PyStatus_Exception(status)) {
        goto exception;
    }

    status = Py_InitializeFromConfig(&config);
    if (PyStatus_Exception(status)) {
        goto exception;
    }
    PyConfig_Clear(&config);

    return Py_RunMain();

exception:
    PyConfig_Clear(&config);
    if (PyStatus_IsExit(status)) {
        return status.exitcode;
    }
    /* Display the error message and exit the process with
       non-zero exit code */
    Py_ExitStatusException(status);
}
```

PyWideStringList

type PyWideStringList

List of `wchar_t*` strings.

If *length* is non-zero, *items* must be non-`NULL` and all strings must be non-`NULL`.

Methods:

PyStatus PyWideStringList_Append(PyWideStringList *list, const wchar_t *item)

Append *item* to *list*.

Python must be preinitialized to call this function.

PyStatus PyWideStringList_Insert(PyWideStringList *list, Py_ssize_t index, const wchar_t *item)

Insert *item* into *list* at *index*.

If *index* is greater than or equal to *list* length, append *item* to *list*.

index must be greater than or equal to `0`.

Python must be preinitialized to call this function.

Structure fields:

Py_ssize_t length

List length.

wchar_t **items

List items.

PyStatus

type PyStatus

Structure to store an initialization function status: success, error or exit.

For an error, it can store the C function name which created the error.

Structure fields:

int exitcode

Exit code. Argument passed to `exit()`.

const char *err_msg

Error message.

const char *func

Name of the function which created an error, can be `NULL`.

Functions to create a status:

PyStatus PyStatus_Ok(void)

Success.

PyStatus PyStatus_Error(const char *err_msg)

Initialization error with a message.

err_msg must not be `NULL`.

PyStatus PyStatus_NoMemory(void)

Memory allocation failure (out of memory).

PyStatus PyStatus_Exit(int exitcode)

Exit Python with the specified exit code.

Functions to handle a status:

int PyStatus_Exception(PyStatus status)

Is the status an error or an exit? If true, the exception must be handled; by calling **`Py_ExitStatusException()`** for example.

int PyStatus_IsError(PyStatus status)

Is the result an error?

int PyStatus_IsExit(PyStatus status)

Is the result an exit?

void Py_ExitStatusException(PyStatus status)

Call `exit(exitcode)` if *status* is an exit. Print the error message and exit with a non-zero exit code if *status* is an error. Must only be called if `PyStatus_Exception(status)` is non-zero.

Note

Internally, Python uses macros which set `PyStatus.func`, whereas functions to create a status set `func` to `NULL`.

Example:

```
PyStatus alloc(void **ptr, size_t size)
{
    *ptr = PyMem_RawMalloc(size);
    if (*ptr == NULL) {
        return PyStatus_NoMemory();
    }
    return PyStatus_Ok();
}
```

```
int main(int argc, char **argv)
{
    void *ptr;
    PyStatus status = alloc(&ptr, 16);
    if (PyStatus_Exception(status)) {
        Py_ExitStatusException(status);
    }
    PyMem_Free(ptr);
    return 0;
}
```

PyPreConfig

type PyPreConfig

Structure used to preinitialize Python.

Function to initialize a preconfiguration:

void PyPreConfig_InitPythonConfig(PyPreConfig *preconfig)

Initialize the preconfiguration with Python Configuration.

void PyPreConfig_InitIsolatedConfig(PyPreConfig *preconfig)

Initialize the preconfiguration with Isolated Configuration.

Structure fields:

int allocator

Name of the Python memory allocators:

- `PYMEM_ALLOCATOR_NOT_SET` (`0`): don’t change memory allocators (use defaults).
- `PYMEM_ALLOCATOR_DEFAULT` (`1`): default memory allocators.
- `PYMEM_ALLOCATOR_DEBUG` (`2`): default memory allocators with debug hooks.
- `PYMEM_ALLOCATOR_MALLOC` (`3`): use `malloc()` of the C library.
- `PYMEM_ALLOCATOR_MALLOC_DEBUG` (`4`): force usage of `malloc()` with debug hooks.
- `PYMEM_ALLOCATOR_PYMALLOC` (`5`): Python pymalloc memory allocator.
- `PYMEM_ALLOCATOR_PYMALLOC_DEBUG` (`6`): Python pymalloc memory allocator with debug hooks.
- `PYMEM_ALLOCATOR_MIMALLOC` (`6`): use `mimalloc`, a fast malloc replacement.
- `PYMEM_ALLOCATOR_MIMALLOC_DEBUG` (`7`): use `mimalloc`, a fast malloc replacement with debug hooks.

`PYMEM_ALLOCATOR_PYMALLOC` and `PYMEM_ALLOCATOR_PYMALLOC_DEBUG` are not supported if Python is **`configured using --without-pymalloc`**.

`PYMEM_ALLOCATOR_MIMALLOC` and `PYMEM_ALLOCATOR_MIMALLOC_DEBUG` are not supported if Python is **`configured using --without-mimalloc`** or if the underlying atomic support isn't available.

See Memory Management.

Default: `PYMEM_ALLOCATOR_NOT_SET`.

int configure_locale

Set the LC_CTYPE locale to the user preferred locale.

If equals to `0`, set **`coerce_c_locale`** and **`coerce_c_locale_warn`** members to `0`.

See the locale encoding.

Default: `1` in Python config, `0` in isolated config.

int coerce_c_locale

If equals to `2`, coerce the C locale.

If equals to `1`, read the LC_CTYPE locale to decide if it should be coerced.

See the locale encoding.

Default: `-1` in Python config, `0` in isolated config.

int coerce_c_locale_warn

If non-zero, emit a warning if the C locale is coerced.

Default: `-1` in Python config, `0` in isolated config.

int dev_mode

Python Development Mode: see **`PyConfig.dev_mode`**.

Default: `-1` in Python mode, `0` in isolated mode.

int isolated

Isolated mode: see **`PyConfig.isolated`**.

Default: `0` in Python mode, `1` in isolated mode.

int legacy_windows_fs_encoding

If non-zero:

- Set **`PyPreConfig.utf8_mode`** to `0`,
- Set **`PyConfig.filesystem_encoding`** to `"mbcs"`,
- Set **`PyConfig.filesystem_errors`** to `"replace"`.

Initialized from the **`PYTHONLEGACYWINDOWSFSENCODING`** environment variable value.

Only available on Windows. `#ifdef MS_WINDOWS` macro can be used for Windows specific code.

Default: `0`.

int parse_argv

If non-zero, **`Py_PreInitializeFromArgs()`** and **`Py_PreInitializeFromBytesArgs()`** parse their `argv` argument the same way the regular Python parses command line arguments: see Command Line Arguments.

Default: `1` in Python config, `0` in isolated config.

int use_environment

Use environment variables? See **`PyConfig.use_environment`**.

Default: `1` in Python config and `0` in isolated config.

int utf8_mode

If non-zero, enable the Python UTF-8 Mode.

Set to `0` or `1` by the **`-X utf8`** command line option and the **`PYTHONUTF8`** environment variable.

Also set to `1` if the `LC_CTYPE` locale is `C` or `POSIX`.

Default: `-1` in Python config and `0` in isolated config.

Preinitialize Python with PyPreConfig

The preinitialization of Python:

- Set the Python memory allocators (**`PyPreConfig.allocator`**)
- Configure the LC_CTYPE locale (locale encoding)
- Set the Python UTF-8 Mode (**`PyPreConfig.utf8_mode`**)

The current preconfiguration (`PyPreConfig` type) is stored in `_PyRuntime.preconfig`.

Functions to preinitialize Python:

PyStatus Py_PreInitialize(const PyPreConfig *preconfig)

Preinitialize Python from *preconfig* preconfiguration.

preconfig must not be `NULL`.

PyStatus Py_PreInitializeFromBytesArgs(const PyPreConfig *preconfig, int argc, char *const *argv)

Preinitialize Python from *preconfig* preconfiguration.

Parse *argv* command line arguments (bytes strings) if **`parse_argv`** of *preconfig* is non-zero.

preconfig must not be `NULL`.

PyStatus Py_PreInitializeFromArgs(const PyPreConfig *preconfig, int argc, wchar_t *const *argv)

Preinitialize Python from *preconfig* preconfiguration.

Parse *argv* command line arguments (wide strings) if **`parse_argv`** of *preconfig* is non-zero.

preconfig must not be `NULL`.

The caller is responsible to handle exceptions (error or exit) using **`PyStatus_Exception()`** and **`Py_ExitStatusException()`**.

For Python Configuration (**`PyPreConfig_InitPythonConfig()`**), if Python is initialized with command line arguments, the command line arguments must also be passed to preinitialize Python, since they have an effect on the pre-configuration like encodings. For example, the **`-X utf8`** command line option enables the Python UTF-8 Mode.

`PyMem_SetAllocator()` can be called after **`Py_PreInitialize()`** and before **`Py_InitializeFromConfig()`** to install a custom memory allocator. It can be called before **`Py_PreInitialize()`** if **`PyPreConfig.allocator`** is set to `PYMEM_ALLOCATOR_NOT_SET`.

Python memory allocation functions like **`PyMem_RawMalloc()`** must not be used before the Python preinitialization, whereas calling directly `malloc()`

and `free()` is always safe. **`Py_DecodeLocale()`** must not be called before the Python preinitialization.

Example using the preinitialization to enable the Python UTF-8 Mode:

```
PyStatus status;
PyPreConfig preconfig;
PyPreConfig_InitPythonConfig(&preconfig);

preconfig.utf8_mode = 1;

status = Py_PreInitialize(&preconfig);
if (PyStatus_Exception(status)) {
    Py_ExitStatusException(status);
}

/* at this point, Python speaks UTF-8 */

Py_Initialize();
/* ... use Python API here ... */
Py_Finalize();
```

PyConfig

type PyConfig

Structure containing most parameters to configure Python.

When done, the **`PyConfig_Clear()`** function must be used to release the configuration memory.

Structure methods:

void PyConfig_InitPythonConfig(PyConfig *config)

Initialize configuration with the Python Configuration.

void PyConfig_InitIsolatedConfig(PyConfig *config)

Initialize configuration with the Isolated Configuration.

PyStatus PyConfig_SetString(PyConfig *config, wchar_t *const *config_str, const wchar_t *str)

Copy the wide character string *str* into `*config_str`.

Preinitialize Python if needed.

PyStatus PyConfig_SetBytesString(PyConfig *config, wchar_t *const *config_str, const char *str)

Decode *str* using **`Py_DecodeLocale()`** and set the result into `*config_str`.

Preinitialize Python if needed.

PyStatus PyConfig_SetArgv(PyConfig *config, int argc, wchar_t *const *argv)

Set command line arguments (**`argv`** member of *config*) from the *argv* list of wide character strings.

Preinitialize Python if needed.

PyStatus PyConfig_SetBytesArgv(PyConfig *config, int argc, char *const *argv)

Set command line arguments (**`argv`** member of *config*) from the *argv* list of bytes strings. Decode bytes using **`Py_DecodeLocale()`**.

Preinitialize Python if needed.

PyStatus PyConfig_SetWideStringList(PyConfig *config, PyWideStringList *list, Py_ssize_t length, wchar_t **items)

Set the list of wide strings *list* to *length* and *items*.

Preinitialize Python if needed.

PyStatus PyConfig_Read(PyConfig *config)

Read all Python configuration.

Fields which are already initialized are left unchanged.

Fields for path configuration are no longer calculated or modified when calling this function, as of Python 3.11.

The **`PyConfig_Read()`** function only parses **`PyConfig.argv`** arguments once: **`PyConfig.parse_argv`** is set to `2` after arguments are parsed. Since Python arguments are stripped from **`PyConfig.argv`**, parsing arguments twice would parse the application options as Python options.

Preinitialize Python if needed.

Changed in version 3.10: The **`PyConfig.argv`** arguments are now only parsed once, **`PyConfig.parse_argv`** is set to `2` after arguments are parsed, and arguments are only parsed if **`PyConfig.parse_argv`** equals `1`.

Changed in version 3.11: `PyConfig_Read()` no longer calculates all paths, and so fields listed under Python Path Configuration may no longer be updated until `Py_InitializeFromConfig()` is called.

void PyConfig_Clear(PyConfig *config)

Release configuration memory.

Most `PyConfig` methods preinitialize Python if needed. In that case, the Python preinitialization configuration (`PyPreConfig`) in based on the `PyConfig`. If configuration fields which are in common with `PyPreConfig` are tuned, they must be set before calling a `PyConfig` method:

- `PyConfig.dev_mode`
- `PyConfig.isolated`
- `PyConfig.parse_argv`
- `PyConfig.use_environment`

Moreover, if `PyConfig_SetArgv()` or `PyConfig_SetBytesArgv()` is used, this method must be called before other methods, since the preinitialization configuration depends on command line arguments (if `parse_argv` is non-zero).

The caller of these methods is responsible to handle exceptions (error or exit) using `PyStatus_Exception()` and `Py_ExitStatusException()`.

Structure fields:

PyWideStringList argv

Set `sys.argv` command line arguments based on `argv`. These parameters are similar to those passed to the program's **`main()`** function with the difference that the first entry should refer to the script file to be executed rather than the executable hosting the Python interpreter. If there isn't a script that will be run, the first entry in `argv` can be an empty string.

Set `parse_argv` to `1` to parse `argv` the same way the regular Python parses Python command line arguments and then to strip Python arguments from `argv`.

If `argv` is empty, an empty string is added to ensure that `sys.argv` always exists and is never empty.

Default: `NULL`.

See also the `orig_argv` member.

int safe_path

If equals to zero, `Py_RunMain()` prepends a potentially unsafe path to **`sys.path`** at startup:

- If **`argv[0]`** is equal to `L"-m"` (`python -m module`), prepend the current working directory.
- If running a script (`python script.py`), prepend the script's directory. If it's a symbolic link, resolve symbolic links.
- Otherwise (`python -c code` and `python`), prepend an empty string, which means the current working directory.

Set to `1` by the **`-P`** command line option and the **`PYTHONSAFEPATH`** environment variable.

Default: `0` in Python config, `1` in isolated config.

Added in version 3.11.

wchar_t *base_exec_prefix

`sys.base_exec_prefix`.

Default: `NULL`.

Part of the Python Path Configuration output.

See also **`PyConfig.exec_prefix`**.

wchar_t *base_executable

Python base executable: **`sys._base_executable`**.

Set by the **`__PYVENV_LAUNCHER__`** environment variable.

Set from **`PyConfig.executable`** if `NULL`.

Default: `NULL`.

Part of the Python Path Configuration output.

See also **`PyConfig.executable`**.

wchar_t *base_prefix

`sys.base_prefix`.

Default: `NULL`.

Part of the Python Path Configuration output.

See also `PyConfig.prefix`.

int buffered_stdio

If equals to `0` and `configure_c_stdio` is non-zero, disable buffering on the C streams stdout and stderr.

Set to `0` by the `-u` command line option and the `PYTHONUNBUFFERED` environment variable.

stdin is always opened in buffered mode.

Default: `1`.

int bytes_warning

If equals to `1`, issue a warning when comparing `bytes` or `bytearray` with `str`, or comparing `bytes` with `int`.

If equal or greater to `2`, raise a `BytesWarning` exception in these cases.

Incremented by the `-b` command line option.

Default: `0`.

int warn_default_encoding

If non-zero, emit a `EncodingWarning` warning when `io.TextIOWrapper` uses its default encoding. See Opt-in EncodingWarning for details.

Default: `0`.

Added in version 3.10.

int code_debug_ranges

If equals to `0`, disables the inclusion of the end line and column mappings in code objects. Also disables traceback printing carets to specific error locations.

Set to `0` by the `PYTHONNODEBUGRANGES` environment variable and by the `-X no_debug_ranges` command line option.

Default: `1`.

Added in version 3.11.

wchar_t *check_hash_pycs_mode

Control the validation behavior of hash-based `.pyc` files: value of the `--check-hash-based-pycs` command line option.

Valid values:

- `L"always"`: Hash the source file for invalidation regardless of value of the ‘check_source’ flag.
- `L"never"`: Assume that hash-based pycs always are valid.
- `L"default"`: The ‘check_source’ flag in hash-based pycs determines invalidation.

Default: `L"default"`.

See also **PEP 552** [https://peps.python.org/pep-0552/] “Deterministic pycs”.

int configure_c_stdio

If non-zero, configure C standard streams:

- On Windows, set the binary mode (`O_BINARY`) on stdin, stdout and stderr.
- If **`buffered_stdio`** equals zero, disable buffering of stdin, stdout and stderr streams.
- If **`interactive`** is non-zero, enable stream buffering on stdin and stdout (only stdout on Windows).

Default: `1` in Python config, `0` in isolated config.

int dev_mode

If non-zero, enable the Python Development Mode.

Set to `1` by the **`-X dev`** option and the **`PYTHONDEVMODE`** environment variable.

Default: `-1` in Python mode, `0` in isolated mode.

int dump_refs

Dump Python references?

If non-zero, dump all objects which are still alive at exit.

Set to `1` by the **`PYTHONDUMPREFS`** environment variable.

Needs a special build of Python with the `Py_TRACE_REFS` macro defined: see the **`configure --with-trace-refs option`**.

Default: `0`.

wchar_t *dump_refs_file

Filename where to dump Python references.

Set by the **`PYTHONDUMPREFSFILE`** environment variable.

Default: `NULL`.

Added in version 3.11.

wchar_t *exec_prefix

The site-specific directory prefix where the platform-dependent Python files are installed: **`sys.exec_prefix`**.

Default: `NULL`.

Part of the Python Path Configuration output.

See also **`PyConfig.base_exec_prefix`**.

wchar_t *executable

The absolute path of the executable binary for the Python interpreter: **`sys.executable`**.

Default: `NULL`.

Part of the Python Path Configuration output.

See also **`PyConfig.base_executable`**.

int faulthandler

Enable faulthandler?

If non-zero, call **`faulthandler.enable()`** at startup.

Set to `1` by **`-X faulthandler`** and the **`PYTHONFAULTHANDLER`** environment variable.

Default: `-1` in Python mode, `0` in isolated mode.

wchar_t *filesystem_encoding

Filesystem encoding: **`sys.getfilesystemencoding()`**.

On macOS, Android and VxWorks: use `"utf-8"` by default.

On Windows: use `"utf-8"` by default, or `"mbcs"` if **`legacy_windows_fs_encoding`** of **`PyPreConfig`** is non-zero.

Default encoding on other platforms:

- `"utf-8"` if **`PyPreConfig.utf8_mode`** is non-zero.
- `"ascii"` if Python detects that `nl_langinfo(CODESET)` announces the ASCII encoding, whereas the `mbstowcs()` function decodes from a different encoding (usually Latin1).
- `"utf-8"` if `nl_langinfo(CODESET)` returns an empty string.
- Otherwise, use the locale encoding: `nl_langinfo(CODESET)` result.

At Python startup, the encoding name is normalized to the Python codec name. For example, `"ANSI_X3.4-1968"` is replaced with `"ascii"`.

See also the **`filesystem_errors`** member.

wchar_t *filesystem_errors

Filesystem error handler: **`sys.getfilesystemencodeerrors()`**.

On Windows: use `"surrogatepass"` by default, or `"replace"` if **`legacy_windows_fs_encoding`** of **`PyPreConfig`** is non-zero.

On other platforms: use `"surrogateescape"` by default.

Supported error handlers:

- `"strict"`
- `"surrogateescape"`
- `"surrogatepass"` (only supported with the UTF-8 encoding)

See also the **`filesystem_encoding`** member.

int use_frozen_modules

If non-zero, use frozen modules.

Set by the **`PYTHON_FROZEN_MODULES`** environment variable.

Default: `1` in a release build, or `0` in a debug build.

unsigned long hash_seed

int use_hash_seed

Randomized hash function seed.

If **`use_hash_seed`** is zero, a seed is chosen randomly at Python startup, and **`hash_seed`** is ignored.

Set by the **`PYTHONHASHSEED`** environment variable.

Default *use_hash_seed* value: `-1` in Python mode, `0` in isolated mode.

wchar_t *home

Set the default Python “home” directory, that is, the location of the standard Python libraries (see **`PYTHONHOME`**).

Set by the **`PYTHONHOME`** environment variable.

Default: `NULL`.

Part of the Python Path Configuration input.

int import_time

If `1`, profile import time. If `2`, include additional output that indicates when an imported module has already been loaded.

Set by the **`-X importtime`** option and the **`PYTHONPROFILEIMPORTTIME`** environment variable.

Default: `0`.

Changed in version 3.14: Added support for `import_time = 2`

int inspect

Enter interactive mode after executing a script or a command.

If greater than `0`, enable inspect: when a script is passed as first argument or the -c option is used, enter interactive mode after executing the script or the command, even when **`sys.stdin`** does not appear to be a terminal.

Incremented by the **`-i`** command line option. Set to `1` if the **`PYTHONINSPECT`** environment variable is non-empty.

Default: `0`.

int install_signal_handlers

Install Python signal handlers?

Default: `1` in Python mode, `0` in isolated mode.

int interactive

If greater than `0`, enable the interactive mode (REPL).

Incremented by the **`-i`** command line option.

Default: `0`.

int int_max_str_digits

Configures the integer string conversion length limitation. An initial value of `-1` means the value will be taken from the command line or environment or otherwise default to 4300 (`sys.int_info.default_max_str_digits`). A value of `0` disables the limitation. Values greater than zero but less than 640 (`sys.int_info.str_digits_check_threshold`) are unsupported and will produce an error.

Configured by the `-X int_max_str_digits` command line flag or the `PYTHONINTMAXSTRDIGITS` environment variable.

Default: `-1` in Python mode. 4300 (`sys.int_info.default_max_str_digits`) in isolated mode.

Added in version 3.12.

int cpu_count

If the value of `cpu_count` is not `-1` then it will override the return values of `os.cpu_count()`, `os.process_cpu_count()`, and `multiprocessing.cpu_count()`.

Configured by the `-X cpu_count=n|default` command line flag or the `PYTHON_CPU_COUNT` environment variable.

Default: `-1`.

Added in version 3.13.

int isolated

If greater than `0`, enable isolated mode:

- Set `safe_path` to `1`: don't prepend a potentially unsafe path to `sys.path` at Python startup, such as the current directory, the script's directory or an empty string.
- Set `use_environment` to `0`: ignore `PYTHON` environment variables.
- Set `user_site_directory` to `0`: don't add the user site directory to `sys.path`.
- Python REPL doesn't import `readline` nor enable default readline configuration on interactive prompts.

Set to `1` by the `-I` command line option.

Default: `0` in Python mode, `1` in isolated mode.

See also the Isolated Configuration and `PyPreConfig.isolated`.

int legacy_windows_stdio

If non-zero, use `io.FileIO` instead of **`io._WindowsConsoleIO`** for `sys.stdin`, `sys.stdout` and `sys.stderr`.

Set to `1` if the `PYTHONLEGACYWINDOWSSTDIO` environment variable is set to a non-empty string.

Only available on Windows. `#ifdef MS_WINDOWS` macro can be used for Windows specific code.

Default: `0`.

See also the **PEP 528** [https://peps.python.org/pep-0528/] (Change Windows console encoding to UTF-8).

int malloc_stats

If non-zero, dump statistics on Python pymalloc memory allocator at exit.

Set to `1` by the `PYTHONMALLOCSTATS` environment variable.

The option is ignored if Python is `configured using the --without-pymalloc option`.

Default: `0`.

wchar_t *platlibdir

Platform library directory name: `sys.platlibdir`.

Set by the `PYTHONPLATLIBDIR` environment variable.

Default: value of the `PLATLIBDIR` macro which is set by the `configure --with-platlibdir option` (default: `"lib"`, or `"DLLs"` on Windows).

Part of the Python Path Configuration input.

Added in version 3.9.

Changed in version 3.11: This macro is now used on Windows to locate the standard library extension modules, typically under `DLLs`. However, for compatibility, note that this value is ignored for any non-standard layouts, including in-tree builds and virtual environments.

wchar_t *pythonpath_env

Module search paths (**`sys.path`**) as a string separated by `DELIM` (**`os.pathsep`**).

Set by the **`PYTHONPATH`** environment variable.

Default: `NULL`.

Part of the Python Path Configuration input.

PyWideStringList module_search_paths

int module_search_paths_set

Module search paths: **`sys.path`**.

If **`module_search_paths_set`** is equal to `0`, **`Py_InitializeFromConfig()`** will replace **`module_search_paths`** and sets **`module_search_paths_set`** to `1`.

Default: empty list (`module_search_paths`) and `0` (`module_search_paths_set`).

Part of the Python Path Configuration output.

int optimization_level

Compilation optimization level:

- `0`: Peephole optimizer, set `__debug__` to `True`.
- `1`: Level 0, remove assertions, set `__debug__` to `False`.
- `2`: Level 1, strip docstrings.

Incremented by the **`-O`** command line option. Set to the **`PYTHONOPTIMIZE`** environment variable value.

Default: `0`.

PyWideStringList orig_argv

The list of the original command line arguments passed to the Python executable: **`sys.orig_argv`**.

If **`orig_argv`** list is empty and **`argv`** is not a list only containing an empty string, **`PyConfig_Read()`** copies **`argv`** into **`orig_argv`** before modifying **`argv`** (if **`parse_argv`** is non-zero).

See also the **`argv`** member and the **`Py_GetArgcArgv()`** function.

Default: empty list.

Added in version 3.10.

int parse_argv

Parse command line arguments?

If equals to `1`, parse **`argv`** the same way the regular Python parses command line arguments, and strip Python arguments from **`argv`**.

The **`PyConfig_Read()`** function only parses **`PyConfig.argv`** arguments once: **`PyConfig.parse_argv`** is set to `2` after arguments are parsed. Since Python arguments are stripped from **`PyConfig.argv`**, parsing arguments twice would parse the application options as Python options.

Default: `1` in Python mode, `0` in isolated mode.

Changed in version 3.10: The **`PyConfig.argv`** arguments are now only parsed if **`PyConfig.parse_argv`** equals to `1`.

int parser_debug

Parser debug mode. If greater than `0`, turn on parser debugging output (for expert only, depending on compilation options).

Incremented by the **`-d`** command line option. Set to the **`PYTHONDEBUG`** environment variable value.

Needs a debug build of Python (the `Py_DEBUG` macro must be defined).

Default: `0`.

int pathconfig_warnings

If non-zero, calculation of path configuration is allowed to log warnings into `stderr`. If equals to `0`, suppress these warnings.

Default: `1` in Python mode, `0` in isolated mode.

Part of the Python Path Configuration input.

Changed in version 3.11: Now also applies on Windows.

wchar_t *prefix

The site-specific directory prefix where the platform independent Python files are installed: **`sys.prefix`**.

Default: `NULL`.

Part of the Python Path Configuration output.

See also `PyConfig.base_prefix`.

wchar_t *program_name

Program name used to initialize `executable` and in early error messages during Python initialization.

- On macOS, use `PYTHONEXECUTABLE` environment variable if set.
- If the `WITH_NEXT_FRAMEWORK` macro is defined, use **`__PYVENV_LAUNCHER__`** environment variable if set.
- Use `argv[0]` of `argv` if available and non-empty.
- Otherwise, use `L"python"` on Windows, or `L"python3"` on other platforms.

Default: `NULL`.

Part of the Python Path Configuration input.

wchar_t *pycache_prefix

Directory where cached `.pyc` files are written: `sys.pycache_prefix`.

Set by the `-X pycache_prefix=PATH` command line option and the `PYTHONPYCACHEPREFIX` environment variable. The command-line option takes precedence.

If `NULL`, `sys.pycache_prefix` is set to `None`.

Default: `NULL`.

int quiet

Quiet mode. If greater than `0`, don’t display the copyright and version at Python startup in interactive mode.

Incremented by the `-q` command line option.

Default: `0`.

wchar_t *run_command

Value of the `-c` command line option.

Used by `Py_RunMain()`.

Default: `NULL`.

wchar_t *run_filename

Filename passed on the command line: trailing command line argument without `-c` or `-m`. It is used by the `Py_RunMain()` function.

For example, it is set to `script.py` by the `python3 script.py arg` command line.

See also the **`PyConfig.skip_source_first_line`** option.

Default: `NULL`.

wchar_t *run_module

Value of the **`-m`** command line option.

Used by **`Py_RunMain()`**.

Default: `NULL`.

wchar_t *run_presite

`package.module` path to module that should be imported before `site.py` is run.

Set by the **`-X presite=package.module`** command-line option and the **`PYTHON_PRESITE`** environment variable. The command-line option takes precedence.

Needs a debug build of Python (the `Py_DEBUG` macro must be defined).

Default: `NULL`.

int show_ref_count

Show total reference count at exit (excluding immortal objects)?

Set to `1` by **`-X showrefcount`** command line option.

Needs a debug build of Python (the `Py_REF_DEBUG` macro must be defined).

Default: `0`.

int site_import

Import the **`site`** module at startup?

If equal to zero, disable the import of the module site and the site-dependent manipulations of **`sys.path`** that it entails.

Also disable these manipulations if the **`site`** module is explicitly imported later (call **`site.main()`** if you want them to be triggered).

Set to `0` by the **`-S`** command line option.

`sys.flags.no_site` is set to the inverted value of **`site_import`**.

Default: `1`.

int skip_source_first_line

If non-zero, skip the first line of the **`PyConfig.run_filename`** source.

It allows the usage of non-Unix forms of `#!cmd`. This is intended for a DOS specific hack only.

Set to `1` by the **`-x`** command line option.

Default: `0`.

wchar_t *stdio_encoding

wchar_t *stdio_errors

Encoding and encoding errors of **`sys.stdin`**, **`sys.stdout`** and **`sys.stderr`** (but **`sys.stderr`** always uses `"backslashreplace"` error handler).

Use the **`PYTHONIOENCODING`** environment variable if it is non-empty.

Default encoding:

- `"UTF-8"` if **`PyPreConfig.utf8_mode`** is non-zero.
- Otherwise, use the locale encoding.

Default error handler:

- On Windows: use `"surrogateescape"`.
- `"surrogateescape"` if **`PyPreConfig.utf8_mode`** is non-zero, or if the LC_CTYPE locale is “C” or “POSIX”.
- `"strict"` otherwise.

See also **`PyConfig.legacy_windows_stdio`**.

int tracemalloc

Enable tracemalloc?

If non-zero, call **`tracemalloc.start()`** at startup.

Set by **`-X tracemalloc=N`** command line option and by the **`PYTHONTRACEMALLOC`** environment variable.

Default: `-1` in Python mode, `0` in isolated mode.

int perf_profiling

Enable the Linux `perf` profiler support?

If equals to `1`, enable support for the Linux `perf` profiler.

If equals to `2`, enable support for the Linux `perf` profiler with DWARF JIT support.

Set to `1` by **`-X perf`** command-line option and the **`PYTHONPERFSUPPORT`** environment variable.

Set to `2` by the **`-X perf_jit`** command-line option and the **`PYTHON_PERF_JIT_SUPPORT`** environment variable.

Default: `-1`.

See also

See Python support for the Linux perf profiler for more information.

Added in version 3.12.

wchar_t *stdlib_dir

Directory of the Python standard library.

Default: `NULL`.

Added in version 3.11.

int use_environment

Use environment variables?

If equals to zero, ignore the environment variables.

Set to `0` by the **`-E`** environment variable.

Default: `1` in Python config and `0` in isolated config.

int use_system_logger

If non-zero, `stdout` and `stderr` will be redirected to the system log.

Only available on macOS 10.12 and later, and on iOS.

Default: `0` (don’t use the system log) on macOS; `1` on iOS (use the system log).

Added in version 3.14.

int user_site_directory

If non-zero, add the user site directory to `sys.path`.

Set to `0` by the `-s` and `-I` command line options.

Set to `0` by the `PYTHONNOUSERSITE` environment variable.

Default: `1` in Python mode, `0` in isolated mode.

int verbose

Verbose mode. If greater than `0`, print a message each time a module is imported, showing the place (filename or built-in module) from which it is loaded.

If greater than or equal to `2`, print a message for each file that is checked for when searching for a module. Also provides information on module cleanup at exit.

Incremented by the `-v` command line option.

Set by the `PYTHONVERBOSE` environment variable value.

Default: `0`.

PyWideStringList warnoptions

Options of the `warnings` module to build warnings filters, lowest to highest priority: `sys.warnoptions`.

The `warnings` module adds `sys.warnoptions` in the reverse order: the last `PyConfig.warnoptions` item becomes the first item of **`warnings.filters`** which is checked first (highest priority).

The `-W` command line options adds its value to `warnoptions`, it can be used multiple times.

The `PYTHONWARNINGS` environment variable can also be used to add warning options. Multiple options can be specified, separated by commas (`,`).

Default: empty list.

int write_bytecode

If equal to `0`, Python won’t try to write `.pyc` files on the import of source modules.

Set to `0` by the **`-B`** command line option and the **`PYTHONDONTWRITEBYTECODE`** environment variable.

`sys.dont_write_bytecode` is initialized to the inverted value of **`write_bytecode`**.

Default: `1`.

PyWideStringList xoptions

Values of the **`-X`** command line options: **`sys._xoptions`**.

Default: empty list.

int _pystats

If non-zero, write performance statistics at Python exit.

Need a special build with the `Py_STATS` macro: see **`--enable-pystats`**.

Default: `0`.

If **`parse_argv`** is non-zero, **`argv`** arguments are parsed the same way the regular Python parses command line arguments, and Python arguments are stripped from **`argv`**.

The **`xoptions`** options are parsed to set other options: see the **`-X`** command line option.

Changed in version 3.9: The `show_alloc_count` field has been removed.

Initialization with PyConfig

Initializing the interpreter from a populated configuration struct is handled by calling **`Py_InitializeFromConfig()`**.

The caller is responsible to handle exceptions (error or exit) using **`PyStatus_Exception()`** and **`Py_ExitStatusException()`**.

If **`PyImport_FrozenModules()`**, **`PyImport_AppendInittab()`** or **`PyImport_ExtendInittab()`** are used, they must be set or called after Python preinitialization and before the Python initialization. If Python is initialized multiple times, **`PyImport_AppendInittab()`** or **`PyImport_ExtendInittab()`** must be called before each Python initialization.

The current configuration (`PyConfig` type) is stored in `PyInterpreterState.config`.

Example setting the program name:

```
void init_python(void)
{
    PyStatus status;

    PyConfig config;
    PyConfig_InitPythonConfig(&config);

    /* Set the program name. Implicitly preinitialize Python. */
    status = PyConfig_SetString(&config, &config.program_name,
                                L"/path/to/my_program");
    if (PyStatus_Exception(status)) {
        goto exception;
    }

    status = Py_InitializeFromConfig(&config);
    if (PyStatus_Exception(status)) {
        goto exception;
    }
    PyConfig_Clear(&config);
    return;

exception:
    PyConfig_Clear(&config);
    Py_ExitStatusException(status);
}
```

More complete example modifying the default configuration, read the configuration, and then override some parameters. Note that since 3.11, many parameters are not calculated until initialization, and so values cannot be read from the configuration structure. Any values set before initialize is called will be left unchanged by initialization:

```
PyStatus init_python(const char *program_name)
{
    PyStatus status;

    PyConfig config;
    PyConfig_InitPythonConfig(&config);

    /* Set the program name before reading the configuration
       (decode byte string from the locale encoding).

       Implicitly preinitialize Python. */
    status = PyConfig_SetBytesString(&config, &config.program_name,
                                     program_name);
    if (PyStatus_Exception(status)) {
        goto done;
    }
    /* Read all configuration at once */
    status = PyConfig_Read(&config);
    if (PyStatus_Exception(status)) {
        goto done;
    }

    /* Specify sys.path explicitly */
    /* If you want to modify the default set of paths, finish
       initialization first and then use PySys_GetObject("path") */
    config.module_search_paths_set = 1;
    status = PyWideStringList_Append(&config.module_search_paths,
                                     L"/path/to/stdlib");
    if (PyStatus_Exception(status)) {
        goto done;
    }
    status = PyWideStringList_Append(&config.module_search_paths,
                                     L"/path/to/more/modules");
    if (PyStatus_Exception(status)) {
        goto done;
    }

    /* Override executable computed by PyConfig_Read() */
    status = PyConfig_SetString(&config, &config.executable,
                                L"/path/to/my_executable");
    if (PyStatus_Exception(status)) {
        goto done;
    }

    status = Py_InitializeFromConfig(&config);

done:
    PyConfig_Clear(&config);
    return status;
}
```

Isolated Configuration

`PyPreConfig_InitIsolatedConfig()` and `PyConfig_InitIsolatedConfig()` functions create a configuration to isolate Python from the system. For example, to embed Python into an application.

This configuration ignores global configuration variables, environment variables, command line arguments (`PyConfig.argv` is not parsed) and user site directory. The C standard streams (ex: `stdout`) and the LC_CTYPE locale are left unchanged. Signal handlers are not installed.

Configuration files are still used with this configuration to determine paths that are unspecified. Ensure `PyConfig.home` is specified to avoid computing the default path configuration.

Python Configuration

`PyPreConfig_InitPythonConfig()` and `PyConfig_InitPythonConfig()` functions create a configuration to build a customized Python which behaves as the regular Python.

Environments variables and command line arguments are used to configure Python, whereas global configuration variables are ignored.

This function enables C locale coercion (**PEP 538** [https://peps.python.org/pep-0538/]) and Python UTF-8 Mode (**PEP 540** [https://peps.python.org/pep-0540/]) depending on the LC_CTYPE locale, `PYTHONUTF8` and `PYTHONCOERCECLOCALE` environment variables.

Python Path Configuration

`PyConfig` contains multiple fields for the path configuration:

- Path configuration inputs:
    - `PyConfig.home`
    - `PyConfig.platlibdir`
    - `PyConfig.pathconfig_warnings`
    - `PyConfig.program_name`
    - `PyConfig.pythonpath_env`
    - current working directory: to get absolute paths
    - `PATH` environment variable to get the program full path (from `PyConfig.program_name`)
    - `__PYVENV_LAUNCHER__` environment variable
    - (Windows only) Application paths in the registry under “SoftwarePythonPythonCoreX.YPythonPath” of HKEY_CURRENT_USER and HKEY_LOCAL_MACHINE (where X.Y is the Python version).
- Path configuration output fields:
    - `PyConfig.base_exec_prefix`
    - `PyConfig.base_executable`
    - `PyConfig.base_prefix`
    - `PyConfig.exec_prefix`
    - `PyConfig.executable`
    - `PyConfig.module_search_paths_set`, `PyConfig.module_search_paths`
    - `PyConfig.prefix`

If at least one “output field” is not set, Python calculates the path configuration to fill unset fields. If `module_search_paths_set` is equal to `0`, `module_search_paths` is overridden and `module_search_paths_set` is set to `1`.

It is possible to completely ignore the function calculating the default path configuration by setting explicitly all path configuration output fields listed above. A string is considered as set even if it is non-empty. `module_search_paths` is considered as set if `module_search_paths_set` is set to `1`. In this case, `module_search_paths` will be used without modification.

Set **`pathconfig_warnings`** to `0` to suppress warnings when calculating the path configuration (Unix only, Windows does not log any warning).

If **`base_prefix`** or **`base_exec_prefix`** fields are not set, they inherit their value from **`prefix`** and **`exec_prefix`** respectively.

`Py_RunMain()` and **`Py_Main()`** modify **`sys.path`**:

- If **`run_filename`** is set and is a directory which contains a `__main__.py` script, prepend **`run_filename`** to **`sys.path`**.
- If **`isolated`** is zero:
    - If **`run_module`** is set, prepend the current directory to **`sys.path`**. Do nothing if the current directory cannot be read.
    - If **`run_filename`** is set, prepend the directory of the filename to **`sys.path`**.
    - Otherwise, prepend an empty string to **`sys.path`**.

If **`site_import`** is non-zero, **`sys.path`** can be modified by the **`site`** module. If **`user_site_directory`** is non-zero and the user's site-package directory exists, the **`site`** module appends the user's site-package directory to **`sys.path`**.

The following configuration files are used by the path configuration:

- `pyvenv.cfg`
- `._pth` file (ex: `python._pth`)
- `pybuilddir.txt` (Unix only)

If a `._pth` file is present:

- Set **`isolated`** to `1`.
- Set **`use_environment`** to `0`.
- Set **`site_import`** to `0`.
- Set **`safe_path`** to `1`.

If **`home`** is not set and a `pyvenv.cfg` file is present in the same directory as **`executable`**, or its parent, **`prefix`** and **`exec_prefix`** are set that location. When this happens, **`base_prefix`** and **`base_exec_prefix`** still keep their value, pointing to the base installation. See Virtual Environments for more information.

The `__PYVENV_LAUNCHER__` environment variable is used to set `PyConfig.base_executable`.

Changed in version 3.14: `prefix`, and `exec_prefix`, are now set to the `pyvenv.cfg` directory. This was previously done by `site`, therefore affected by `-S`.

Py_GetArgcArgv()

void Py_GetArgcArgv(int *argc, wchar_t ***argv)

Get the original command line arguments, before Python modified them.

See also `PyConfig.orig_argv` member.

Delaying main module execution

In some embedding use cases, it may be desirable to separate interpreter initialization from the execution of the main module.

This separation can be achieved by setting `PyConfig.run_command` to the empty string during initialization (to prevent the interpreter from dropping into the interactive prompt), and then subsequently executing the desired main module code using `__main__.__dict__` as the global namespace.

Memory Management

Overview

Memory management in Python involves a private heap containing all Python objects and data structures. The management of this private heap is ensured internally by the *Python memory manager*. The Python memory manager has different components which deal with various dynamic storage management aspects, like sharing, segmentation, preallocation or caching.

At the lowest level, a raw memory allocator ensures that there is enough room in the private heap for storing all Python-related data by interacting with the memory manager of the operating system. On top of the raw memory allocator, several object-specific allocators operate on the same heap and implement distinct memory management policies adapted to the peculiarities of every object type. For example, integer objects are managed differently within the heap than strings, tuples or dictionaries because integers imply different storage requirements and speed/space tradeoffs. The Python memory manager thus delegates some of the work to the object-specific allocators, but ensures that the latter operate within the bounds of the private heap.

It is important to understand that the management of the Python heap is performed by the interpreter itself and that the user has no control over it, even if they regularly manipulate object pointers to memory blocks inside that heap. The allocation of heap space for Python objects and other internal buffers is performed on demand by the Python memory manager through the Python/C API functions listed in this document.

To avoid memory corruption, extension writers should never try to operate on Python objects with the functions exported by the C library: **`malloc()`**, **`calloc()`**, **`realloc()`** and **`free()`**. This will result in mixed calls between the C allocator and the Python memory manager with fatal consequences, because they implement different algorithms and operate on different heaps. However, one may safely allocate and release memory blocks with the C library allocator for individual purposes, as shown in the following example:

```
PyObject *res;
char *buf = (char *) malloc(BUFSIZ); /* for I/O */

if (buf == NULL)
    return PyErr_NoMemory();
...Do some I/O operation involving buf...
res = PyBytes_FromString(buf);
free(buf); /* malloc'ed */
return res;
```

In this example, the memory request for the I/O buffer is handled by the C library allocator. The Python memory manager is involved only in the allocation of the bytes object returned as a result.

In most situations, however, it is recommended to allocate memory from the Python heap specifically because the latter is under control of the Python memory manager. For example, this is required when the interpreter is extended with new object types written in C. Another reason for using the Python heap is the desire to *inform* the Python memory manager about the memory needs of the extension module. Even when the requested memory is used exclusively for internal, highly specific purposes, delegating all memory requests to the Python memory manager causes the interpreter to have a more accurate image of its memory footprint as a whole. Consequently, under certain circumstances, the Python memory manager may or may not trigger appropriate actions, like garbage collection, memory compaction or other preventive procedures. Note that by using the C library allocator as shown in the previous example, the allocated memory for the I/O buffer escapes completely the Python memory manager.

See also

The **`PYTHONMALLOC`** environment variable can be used to configure the memory allocators used by Python.

The **`PYTHONMALLOCSTATS`** environment variable can be used to print statistics of the pymalloc memory allocator every time a new pymalloc object arena is created, and on shutdown.

Allocator Domains

All allocating functions belong to one of three different “domains” (see also **`PyMemAllocatorDomain`**). These domains represent different allocation strategies and are optimized for different purposes. The specific details on how every domain allocates memory or what internal functions each domain calls is considered an implementation detail, but for debugging purposes a simplified table can be found at Default Memory Allocators. The APIs used to allocate and free a block of memory must be from the same domain. For example, **`PyMem_Free()`** must be used to free memory allocated using **`PyMem_Malloc()`**.

The three allocation domains are:

- Raw domain: intended for allocating memory for general-purpose memory buffers where the allocation *must* go to the system allocator or where the allocator can operate without an attached thread state. The memory is requested directly from the system. See Raw Memory Interface.
- “Mem” domain: intended for allocating memory for Python buffers and general-purpose memory buffers where the allocation must be performed with an attached thread state. The memory is taken from the Python private heap. See Memory Interface.
- Object domain: intended for allocating memory for Python objects. The memory is taken from the Python private heap. See Object allocators.

Note

The free-threaded build requires that only Python objects are allocated using the “object” domain and that all Python objects are allocated using that domain. This differs from the prior Python versions, where this was only a best practice and not a hard requirement.

For example, buffers (non-Python objects) should be allocated using **`PyMem_Malloc()`**, **`PyMem_RawMalloc()`**, or **`malloc()`**, but not **`PyObject_Malloc()`**.

See Memory Allocation APIs.

Raw Memory Interface

The following function sets are wrappers to the system allocator. These functions are thread-safe, so a thread state does not need to be attached.

The default raw memory allocator uses the following functions: **`malloc()`**, **`calloc()`**, **`realloc()`** and **`free()`**; call `malloc(1)` (or `calloc(1, 1)`) when requesting zero bytes.

Added in version 3.4.

void *PyMem_RawMalloc(size_t n)

Part of the Stable ABI since version 3.13.
Allocates *n* bytes and returns a pointer of type void* to the allocated memory, or `NULL` if the request fails.

Requesting zero bytes returns a distinct non-`NULL` pointer if possible, as if `PyMem_RawMalloc(1)` had been called instead. The memory will not have been initialized in any way.

void *PyMem_RawCalloc(size_t nelem, size_t elsize)

Part of the Stable ABI since version 3.13.
Allocates *nelem* elements each whose size in bytes is *elsize* and returns a pointer of type void* to the allocated memory, or `NULL` if the request fails. The memory is initialized to zeros.

Requesting zero elements or elements of size zero bytes returns a distinct non-`NULL` pointer if possible, as if `PyMem_RawCalloc(1, 1)` had been called instead.

Added in version 3.5.

void *PyMem_RawRealloc(void *p, size_t n)

Part of the Stable ABI since version 3.13.
Resizes the memory block pointed to by *p* to *n* bytes. The contents will be unchanged to the minimum of the old and the new sizes.

If *p* is `NULL`, the call is equivalent to `PyMem_RawMalloc(n)`; else if *n* is equal to zero, the memory block is resized but is not freed, and the returned pointer is non-`NULL`.

Unless *p* is `NULL`, it must have been returned by a previous call to **`PyMem_RawMalloc()`**, **`PyMem_RawRealloc()`** or **`PyMem_RawCalloc()`**.

If the request fails, **`PyMem_RawRealloc()`** returns `NULL` and *p* remains a valid pointer to the previous memory area.

void PyMem_RawFree(void *p)

Part of the Stable ABI since version 3.13.
Frees the memory block pointed to by *p*, which must have been returned by a previous call to **`PyMem_RawMalloc()`**, **`PyMem_RawRealloc()`** or **`PyMem_RawCalloc()`**. Otherwise, or if `PyMem_RawFree(p)` has been called before, undefined behavior occurs.

If *p* is `NULL`, no operation is performed.

Memory Interface

The following function sets, modeled after the ANSI C standard, but specifying behavior when requesting zero bytes, are available for allocating and releasing memory from the

Python heap.

The default memory allocator uses the pymalloc memory allocator.

Warning

There must be an attached thread state when using these functions.

Changed in version 3.6: The default allocator is now pymalloc instead of system **`malloc()`**.

void *PyMem_Malloc(size_t n)

Part of the Stable ABI.

Allocates *n* bytes and returns a pointer of type void* to the allocated memory, or `NULL` if the request fails.

Requesting zero bytes returns a distinct non-`NULL` pointer if possible, as if `PyMem_Malloc(1)` had been called instead. The memory will not have been initialized in any way.

void *PyMem_Calloc(size_t nelem, size_t elsize)

Part of the Stable ABI since version 3.7.

Allocates *nelem* elements each whose size in bytes is *elsize* and returns a pointer of type void* to the allocated memory, or `NULL` if the request fails. The memory is initialized to zeros.

Requesting zero elements or elements of size zero bytes returns a distinct non-`NULL` pointer if possible, as if `PyMem_Calloc(1, 1)` had been called instead.

Added in version 3.5.

void *PyMem_Realloc(void *p, size_t n)

Part of the Stable ABI.

Resizes the memory block pointed to by *p* to *n* bytes. The contents will be unchanged to the minimum of the old and the new sizes.

If *p* is `NULL`, the call is equivalent to `PyMem_Malloc(n)`; else if *n* is equal to zero, the memory block is resized but is not freed, and the returned pointer is non-`NULL`.

Unless *p* is `NULL`, it must have been returned by a previous call to **`PyMem_Malloc()`**, **`PyMem_Realloc()`** or **`PyMem_Calloc()`**.

If the request fails, **`PyMem_Realloc()`** returns `NULL` and *p* remains a valid pointer to the previous memory area.

void PyMem_Free(void *p)

Part of the Stable ABI.

Frees the memory block pointed to by *p*, which must have been returned by a previous call to **`PyMem_Malloc()`**, **`PyMem_Realloc()`** or **`PyMem_Calloc()`**. Otherwise, or if `PyMem_Free(p)` has been called before, undefined behavior occurs.

If *p* is `NULL`, no operation is performed.

The following type-oriented macros are provided for convenience. Note that *TYPE* refers to any C type.

PyMem_New(TYPE, n)

Same as **`PyMem_Malloc()`**, but allocates `(n * sizeof(TYPE))` bytes of memory. Returns a pointer cast to `TYPE*`. The memory will not have been initialized in any way.

PyMem_Resize(p, TYPE, n)

Same as **`PyMem_Realloc()`**, but the memory block is resized to `(n * sizeof(TYPE))` bytes. Returns a pointer cast to `TYPE*`. On return, *p* will be a pointer to the new memory area, or `NULL` in the event of failure.

This is a C preprocessor macro; *p* is always reassigned. Save the original value of *p* to avoid losing memory when handling errors.

void PyMem_Del(void *p)

Same as **`PyMem_Free()`**.

In addition, the following macro sets are provided for calling the Python memory allocator directly, without involving the C API functions listed above. However, note that their use does not preserve binary compatibility across Python versions and is therefore deprecated in extension modules.

- `PyMem_MALLOC(size)`
- `PyMem_NEW(type, size)`
- `PyMem_REALLOC(ptr, size)`
- `PyMem_RESIZE(ptr, type, size)`
- `PyMem_FREE(ptr)`
- `PyMem_DEL(ptr)`

Object allocators

The following function sets, modeled after the ANSI C standard, but specifying behavior when requesting zero bytes, are available for allocating and releasing memory from the Python heap.

Note

There is no guarantee that the memory returned by these allocators can be successfully cast to a Python object when intercepting the allocating functions in this domain by the methods described in the Customize Memory Allocators section.

The default object allocator uses the pymalloc memory allocator.

Warning

There must be an attached thread state when using these functions.

void *PyObject_Malloc(size_t n)

Part of the Stable ABI.
Allocates *n* bytes and returns a pointer of type void* to the allocated memory, or `NULL` if the request fails.

Requesting zero bytes returns a distinct non-`NULL` pointer if possible, as if `PyObject_Malloc(1)` had been called instead. The memory will not have been initialized in any way.

void *PyObject_Calloc(size_t nelem, size_t elsize)

Part of the Stable ABI since version 3.7.
Allocates *nelem* elements each whose size in bytes is *elsize* and returns a pointer of type void* to the allocated memory, or `NULL` if the request fails. The memory is initialized to zeros.

Requesting zero elements or elements of size zero bytes returns a distinct non-`NULL` pointer if possible, as if `PyObject_Calloc(1, 1)` had been called instead.

Added in version 3.5.

void *PyObject_Realloc(void *p, size_t n)

Part of the Stable ABI.
Resizes the memory block pointed to by *p* to *n* bytes. The contents will be unchanged to the minimum of the old and the new sizes.

If *p* is `NULL`, the call is equivalent to `PyObject_Malloc(n)`; else if *n* is equal to zero, the memory block is resized but is not freed, and the returned pointer is non-`NULL`.

Unless *p* is `NULL`, it must have been returned by a previous call to **`PyObject_Malloc()`**, **`PyObject_Realloc()`** or **`PyObject_Calloc()`**.

If the request fails, **`PyObject_Realloc()`** returns `NULL` and *p* remains a valid pointer to the previous memory area.

void PyObject_Free(void *p)

Part of the Stable ABI.
Frees the memory block pointed to by *p*, which must have been returned by a previous call to **`PyObject_Malloc()`**, **`PyObject_Realloc()`** or **`PyObject_Calloc()`**. Otherwise, or if `PyObject_Free(p)` has been called before, undefined behavior occurs.

If *p* is `NULL`, no operation is performed.

Do not call this directly to free an object’s memory; call the type’s **`tp_free`** slot instead.

Do not use this for memory allocated by **`PyObject_GC_New`** or **`PyObject_GC_NewVar`**; use **`PyObject_GC_Del()`** instead.

See also

- **`PyObject_GC_Del()`** is the equivalent of this function for memory allocated by types that support garbage collection.
- **`PyObject_Malloc()`**
- **`PyObject_Realloc()`**
- **`PyObject_Calloc()`**
- **`PyObject_New`**
- **`PyObject_NewVar`**
- **`PyType_GenericAlloc()`**
- **`tp_free`**

Default Memory Allocators

Default memory allocators:

Configuration	**Name**	**PyMem_RawMalloc**	**PyMem_Malloc**	**PyObject_Malloc**
Release build	`"pymalloc"`	`malloc`	`pymalloc`	`pymalloc`
Debug build	`"pymalloc_debug"`	`malloc` + debug	`pymalloc` + debug	`pymalloc` + debug
Release build, without pymalloc	`"malloc"`	`malloc`	`malloc`	`malloc`
Debug build, without pymalloc	`"malloc_debug"`	`malloc` + debug	`malloc` + debug	`malloc` + debug

Legend:

- Name: value for **`PYTHONMALLOC`** environment variable.
- `malloc`: system allocators from the standard C library, C functions: **`malloc()`**, **`calloc()`**, **`realloc()`** and **`free()`**.
- `pymalloc`: pymalloc memory allocator.
- `mimalloc`: mimalloc memory allocator. The pymalloc allocator will be used if mimalloc support isn't available.
- "+ debug": with debug hooks on the Python memory allocators.
- "Debug build": Python build in debug mode.

Customize Memory Allocators

Added in version 3.4.

type PyMemAllocatorEx

Structure used to describe a memory block allocator. The structure has the following fields:

Field	**Meaning**
`void *ctx`	user context passed as first argument
`void* malloc(void *ctx, size_t size)`	allocate a memory block
`void* calloc(void *ctx, size_t nelem, size_t elsize)`	allocate a memory block initialized with zeros
`void* realloc(void *ctx, void *ptr, size_t new_size)`	allocate or resize a memory block

Field	**Meaning**
`void free(void *ctx, void *ptr)`	free a memory block

Changed in version 3.5: The **`PyMemAllocator`** structure was renamed to **`PyMemAllocatorEx`** and a new `calloc` field was added.

type PyMemAllocatorDomain

Enum used to identify an allocator domain. Domains:

PYMEM_DOMAIN_RAW

Functions:

- **`PyMem_RawMalloc()`**
- **`PyMem_RawRealloc()`**
- **`PyMem_RawCalloc()`**
- **`PyMem_RawFree()`**

PYMEM_DOMAIN_MEM

Functions:

- **`PyMem_Malloc()`**,
- **`PyMem_Realloc()`**
- **`PyMem_Calloc()`**
- **`PyMem_Free()`**

PYMEM_DOMAIN_OBJ

Functions:

- **`PyObject_Malloc()`**
- **`PyObject_Realloc()`**
- **`PyObject_Calloc()`**
- **`PyObject_Free()`**

void PyMem_GetAllocator(PyMemAllocatorDomain domain, PyMemAllocatorEx *allocator)

Get the memory block allocator of the specified domain.

void PyMem_SetAllocator(PyMemAllocatorDomain domain, PyMemAllocatorEx *allocator)

Set the memory block allocator of the specified domain.

The new allocator must return a distinct non-`NULL` pointer when requesting zero bytes.

For the **`PYMEM_DOMAIN_RAW`** domain, the allocator must be thread-safe: a thread state is not attached when the allocator is called.

For the remaining domains, the allocator must also be thread-safe: the allocator may be called in different interpreters that do not share a GIL.

If the new allocator is not a hook (does not call the previous allocator), the **`PyMem_SetupDebugHooks()`** function must be called to reinstall the debug hooks on top on the new allocator.

See also **`PyPreConfig.allocator`** and Preinitialize Python with PyPreConfig.

Warning

`PyMem_SetAllocator()` does have the following contract:

- It can be called after `Py_PreInitialize()` and before `Py_InitializeFromConfig()` to install a custom memory allocator. There are no restrictions over the installed allocator other than the ones imposed by the domain (for instance, the Raw Domain allows the allocator to be called without an attached thread state). See the section on allocator domains for more information.
- If called after Python has finish initializing (after `Py_InitializeFromConfig()` has been called) the allocator **must** wrap the existing allocator. Substituting the current allocator for some other arbitrary one is **not supported**.

Changed in version 3.12: All allocators must be thread-safe.

void PyMem_SetupDebugHooks(void)

Setup debug hooks in the Python memory allocators to detect memory errors.

Debug hooks on the Python memory allocators

When Python is built in debug mode, the `PyMem_SetupDebugHooks()` function is called at the Python preinitialization to setup debug hooks on Python memory allocators to detect memory errors.

The `PYTHONMALLOC` environment variable can be used to install debug hooks on a Python compiled in release mode (ex: `PYTHONMALLOC=debug`).

The `PyMem_SetupDebugHooks()` function can be used to set debug hooks after calling `PyMem_SetAllocator()`.

These debug hooks fill dynamically allocated memory blocks with special, recognizable bit patterns. Newly allocated memory is filled with the byte `0xCD` (`PYMEM_CLEANBYTE`), freed memory is filled with the byte `0xDD` (`PYMEM_DEADBYTE`). Memory blocks are surrounded by “forbidden bytes” filled with the byte `0xFD` (`PYMEM_FORBIDDENBYTE`). Strings of these bytes are unlikely to be valid addresses, floats, or ASCII strings.

Runtime checks:

- Detect API violations. For example, detect if `PyObject_Free()` is called on a memory block allocated by `PyMem_Malloc()`.
- Detect write before the start of the buffer (buffer underflow).
- Detect write after the end of the buffer (buffer overflow).
- Check that there is an attached thread state when allocator functions of `PYMEM_DOMAIN_OBJ` (ex: `PyObject_Malloc()`) and `PYMEM_DOMAIN_MEM` (ex: `PyMem_Malloc()`) domains are called.

On error, the debug hooks use the `tracemalloc` module to get the traceback where a memory block was allocated. The traceback is only displayed if `tracemalloc` is tracing Python memory allocations and the memory block was traced.

Let *S* = `sizeof(size_t)`. `2*S` bytes are added at each end of each block of *N* bytes requested. The memory layout is like so, where p represents the address returned by a malloc-like or realloc-like function (`p[i:j]` means the slice of bytes from `*(p+i)` inclusive up to `*(p+j)` exclusive; note that the treatment of negative indices differs from a Python slice):

`p[-2*S:-S]`
Number of bytes originally asked for. This is a size_t, big-endian (easier to read in a memory dump).

`p[-S]`
API identifier (ASCII character):

- `'r'` for **`PYMEM_DOMAIN_RAW`**.
- `'m'` for **`PYMEM_DOMAIN_MEM`**.
- `'o'` for **`PYMEM_DOMAIN_OBJ`**.

`p[-S+1:0]`
Copies of PYMEM_FORBIDDENBYTE. Used to catch under- writes and reads.

`p[0:N]`
The requested memory, filled with copies of PYMEM_CLEANBYTE, used to catch reference to uninitialized memory. When a realloc-like function is called requesting a larger memory block, the new excess bytes are also filled with PYMEM_CLEANBYTE. When a free-like function is called, these are overwritten with PYMEM_DEADBYTE, to catch reference to freed memory. When a realloc- like function is called requesting a smaller memory block, the excess old bytes are also filled with PYMEM_DEADBYTE.

`p[N:N+S]`
Copies of PYMEM_FORBIDDENBYTE. Used to catch over- writes and reads.

`p[N+S:N+2*S]`
Only used if the `PYMEM_DEBUG_SERIALNO` macro is defined (not defined by default).

A serial number, incremented by 1 on each call to a malloc-like or realloc-like function. Big-endian **`size_t`**. If “bad memory” is detected later, the serial number gives an excellent way to set a breakpoint on the next run, to capture the instant at which this block was passed out. The static function bumpserialno() in obmalloc.c is the only place the serial number is incremented, and exists so you can set such a breakpoint easily.

A realloc-like or free-like function first checks that the PYMEM_FORBIDDENBYTE bytes at each end are intact. If they’ve been altered, diagnostic output is written to stderr, and the program is aborted via Py_FatalError(). The other main failure mode is provoking a memory error when a program reads up one of the special bit patterns and tries to use it as an address. If you get in a debugger then and look at the object, you’re likely to see that it’s entirely filled with PYMEM_DEADBYTE (meaning freed memory is getting used) or PYMEM_CLEANBYTE (meaning uninitialized memory is getting used).

Changed in version 3.6: The **`PyMem_SetupDebugHooks()`** function now also works on Python compiled in release mode. On error, the debug hooks now use **`tracemalloc`** to get the traceback where a memory block was allocated. The debug hooks now also check if there is an attached thread state when functions of **`PYMEM_DOMAIN_OBJ`** and **`PYMEM_DOMAIN_MEM`** domains are called.

Changed in version 3.8: Byte patterns `0xCB` (`PYMEM_CLEANBYTE`), `0xDB` (`PYMEM_DEADBYTE`) and `0xFB` (`PYMEM_FORBIDDENBYTE`) have been replaced with `0xCD`, `0xDD` and `0xFD` to use the same values than Windows CRT debug `malloc()` and `free()`.

The pymalloc allocator

Python has a *pymalloc* allocator optimized for small objects (smaller or equal to 512 bytes) with a short lifetime. It uses memory mappings called “arenas” with a fixed size of either 256 KiB on 32-bit platforms or 1 MiB on 64-bit platforms. It falls back to `PyMem_RawMalloc()` and `PyMem_RawRealloc()` for allocations larger than 512 bytes.

pymalloc is the default allocator of the `PYMEM_DOMAIN_MEM` (ex: `PyMem_Malloc()`) and `PYMEM_DOMAIN_OBJ` (ex: `PyObject_Malloc()`) domains.

The arena allocator uses the following functions:

- `VirtualAlloc()` and `VirtualFree()` on Windows,
- `mmap()` and `munmap()` if available,
- `malloc()` and `free()` otherwise.

This allocator is disabled if Python is configured with the `--without-pymalloc` option. It can also be disabled at runtime using the `PYTHONMALLOC` environment variable (ex: `PYTHONMALLOC=malloc`).

Typically, it makes sense to disable the pymalloc allocator when building Python with AddressSanitizer (`--with-address-sanitizer`) which helps uncover low level bugs within the C code.

Customize pymalloc Arena Allocator

Added in version 3.4.

type PyObjectArenaAllocator

Structure used to describe an arena allocator. The structure has three fields:

Field	**Meaning**
`void *ctx`	user context passed as first argument
`void* alloc(void *ctx, size_t size)`	allocate an arena of size bytes
`void free(void *ctx, void *ptr, size_t size)`	free an arena

void PyObject_GetArenaAllocator(PyObjectArenaAllocator *allocator)

Get the arena allocator.

void PyObject_SetArenaAllocator(PyObjectArenaAllocator *allocator)

Set the arena allocator.

The mimalloc allocator

Added in version 3.13.

Python supports the mimalloc allocator when the underlying platform support is available. mimalloc “is a general purpose allocator with excellent performance characteristics. Initially developed by Daan Leijen for the runtime systems of the Koka and Lean languages.”

tracemalloc C API

Added in version 3.7.

int PyTraceMalloc_Track(unsigned int domain, uintptr_t ptr, size_t size)

Track an allocated memory block in the **`tracemalloc`** module.

Return `0` on success, return `-1` on error (failed to allocate memory to store the trace). Return `-2` if tracemalloc is disabled.

If memory block is already tracked, update the existing trace.

int PyTraceMalloc_Untrack(unsigned int domain, uintptr_t ptr)

Untrack an allocated memory block in the **`tracemalloc`** module. Do nothing if the block was not tracked.

Return `-2` if tracemalloc is disabled, otherwise return `0`.

Examples

Here is the example from section Overview, rewritten so that the I/O buffer is allocated from the Python heap by using the first function set:

```
PyObject *res;
char *buf = (char *) PyMem_Malloc(BUFSIZ); /* for I/O */

if (buf == NULL)
    return PyErr_NoMemory();
/* ...Do some I/O operation involving buf... */
res = PyBytes_FromString(buf);
PyMem_Free(buf); /* allocated with PyMem_Malloc */
return res;
```

The same code using the type-oriented function set:

```
PyObject *res;
char *buf = PyMem_New(char, BUFSIZ); /* for I/O */

if (buf == NULL)
    return PyErr_NoMemory();
/* ...Do some I/O operation involving buf... */
res = PyBytes_FromString(buf);
PyMem_Free(buf); /* allocated with PyMem_New */
return res;
```

Note that in the two examples above, the buffer is always manipulated via functions belonging to the same set. Indeed, it is required to use the same memory API family for a given memory block, so that the risk of mixing different allocators is reduced to a minimum. The following code sequence contains two errors, one of which is labeled as *fatal* because it mixes two different allocators operating on different heaps.

```
char *buf1 = PyMem_New(char, BUFSIZ);
char *buf2 = (char *) malloc(BUFSIZ);
char *buf3 = (char *) PyMem_Malloc(BUFSIZ);
...
PyMem_Del(buf3);  /* Wrong -- should be PyMem_Free() */
free(buf2);       /* Right -- allocated via malloc() */
free(buf1);       /* Fatal -- should be PyMem_Free()  */
```

In addition to the functions aimed at handling raw memory blocks from the Python heap, objects in Python are allocated and released with **`PyObject_New`**, **`PyObject_NewVar`** and

`PyObject_Free()`.

These will be explained in the next chapter on defining and implementing new object types in C.

Object Implementation Support

This chapter describes the functions, types, and macros used when defining new object types.

Allocating Objects on the Heap

PyObject *_PyObject_New(PyTypeObject *type)

Return value: New reference.

PyVarObject *_PyObject_NewVar(PyTypeObject *type, Py_ssize_t size)

Return value: New reference.

PyObject *PyObject_Init(PyObject *op, PyTypeObject *type)

Return value: Borrowed reference. Part of the Stable ABI.

Initialize a newly allocated object *op* with its type and initial reference. Returns the initialized object. Other fields of the object are not initialized. Despite its name, this function is unrelated to the object's `__init__()` method (`tp_init` slot). Specifically, this function does **not** call the object's `__init__()` method.

In general, consider this function to be a low-level routine. Use `tp_alloc` where possible. For implementing `tp_alloc` for your type, prefer `PyType_GenericAlloc()` or `PyObject_New()`.

Note

This function only initializes the object's memory corresponding to the initial `PyObject` structure. It does not zero the rest.

PyVarObject *PyObject_InitVar(PyVarObject *op, PyTypeObject *type, Py_ssize_t size)

Return value: Borrowed reference. Part of the Stable ABI.
This does everything `PyObject_Init()` does, and also initializes the length information for a variable-size object.

Note

This function only initializes some of the object's memory. It does not zero the rest.

PyObject_New(TYPE, typeobj)

Allocates a new Python object using the C structure type *TYPE* and the Python type object *typeobj* (`PyTypeObject*`) by calling `PyObject_Malloc()` to allocate memory and initializing it like `PyObject_Init()`. The caller will own the only reference to the object (i.e. its reference count will be one).

Avoid calling this directly to allocate memory for an object; call the type's `tp_alloc` slot instead.

When populating a type's `tp_alloc` slot, `PyType_GenericAlloc()` is preferred over a custom function that simply calls this macro.

This macro does not call `tp_alloc`, `tp_new` (`__new__()`), or `tp_init` (`__init__()`).

This cannot be used for objects with `Py_TPFLAGS_HAVE_GC` set in `tp_flags`; use `PyObject_GC_New` instead.

Memory allocated by this macro must be freed with `PyObject_Free()` (usually called via the object's `tp_free` slot).

Note

The returned memory is not guaranteed to have been completely zeroed before it was initialized.

Note

This macro does not construct a fully initialized object of the given type; it merely allocates memory and prepares it for further initialization by **`tp_init`**. To construct a fully initialized object, call *typeobj* instead. For example:

```
PyObject *foo = PyObject_CallNoArgs((PyObject
*)&PyFoo_Type);
```

See also

- **`PyObject_Free()`**
- **`PyObject_GC_New`**
- **`PyType_GenericAlloc()`**
- **`tp_alloc`**

PyObject_NewVar(TYPE, typeobj, size)

Like **`PyObject_New`** except:

- It allocates enough memory for the *TYPE* structure plus *size* (`Py_ssize_t`) fields of the size given by the **`tp_itemsize`** field of *typeobj*.
- The memory is initialized like **`PyObject_InitVar()`**.

This is useful for implementing objects like tuples, which are able to determine their size at construction time. Embedding the array of fields into the same allocation decreases the number of allocations, improving the memory management efficiency.

Avoid calling this directly to allocate memory for an object; call the type’s `tp_alloc` slot instead.

When populating a type’s `tp_alloc` slot, `PyType_GenericAlloc()` is preferred over a custom function that simply calls this macro.

This cannot be used for objects with `Py_TPFLAGS_HAVE_GC` set in `tp_flags`; use `PyObject_GC_NewVar` instead.

Memory allocated by this function must be freed with `PyObject_Free()` (usually called via the object’s `tp_free` slot).

Note

The returned memory is not guaranteed to have been completely zeroed before it was initialized.

Note

This macro does not construct a fully initialized object of the given type; it merely allocates memory and prepares it for further initialization by `tp_init`. To construct a fully initialized object, call *typeobj* instead. For example:

```
PyObject *list_instance = PyObject_CallNoArgs((PyObject
*)&PyList_Type);
```

- `PyObject_GC_NewVar`

- `PyType_GenericAlloc()`
- `tp_alloc`

PyObject _Py_NoneStruct

Object which is visible in Python as `None`. This should only be accessed using the `Py_None` macro, which evaluates to a pointer to this object.

See also

Module Objects

To allocate and create extension modules.

Deprecated aliases

These are soft deprecated aliases to existing functions and macros. They exist solely for backwards compatibility.

Deprecated alias	Function
PyObject_NEW(type, typeobj)	`PyObject_New`
PyObject_NEW_VAR(type, typeobj, n)	`PyObject_NewVar`
PyObject_INIT(op, typeobj)	`PyObject_Init()`
PyObject_INIT_VAR(op, typeobj, n)	`PyObject_InitVar()`
PyObject_MALLOC(n)	`PyObject_Malloc()`

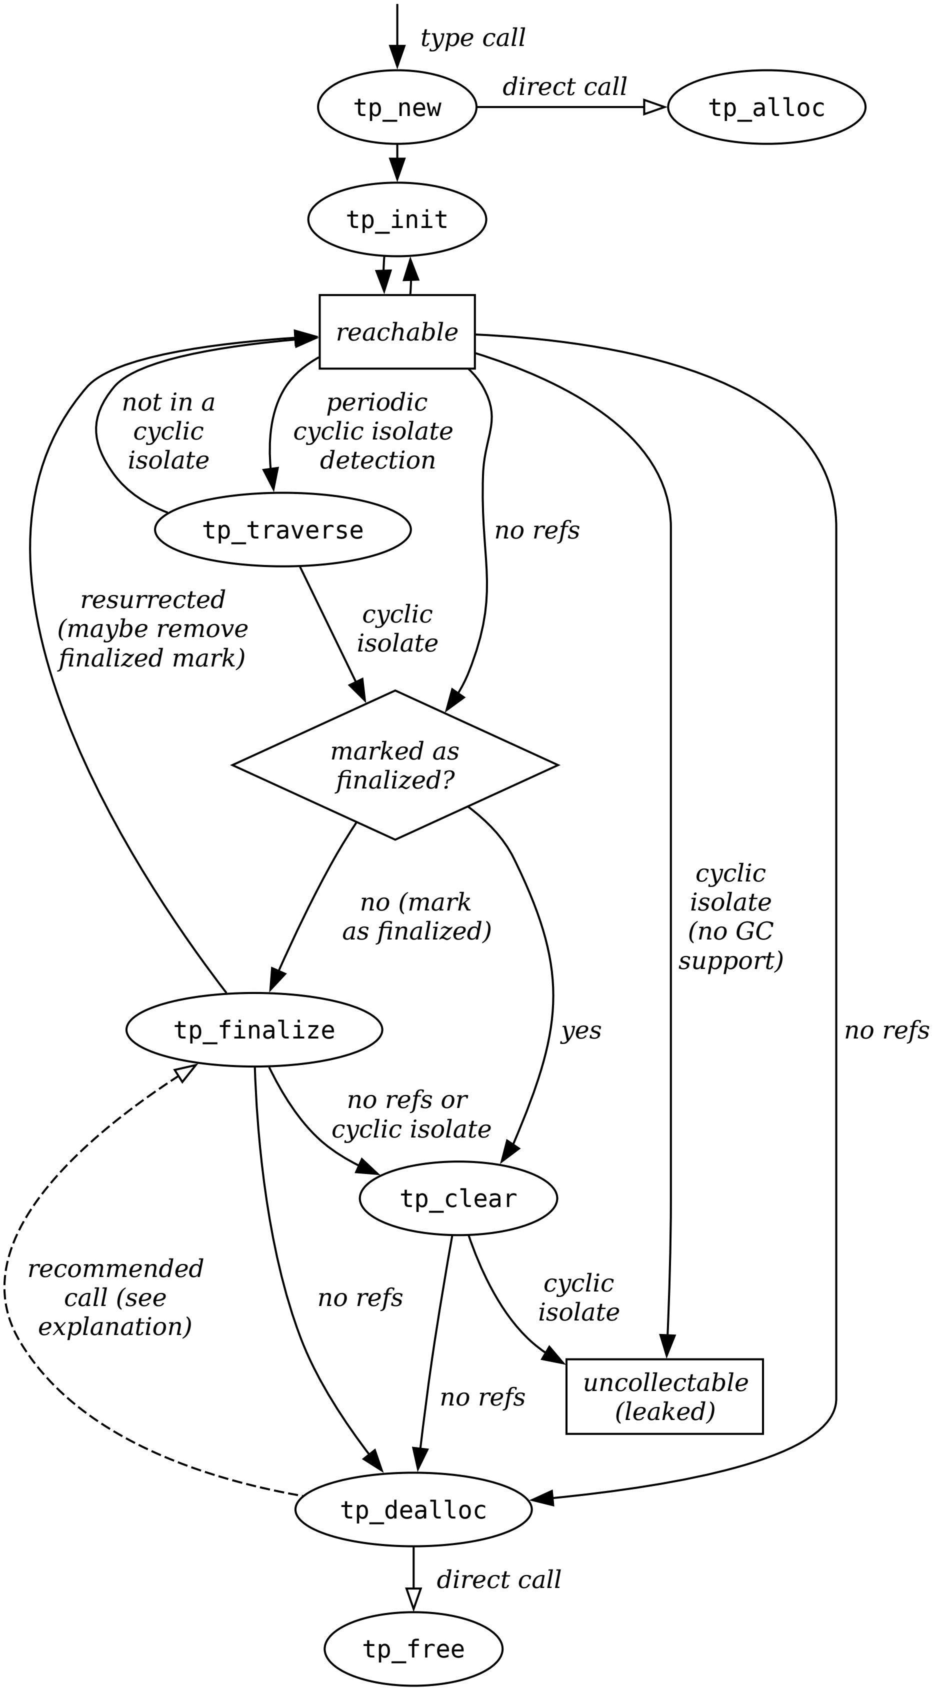
Deprecated alias	Function
PyObject_REALLOC(p, n)	`PyObject_Realloc()`
PyObject_FREE(p)	`PyObject_Free()`
PyObject_DEL(p)	`PyObject_Free()`
PyObject_Del(p)	`PyObject_Free()`

Object Life Cycle

This section explains how a type's slots relate to each other throughout the life of an object. It is not intended to be a complete canonical reference for the slots; instead, refer to the slot-specific documentation in Type Object Structures for details about a particular slot.

Life Events

The figure below illustrates the order of events that can occur throughout an object's life. An arrow from *A* to *B* indicates that event *B* can occur after event *A* has occurred, with the arrow's label indicating the condition that must be true for *B* to occur after *A*.



type call
tp_new
direct call
tp_alloc
tp_init
reachable
not in a cyclic isolate
periodic cyclic isolate detection
no refs
tp_traverse
resurrected (maybe remove finalized mark)
cyclic isolate
marked as finalized?
no (mark as finalized)
yes
cyclic isolate (no GC support)
no refs
tp_finalize
no refs or cyclic isolate
tp_clear
recommended call (see explanation)
no refs
cyclic isolate
no refs
uncollectable (leaked)
tp_dealloc
direct call
tp_free

Explanation:

- When a new object is constructed by calling its type:
  1. `tp_new` is called to create a new object.
  2. `tp_alloc` is directly called by `tp_new` to allocate the memory for the new object.
  3. `tp_init` initializes the newly created object. **`tp_init`** can be called again to re-initialize an object, if desired. The **`tp_init`** call can also be skipped entirely, for example by Python code calling `__new__()`.
- After **`tp_init`** completes, the object is ready to use.
- Some time after the last reference to an object is removed:
  1. If an object is not marked as *finalized*, it might be finalized by marking it as *finalized* and calling its `tp_finalize` function. Python does *not* finalize an object when the last reference to it is deleted; use `PyObject_CallFinalizerFromDealloc()` to ensure that `tp_finalize` is always called.
  2. If the object is marked as finalized, `tp_clear` might be called by the garbage collector to clear references held by the object. It is *not* called when the object's reference count reaches zero.
  3. `tp_dealloc` is called to destroy the object. To avoid code duplication, `tp_dealloc` typically calls into `tp_clear` to free up the object's references.
  4. When `tp_dealloc` finishes object destruction, it directly calls `tp_free` (usually set to `PyObject_Free()` or `PyObject_GC_Del()` automatically as appropriate for the type) to deallocate the memory.
- The `tp_finalize` function is permitted to add a reference to the object if desired. If it does, the object is *resurrected*, preventing its pending destruction. (Only **`tp_finalize`** is allowed to resurrect an object; `tp_clear` and `tp_dealloc` cannot without calling into **`tp_finalize`**.)

  Resurrecting an object may or may not cause the object's *finalized* mark to be removed. Currently, Python does not remove the *finalized* mark from a resurrected object if it supports garbage collection (i.e., the `Py_TPFLAGS_HAVE_GC` flag is set) but does remove the mark if the object does not support garbage collection; either or both of these behaviors may change in the future.
- `tp_dealloc` can optionally call `tp_finalize` via `PyObject_CallFinalizerFromDealloc()` if it wishes to reuse that code to help with object destruction. This is recommended because it guarantees that `tp_finalize` is always called before destruction. See the `tp_dealloc` documentation for example code.
- If the object is a member of a cyclic isolate and either `tp_clear` fails to break the reference cycle or the cyclic isolate is not detected (perhaps `gc.disable()` was called, or the `Py_TPFLAGS_HAVE_GC` flag was erroneously omitted in one of the involved types), the objects remain indefinitely uncollectable (they "leak"). See `gc.garbage`.

If the object is marked as supporting garbage collection (the `Py_TPFLAGS_HAVE_GC` flag is set in `tp_flags`), the following events are also possible:

- The garbage collector occasionally calls `tp_traverse` to identify cyclic isolates.
- When the garbage collector discovers a cyclic isolate, it finalizes one of the objects in the group by marking it as *finalized* and calling its `tp_finalize` function, if it has one. This repeats until the cyclic isolate doesn't exist or all of the objects have been finalized.
- `tp_finalize` is permitted to resurrect the object by adding a reference from outside the cyclic isolate. The new reference causes the group of objects to no longer form a cyclic isolate (the reference cycle may still exist, but if it does the objects are no longer isolated).

- When the garbage collector discovers a cyclic isolate and all of the objects in the group have already been marked as *finalized*, the garbage collector clears one or more of the uncleared objects in the group (possibly concurrently) by calling each's `tp_clear` function. This repeats as long as the cyclic isolate still exists and not all of the objects have been cleared.

Cyclic Isolate Destruction

Listed below are the stages of life of a hypothetical cyclic isolate that continues to exist after each member object is finalized or cleared. It is a memory leak if a cyclic isolate progresses through all of these stages; it should vanish once all objects are cleared, if not sooner. A cyclic isolate can vanish either because the reference cycle is broken or because the objects are no longer isolated due to finalizer resurrection (see `tp_finalize`).

0. **Reachable** (not yet a cyclic isolate): All objects are in their normal, reachable state. A reference cycle could exist, but an external reference means the objects are not yet isolated.
1. **Unreachable but consistent:** The final reference from outside the cyclic group of objects has been removed, causing the objects to become isolated (thus a cyclic isolate is born). None of the group's objects have been finalized or cleared yet. The cyclic isolate remains at this stage until some future run of the garbage collector (not necessarily the next run because the next run might not scan every object).
2. **Mix of finalized and not finalized:** Objects in a cyclic isolate are finalized one at a time, which means that there is a period of time when the cyclic isolate is composed of a mix of finalized and non-finalized

objects. Finalization order is unspecified, so it can appear random. A finalized object must behave in a sane manner when non-finalized objects interact with it, and a non-finalized object must be able to tolerate the finalization of an arbitrary subset of its referents.

3. **All finalized:** All objects in a cyclic isolate are finalized before any of them are cleared.
4. **Mix of finalized and cleared:** The objects can be cleared serially or concurrently (but with the GIL held); either way, some will finish before others. A finalized object must be able to tolerate the clearing of a subset of its referents. **PEP 442** [https://peps.python.org/pep-0442/] calls this stage “cyclic trash”.
5. **Leaked:** If a cyclic isolate still exists after all objects in the group have been finalized and cleared, then the objects remain indefinitely uncollectable (see `gc.garbage`). It is a bug if a cyclic isolate reaches this stage—it means the `tp_clear` methods of the participating objects have failed to break the reference cycle as required.

If `tp_clear` did not exist, then Python would have no way to safely break a reference cycle. Simply destroying an object in a cyclic isolate would result in a dangling pointer, triggering undefined behavior when an object referencing the destroyed object is itself destroyed. The clearing step makes object destruction a two-phase process: first `tp_clear` is called to partially destroy the objects enough to detangle them from each other, then `tp_dealloc` is called to complete the destruction.

Unlike clearing, finalization is not a phase of destruction. A finalized object must still behave properly by continuing to fulfill its design contracts. An object’s finalizer is allowed to execute arbitrary Python code, and is even allowed to prevent the impending destruction by adding a reference.

The finalizer is only related to destruction by call order—if it runs, it runs before destruction, which starts with **`tp_clear`** (if called) and concludes with **`tp_dealloc`**.

The finalization step is not necessary to safely reclaim the objects in a cyclic isolate, but its existence makes it easier to design types that behave in a sane manner when objects are cleared. Clearing an object might necessarily leave it in a broken, partially destroyed state—it might be unsafe to call any of the cleared object's methods or access any of its attributes. With finalization, only finalized objects can possibly interact with cleared objects; non-finalized objects are guaranteed to interact with only non-cleared (but potentially finalized) objects.

To summarize the possible interactions:

- A non-finalized object might have references to or from non-finalized and finalized objects, but not to or from cleared objects.
- A finalized object might have references to or from non-finalized, finalized, and cleared objects.
- A cleared object might have references to or from finalized and cleared objects, but not to or from non-finalized objects.

Without any reference cycles, an object can be simply destroyed once its last reference is deleted; the finalization and clearing steps are not necessary to safely reclaim unused objects. However, it can be useful to automatically call **`tp_finalize`** and **`tp_clear`** before destruction anyway because type design is simplified when all objects always experience the same series of events regardless of whether they participated in a cyclic isolate. Python currently only calls **`tp_finalize`** and **`tp_clear`** as needed to destroy a cyclic isolate; this may change in a future version.

Functions

To allocate and free memory, see Allocating Objects on the Heap.

void PyObject_CallFinalizer(PyObject *op)

Finalizes the object as described in `tp_finalize`. Call this function (or `PyObject_CallFinalizerFromDealloc()`) instead of calling `tp_finalize` directly because this function may deduplicate multiple calls to `tp_finalize`. Currently, calls are only deduplicated if the type supports garbage collection (i.e., the `Py_TPFLAGS_HAVE_GC` flag is set); this may change in the future.

int PyObject_CallFinalizerFromDealloc(PyObject *op)

Same as `PyObject_CallFinalizer()` but meant to be called at the beginning of the object's destructor (`tp_dealloc`). There must not be any references to the object. If the object's finalizer resurrects the object, this function returns -1; no further destruction should happen. Otherwise, this function returns 0 and destruction can continue normally.

See also

`tp_dealloc` for example code.

Common Object Structures

There are a large number of structures which are used in the definition of object types for Python. This section describes these structures and how they are used.

Base object types and macros

All Python objects ultimately share a small number of fields at the beginning of the object's representation in memory. These are represented by the **`PyObject`** and **`PyVarObject`** types, which are defined, in turn, by the expansions of some macros also used, whether directly or indirectly, in the definition of all other Python objects. Additional macros can be found under reference counting.

type PyObject

Part of the Limited API. (Only some members are part of the stable ABI.)
All object types are extensions of this type. This is a type which contains the information Python needs to treat a pointer to an object as an object. In a normal "release" build, it contains only the object's reference count and a pointer to the corresponding type object. Nothing is actually declared to be a **`PyObject`**, but every pointer to a Python object can be cast to a PyObject*.

The members must not be accessed directly; instead use macros such as **`Py_REFCNT`** and **`Py_TYPE`**.

Py_ssize_t ob_refcnt

Part of the Stable ABI.

The object’s reference count, as returned by **`Py_REFCNT`**. Do not use this field directly; instead use functions and macros such as **`Py_REFCNT`**, **`Py_INCREF()`** and **`Py_DecRef()`**.

The field type may be different from `Py_ssize_t`, depending on build configuration and platform.

PyTypeObject *ob_type

Part of the Stable ABI.
The object’s type. Do not use this field directly; use **`Py_TYPE`** and **`Py_SET_TYPE()`** instead.

type PyVarObject

Part of the Limited API. (Only some members are part of the stable ABI.)
An extension of **`PyObject`** that adds the **`ob_size`** field. This is intended for objects that have some notion of *length*.

As with **`PyObject`**, the members must not be accessed directly; instead use macros such as **`Py_SIZE`**, **`Py_REFCNT`** and **`Py_TYPE`**.

Py_ssize_t ob_size

Part of the Stable ABI.
A size field, whose contents should be considered an object’s internal implementation detail.

Do not use this field directly; use **`Py_SIZE`** instead.

Object creation functions such as **`PyObject_NewVar()`** will generally set this field to the requested size (number of items). After creation, arbitrary values can be stored in **`ob_size`** using **`Py_SET_SIZE`**.

To get an object’s publicly exposed length, as returned by the Python function **`len()`**, use **`PyObject_Length()`**

instead.

PyObject_HEAD

This is a macro used when declaring new types which represent objects without a varying length. The PyObject_HEAD macro expands to:

```
PyObject ob_base;
```

See documentation of **`PyObject`** above.

PyObject_VAR_HEAD

This is a macro used when declaring new types which represent objects with a length that varies from instance to instance. The PyObject_VAR_HEAD macro expands to:

```
PyVarObject ob_base;
```

See documentation of **`PyVarObject`** above.

PyTypeObject PyBaseObject_Type

Part of the Stable ABI.
The base class of all other objects, the same as **`object`** in Python.

int Py_Is(PyObject *x, PyObject *y)

Part of the Stable ABI since version 3.10.
Test if the *x* object is the *y* object, the same as `x is y` in Python.

Added in version 3.10.

int Py_IsNone(PyObject *x)

Part of the Stable ABI since version 3.10.
Test if an object is the `None` singleton, the same as `x is None` in Python.

Added in version 3.10.

int Py_IsTrue(PyObject *x)

Part of the Stable ABI since version 3.10.
Test if an object is the `True` singleton, the same as `x is True` in Python.

Added in version 3.10.

int Py_IsFalse(PyObject *x)

Part of the Stable ABI since version 3.10.
Test if an object is the `False` singleton, the same as `x is False` in Python.

Added in version 3.10.

PyTypeObject *Py_TYPE(PyObject *o)

Return value: Borrowed reference. Part of the Stable ABI since version 3.14.
Get the type of the Python object *o*.

The returned reference is borrowed from *o*. Do not release it with **`Py_DECREF()`** or similar.

Changed in version 3.11: **`Py_TYPE()`** is changed to an inline static function. The parameter type is no longer const PyObject*.

int Py_IS_TYPE(PyObject *o, PyTypeObject *type)

Return non-zero if the object *o* type is *type*. Return zero otherwise. Equivalent to: `Py_TYPE(o) == type`.

Added in version 3.9.

void Py_SET_TYPE(PyObject *o, PyTypeObject *type)

Set the type of object *o* to *type*, without any checking or reference counting.

This is a very low-level operation. Consider instead setting the Python attribute **`__class__`** using **`PyObject_SetAttrString()`** or similar.

Note that assigning an incompatible type can lead to undefined behavior.

If *type* is a heap type, the caller must create a new reference to it. Similarly, if the old type of *o* is a heap type, the caller must release a reference to that type.

Added in version 3.9.

Py_ssize_t Py_SIZE(PyVarObject *o)

Get the **`ob_size`** field of *o*.

Changed in version 3.11: **`Py_SIZE()`** is changed to an inline static function. The parameter type is no longer const PyVarObject*.

void Py_SET_SIZE(PyVarObject *o, Py_ssize_t size)

Set the **`ob_size`** field of *o* to *size*.

Added in version 3.9.

PyObject_HEAD_INIT(type)

This is a macro which expands to initialization values for a new **`PyObject`** type. This macro expands to:

```
_PyObject_EXTRA_INIT
1, type,
```

PyVarObject_HEAD_INIT(type, size)

This is a macro which expands to initialization values for a new **`PyVarObject`** type, including the **`ob_size`** field. This macro expands to:

```
_PyObject_EXTRA_INIT
1, type, size,
```

Implementing functions and methods

type PyCFunction

Part of the Stable ABI.

Type of the functions used to implement most Python callables in C. Functions of this type take two PyObject* parameters and return one such value. If the return value is `NULL`, an exception shall have been set. If not `NULL`, the return value is interpreted as the return value of the function as exposed in Python. The function must return a new reference.

The function signature is:

```
PyObject *PyCFunction(PyObject *self,
                      PyObject *args);
```

type PyCFunctionWithKeywords

Part of the Stable ABI.

Type of the functions used to implement Python callables in C with signature METH_VARARGS | METH_KEYWORDS. The function signature is:

```
PyObject *PyCFunctionWithKeywords(PyObject *self,
                                  PyObject *args,
                                  PyObject *kwargs);
```

type PyCFunctionFast

Part of the Stable ABI since version 3.13.

Type of the functions used to implement Python callables in C with signature **`METH_FASTCALL`**. The function signature is:

```
PyObject *PyCFunctionFast(PyObject *self,
                          PyObject *const *args,
                          Py_ssize_t nargs);
```

type PyCFunctionFastWithKeywords

Part of the Stable ABI since version 3.13.
Type of the functions used to implement Python callables in C with signature METH_FASTCALL | METH_KEYWORDS. The function signature is:

```
PyObject *PyCFunctionFastWithKeywords(PyObject *self,
                                      PyObject *const *args,
                                      Py_ssize_t nargs,
                                      PyObject *kwnames);
```

type PyCMethod

Type of the functions used to implement Python callables in C with signature METH_METHOD | METH_FASTCALL | METH_KEYWORDS. The function signature is:

```
PyObject *PyCMethod(PyObject *self,
                    PyTypeObject *defining_class,
                    PyObject *const *args,
                    Py_ssize_t nargs,
                    PyObject *kwnames)
```

Added in version 3.9.

type PyMethodDef

Part of the Stable ABI (including all members).
Structure used to describe a method of an extension type. This structure has four fields:

const char *ml_name

Name of the method.

PyCFunction ml_meth

Pointer to the C implementation.

int ml_flags

Flags bits indicating how the call should be constructed.

const char *ml_doc

Points to the contents of the docstring.

The **`ml_meth`** is a C function pointer. The functions may be of different types, but they always return PyObject*. If the function is not of the **`PyCFunction`**, the compiler will require a cast in the method table. Even though **`PyCFunction`** defines the first parameter as PyObject*, it is common that the method implementation uses the specific C type of the *self* object.

The **`ml_flags`** field is a bitfield which can include the following flags. The individual flags indicate either a calling convention or a binding convention.

There are these calling conventions:

METH_VARARGS

Part of the Stable ABI.

This is the typical calling convention, where the methods have the type **`PyCFunction`**. The function expects two PyObject* values. The first one is the *self* object for methods; for module functions, it is the module object. The second parameter (often called *args*) is a tuple object representing all arguments. This parameter is typically processed using **`PyArg_ParseTuple()`** or **`PyArg_UnpackTuple()`**.

METH_KEYWORDS

Can only be used in certain combinations with other flags: METH_VARARGS | METH_KEYWORDS, METH_FASTCALL | METH_KEYWORDS and METH_METHOD | METH_FASTCALL | METH_KEYWORDS.

METH_VARARGS | METH_KEYWORDS

Methods with these flags must be of type `PyCFunctionWithKeywords`. The function expects three parameters: *self*, *args*, *kwargs* where *kwargs* is a dictionary of all the keyword arguments or possibly `NULL` if there are no keyword arguments. The parameters are typically processed using `PyArg_ParseTupleAndKeywords()`.

METH_FASTCALL

Part of the Stable ABI since version 3.7.
Fast calling convention supporting only positional arguments. The methods have the type `PyCFunctionFast`. The first parameter is *self*, the second parameter is a C array of PyObject* values indicating the arguments and the third parameter is the number of arguments (the length of the array).

Added in version 3.7.

Changed in version 3.10: `METH_FASTCALL` is now part of the stable ABI.

METH_FASTCALL | METH_KEYWORDS

Extension of `METH_FASTCALL` supporting also keyword arguments, with methods of type `PyCFunctionFastWithKeywords`. Keyword arguments are passed the same way as in the vectorcall protocol: there is an additional fourth PyObject* parameter which is a tuple representing the names of the keyword arguments (which are guaranteed to be strings) or possibly `NULL` if there are no keywords. The values of the keyword arguments are stored in the *args* array, after the positional arguments.

Added in version 3.7.

METH_METHOD

Part of the Stable ABI since version 3.7.
Can only be used in the combination with other flags: METH_METHOD | METH_FASTCALL | METH_KEYWORDS.

METH_METHOD | METH_FASTCALL | METH_KEYWORDS

Extension of METH_FASTCALL | METH_KEYWORDS supporting the *defining class*, that is, the class that contains the method in question. The defining class might be a superclass of `Py_TYPE(self)`.

The method needs to be of type **`PyCMethod`**, the same as for `METH_FASTCALL | METH_KEYWORDS` with `defining_class` argument added after `self`.

Added in version 3.9.

METH_NOARGS

Part of the Stable ABI.
Methods without parameters don’t need to check whether arguments are given if they are listed with the **`METH_NOARGS`** flag. They need to be of type **`PyCFunction`**. The first parameter is typically named *self* and will hold a reference to the module or object instance. In all cases the second parameter will be `NULL`.

The function must have 2 parameters. Since the second parameter is unused, **`Py_UNUSED`** can be used to prevent a compiler warning.

METH_O

Part of the Stable ABI.
Methods with a single object argument can be listed with the **`METH_O`** flag, instead of invoking **`PyArg_ParseTuple()`** with a `"O"` argument. They have the type **`PyCFunction`**, with the *self* parameter, and a PyObject* parameter representing the single argument.

These two constants are not used to indicate the calling convention but the binding when use with methods of classes. These may not be used for functions defined for modules. At most one of these flags may be set for any given method.

METH_CLASS

Part of the Stable ABI.
The method will be passed the type object as the first parameter rather than an instance of the type. This is used to create *class methods*, similar to what is created when using the **`classmethod()`** built-in function.

METH_STATIC

Part of the Stable ABI.
The method will be passed `NULL` as the first parameter rather than an instance of the type. This is used to create *static methods*, similar to what is created when using the **`staticmethod()`** built-in function.

One other constant controls whether a method is loaded in place of another definition with the same method name.

METH_COEXIST

Part of the Stable ABI.
The method will be loaded in place of existing definitions. Without *METH_COEXIST*, the default is to skip repeated definitions. Since slot wrappers are loaded before the method table, the existence of a *sq_contains* slot, for

example, would generate a wrapped method named `__contains__()` and preclude the loading of a corresponding PyCFunction with the same name. With the flag defined, the PyCFunction will be loaded in place of the wrapper object and will co-exist with the slot. This is helpful because calls to PyCFunctions are optimized more than wrapper object calls.

PyTypeObject PyCMethod_Type

The type object corresponding to Python C method objects. This is available as **`types.BuiltinMethodType`** in the Python layer.

int PyCMethod_Check(PyObject *op)

Return true if *op* is an instance of the **`PyCMethod_Type`** type or a subtype of it. This function always succeeds.

int PyCMethod_CheckExact(PyObject *op)

This is the same as **`PyCMethod_Check()`**, but does not account for subtypes.

PyObject *PyCMethod_New(PyMethodDef *ml, PyObject *self, PyObject *module, PyTypeObject *cls)

Return value: New reference. Part of the Stable ABI since version 3.9.
Turn *ml* into a Python callable object. The caller must ensure that *ml* outlives the callable. Typically, *ml* is defined as a static variable.

The *self* parameter will be passed as the *self* argument to the C function in `ml->ml_meth` when invoked. *self* can be `NULL`.

The callable object's `__module__` attribute can be set from the given *module* argument. *module* should be a Python string, which will be used as name of the module the function is defined in. If unavailable, it can be set to `None` or `NULL`.

See also

`function.__module__`

The *cls* parameter will be passed as the *defining_class* argument to the C function. Must be set if `METH_METHOD` is set on `ml->ml_flags`.

Added in version 3.9.

PyTypeObject PyCFunction_Type

Part of the Stable ABI.

The type object corresponding to Python C function objects. This is available as `types.BuiltinFunctionType` in the Python layer.

int PyCFunction_Check(PyObject *op)

Return true if *op* is an instance of the `PyCFunction_Type` type or a subtype of it. This function always succeeds.

int PyCFunction_CheckExact(PyObject *op)

This is the same as `PyCFunction_Check()`, but does not account for subtypes.

PyObject *PyCFunction_NewEx(PyMethodDef *ml, PyObject *self, PyObject *module)

Return value: New reference. Part of the Stable ABI.

Equivalent to `PyCMethod_New(ml, self, module, NULL)`.

PyObject *PyCFunction_New(PyMethodDef *ml, PyObject *self)

Return value: New reference. Part of the Stable ABI since version 3.4.
Equivalent to `PyCMethod_New(ml, self, NULL, NULL)`.

int PyCFunction_GetFlags(PyObject *func)

Part of the Stable ABI.
Get the function's flags on *func* as they were passed to **`ml_flags`**.

If *func* is not a C function object, this fails with an exception. *func* must not be `NULL`.

This function returns the function's flags on success, and `-1` with an exception set on failure.

int PyCFunction_GET_FLAGS(PyObject *func)

This is the same as **`PyCFunction_GetFlags()`**, but without error or type checking.

PyCFunction PyCFunction_GetFunction(PyObject *func)

Part of the Stable ABI.
Get the function pointer on *func* as it was passed to **`ml_meth`**.

If *func* is not a C function object, this fails with an exception. *func* must not be `NULL`.

This function returns the function pointer on success, and `NULL` with an exception set on failure.

int PyCFunction_GET_FUNCTION(PyObject *func)

This is the same as **`PyCFunction_GetFunction()`**, but without error or type checking.

PyObject *PyCFunction_GetSelf(PyObject *func)

Part of the Stable ABI.

Get the “self” object on *func*. This is the object that would be passed to the first argument of a `PyCFunction`. For C function objects created through a `PyMethodDef` on a `PyModuleDef`, this is the resulting module object.

If *func* is not a C function object, this fails with an exception. *func* must not be `NULL`.

This function returns a borrowed reference to the “self” object on success, and `NULL` with an exception set on failure.

PyObject *PyCFunction_GET_SELF(PyObject *func)

This is the same as `PyCFunction_GetSelf()`, but without error or type checking.

Accessing attributes of extension types

type PyMemberDef

Part of the Stable ABI (including all members).
Structure which describes an attribute of a type which corresponds to a C struct member. When defining a class, put a NULL-terminated array of these structures in the `tp_members` slot.

Its fields are, in order:

const char *name

Name of the member. A NULL value marks the end of a `PyMemberDef[]` array.

The string should be static, no copy is made of it.

int type

The type of the member in the C struct. See Member types for the possible values.

Py_ssize_t offset

The offset in bytes that the member is located on the type's object struct.

int flags

Zero or more of the Member flags, combined using bitwise OR.

const char *doc

The docstring, or NULL. The string should be static, no copy is made of it. Typically, it is defined using **`PyDoc_STR`**.

By default (when **`flags`** is `0`), members allow both read and write access. Use the **`Py_READONLY`** flag for read-only access. Certain types, like **`Py_T_STRING`**, imply **`Py_READONLY`**. Only **`Py_T_OBJECT_EX`** (and legacy **`T_OBJECT`**) members can be deleted.

For heap-allocated types (created using **`PyType_FromSpec()`** or similar), `PyMemberDef` may contain a definition for the special member `"__vectorcalloffset__"`, corresponding to **`tp_vectorcall_offset`** in type objects. This member must be defined with `Py_T_PYSSIZET`, and either `Py_READONLY` or `Py_READONLY | Py_RELATIVE_OFFSET`. For example:

```
static PyMemberDef spam_type_members[] = {
    {"__vectorcalloffset__", Py_T_PYSSIZET,
     offsetof(Spam_object, vectorcall), Py_READONLY},
    {NULL}  /* Sentinel */
};
```

(You may need to `#include <stddef.h>` for **`offsetof()`**.)

The legacy offsets **`tp_dictoffset`** and **`tp_weaklistoffset`** can be defined similarly using `"__dictoffset__"` and `"__weaklistoffset__"` members, but extensions are strongly encouraged to use **`Py_TPFLAGS_MANAGED_DICT`** and **`Py_TPFLAGS_MANAGED_WEAKREF`** instead.

Changed in version 3.12: `PyMemberDef` is always available. Previously, it required including `"structmember.h"`.

Changed in version 3.14: **`Py_RELATIVE_OFFSET`** is now allowed for `"__vectorcalloffset__"`, `"__dictoffset__"` and `"__weaklistoffset__"`.

PyObject *PyMember_GetOne(const char *obj_addr, struct PyMemberDef *m)

Part of the Stable ABI.
Get an attribute belonging to the object at address *obj_addr*. The attribute is described by `PyMemberDef` *m*. Returns `NULL` on error.

Changed in version 3.12: `PyMember_GetOne` is always available. Previously, it required including `"structmember.h"`.

int PyMember_SetOne(char *obj_addr, struct PyMemberDef *m, PyObject *o)

Part of the Stable ABI.
Set an attribute belonging to the object at address *obj_addr* to object *o*. The attribute to set is described by `PyMemberDef` *m*. Returns `0` if successful and a negative value on failure.

Changed in version 3.12: `PyMember_SetOne` is always available. Previously, it required including `"structmember.h"`.

Member flags

The following flags can be used with **`PyMemberDef.flags`**:

Py_READONLY

Part of the Stable ABI since version 3.12.
Not writable.

Py_AUDIT_READ

Part of the Stable ABI since version 3.12.
Emit an `object.__getattr__` audit event before reading.

Py_RELATIVE_OFFSET

Part of the Stable ABI since version 3.12.
Indicates that the **`offset`** of this `PyMemberDef` entry indicates an offset from the subclass-specific data, rather than from `PyObject`.

Can only be used as part of the **`Py_tp_members`** **`slot`** when creating a class using negative **`basicsize`**. It is mandatory in that case. When setting **`tp_members`** from the slot during class creation, Python clears the flag and sets **`PyMemberDef.offset`** to the offset from the `PyObject` struct.

Changed in version 3.10: The **`RESTRICTED`**, **`READ_RESTRICTED`** and **`WRITE_RESTRICTED`** macros available with `#include "structmember.h"` are deprecated. **`READ_RESTRICTED`** and **`RESTRICTED`** are equivalent to **`Py_AUDIT_READ`**; **`WRITE_RESTRICTED`** does nothing.

Changed in version 3.12: The **`READONLY`** macro was renamed to **`Py_READONLY`**. The **`PY_AUDIT_READ`** macro was renamed with the `Py_` prefix. The new names are now always available. Previously, these required `#include "structmember.h"`. The header is still available and it provides the old names.

Member types

`PyMemberDef.type` can be one of the following macros corresponding to various C types. When the member is accessed in Python, it will be converted to the equivalent Python type. When it is set from Python, it will be converted back to the C type. If that is not possible, an exception such as `TypeError` or `ValueError` is raised.

Unless marked (D), attributes defined this way cannot be deleted using e.g. `del` or `delattr()`.

Macro name	C type	Python type
Py_T_BYTE *Part of the Stable ABI since version 3.12.*	char	`int`
Py_T_SHORT *Part of the Stable ABI since version 3.12.*	short	`int`
Py_T_INT *Part of the Stable ABI since version 3.12.*	int	`int`
Py_T_LONG *Part of the Stable ABI since version 3.12.*	long	`int`

Macro name	C type	Python type
Py_T_LONGLONG *Part of the Stable ABI since version 3.12.*	long long	`int`
Py_T_UBYTE *Part of the Stable ABI since version 3.12.*	unsigned char	`int`
Py_T_UINT *Part of the Stable ABI since version 3.12.*	unsigned int	`int`
Py_T_USHORT *Part of the Stable ABI since version 3.12.*	unsigned short	`int`
Py_T_ULONG *Part of the Stable ABI since version 3.12.*	unsigned long	`int`
Py_T_ULONGLONG *Part of the Stable ABI since version 3.12.*	unsigned long long	`int`
Py_T_PYSSIZET	Py_ssize_t	`int`

Macro name	**C type**	**Python type**
Part of the Stable ABI since version 3.12.		
Py_T_FLOAT *Part of the Stable ABI since version 3.12.*	float	`float`
Py_T_DOUBLE *Part of the Stable ABI since version 3.12.*	double	`float`
Py_T_BOOL *Part of the Stable ABI since version 3.12.*	char (written as 0 or 1)	`bool`
Py_T_STRING *Part of the Stable ABI since version 3.12.*	const char* (*)	`str` (RO)
Py_T_STRING_INPLACE *Part of the Stable ABI since version 3.12.*	const char[] (*)	`str` (RO)
Py_T_CHAR *Part of the Stable ABI since version 3.12.*	char (0-127)	`str` (**)

Macro name	**C type**	**Python type**
Py_T_OBJECT_EX *Part of the Stable ABI since version 3.12.*	PyObject*	**`object`** (D)

(*): Zero-terminated, UTF8-encoded C string. With **`Py_T_STRING`** the C representation is a pointer; with **`Py_T_STRING_INPLACE`** the string is stored directly in the structure.

(**): String of length 1. Only ASCII is accepted.

(RO): Implies **`Py_READONLY`**.

(D): Can be deleted, in which case the pointer is set to `NULL`. Reading a `NULL` pointer raises **`AttributeError`**.

Added in version 3.12: In previous versions, the macros were only available with `#include "structmember.h"` and were named without the `Py_` prefix (e.g. as `T_INT`). The header is still available and contains the old names, along with the following deprecated types:

T_OBJECT

Like `Py_T_OBJECT_EX`, but `NULL` is converted to `None`. This results in surprising behavior in Python: deleting the attribute effectively sets it to `None`.

T_NONE

Always `None`. Must be used with **`Py_READONLY`**.

Defining Getters and Setters

type PyGetSetDef

Part of the Stable ABI (including all members).
Structure to define property-like access for a type. See also description of the `PyTypeObject.tp_getset` slot.

const char *name

attribute name

getter get

C function to get the attribute.

setter set

Optional C function to set or delete the attribute. If `NULL`, the attribute is read-only.

const char *doc

optional docstring

void *closure

Optional user data pointer, providing additional data for getter and setter.

typedef PyObject *(*getter)(PyObject*, void*)

Part of the Stable ABI.
The `get` function takes one PyObject* parameter (the instance) and a user data pointer (the associated `closure`):

It should return a new reference on success or `NULL` with a set exception on failure.

typedef int (*setter)(PyObject*, PyObject*, void*)

Part of the Stable ABI.
`set` functions take two PyObject* parameters (the instance and the value to be set) and a user data pointer (the associated `closure`):

In case the attribute should be deleted the second parameter is `NULL`. Should return `0` on success or `-1` with a set exception on failure.

Type Object Structures

Perhaps one of the most important structures of the Python object system is the structure that defines a new type: the `PyTypeObject` structure. Type objects can be handled using any of the `PyObject_*` or `PyType_*` functions, but do not offer much that's interesting to most Python applications. These objects are fundamental to how objects behave, so they are very important to the interpreter itself and to any extension module that implements new types.

Type objects are fairly large compared to most of the standard types. The reason for the size is that each type object stores a large number of values, mostly C function pointers, each of which implements a small part of the type's functionality. The fields of the type object are examined in detail in this section. The fields will be described in the order in which they occur in the structure.

In addition to the following quick reference, the Examples section provides at-a-glance insight into the meaning and use of `PyTypeObject`.

Quick Reference

"tp slots"

PyTypeObject Slot [[1]]	**Type**	**special methods/attrs**	**Info [[2]]**

[1]

(): A slot name in parentheses indicates it is (effectively) deprecated.

<>: Names in angle brackets should be initially set to `NULL` and treated as read-only.

[]: Names in square brackets are for internal use only.

<R> (as a prefix) means the field is required (must be non-`NULL`).

[2]

Columns:

“O”: set on `PyBaseObject_Type`

“T”: set on `PyType_Type`

“D”: default (if slot is set to `NULL`)

```
X - PyType_Ready sets this value if it is NULL
~ - PyType_Ready always sets this value (it should be NULL)
? - PyType_Ready may set this value depending on other slots

Also see the inheritance column ("I").
```

“I”: inheritance

```
X - type slot is inherited via *PyType_Ready* if defined with a
*NULL* value
% - the slots of the sub-struct are inherited individually
G - inherited, but only in combination with other slots; see the
slot's description
? - it's complicated; see the slot's description
```

Note that some slots are effectively inherited through the normal attribute lookup chain.

sub-slots

PyTypeObject Definition

The structure definition for `PyTypeObject` can be found in `Include/cpython/object.h`. For convenience of reference, this repeats the definition found there:

```
typedef struct _typeobject {
    PyObject_VAR_HEAD
    const char *tp_name; /* For printing, in format "<module>.<name>"
*/
    Py_ssize_t tp_basicsize, tp_itemsize; /* For allocation */

    /* Methods to implement standard operations */

    destructor tp_dealloc;
    Py_ssize_t tp_vectorcall_offset;
    getattrfunc tp_getattr;
    setattrfunc tp_setattr;
    PyAsyncMethods *tp_as_async; /* formerly known as tp_compare
(Python 2)
                                    or tp_reserved (Python 3) */
    reprfunc tp_repr;

    /* Method suites for standard classes */

    PyNumberMethods *tp_as_number;
    PySequenceMethods *tp_as_sequence;
    PyMappingMethods *tp_as_mapping;

    /* More standard operations (here for binary compatibility) */

    hashfunc tp_hash;
    ternaryfunc tp_call;
    reprfunc tp_str;
    getattrofunc tp_getattro;
    setattrofunc tp_setattro;

    /* Functions to access object as input/output buffer */
    PyBufferProcs *tp_as_buffer;

    /* Flags to define presence of optional/expanded features */
    unsigned long tp_flags;

    const char *tp_doc; /* Documentation string */

    /* Assigned meaning in release 2.0 */
    /* call function for all accessible objects */
    traverseproc tp_traverse;

    /* delete references to contained objects */
    inquiry tp_clear;
    /* Assigned meaning in release 2.1 */
    /* rich comparisons */
    richcmpfunc tp_richcompare;

    /* weak reference enabler */
    Py_ssize_t tp_weaklistoffset;

    /* Iterators */
    getiterfunc tp_iter;
    iternextfunc tp_iternext;

    /* Attribute descriptor and subclassing stuff */
    PyMethodDef *tp_methods;
    PyMemberDef *tp_members;
    PyGetSetDef *tp_getset;
    // Strong reference on a heap type, borrowed reference on a
static type
    PyTypeObject *tp_base;
    PyObject *tp_dict;
    descrgetfunc tp_descr_get;
    descrsetfunc tp_descr_set;
    Py_ssize_t tp_dictoffset;
    initproc tp_init;
    allocfunc tp_alloc;
    newfunc tp_new;
    freefunc tp_free; /* Low-level free-memory routine */

    PyObject *tp_mro; /* method resolution order */
    PyObject *tp_cache; /* no longer used */
    void *tp_subclasses;  /* for static builtin types this is an
index */
    PyObject *tp_weaklist; /* not used for static builtin types */
    destructor tp_del;

    /* Type attribute cache version tag. Added in version 2.6.
     * If zero, the cache is invalid and must be initialized.
     */
    unsigned int tp_version_tag;

    destructor tp_finalize;
    vectorcallfunc tp_vectorcall;

    /* bitset of which type-watchers care about this type */
    unsigned char tp_watched;
    /* Number of tp_version_tag values used.
     * Set to _Py_ATTR_CACHE_UNUSED if the attribute cache is
     * disabled for this type (e.g. due to custom MRO entries).
     * Otherwise, limited to MAX_VERSIONS_PER_CLASS (defined
elsewhere).
     */
    uint16_t tp_versions_used;
} PyTypeObject;
```

PyObject Slots

The type object structure extends the **`PyVarObject`** structure. The **`ob_size`** field is used for dynamic types (created by **`type_new()`**, usually called from a class statement). Note that **`PyType_Type`** (the metatype) initializes **`tp_itemsize`**, which means that its instances (i.e. type objects) *must* have the **`ob_size`** field.

`PyObject.ob_refcnt`

The type object's reference count is initialized to `1` by the `PyObject_HEAD_INIT` macro. Note that for statically allocated type objects, the type's instances (objects whose **`ob_type`** points back to the type) do *not* count as references. But for dynamically allocated type objects, the instances *do* count as references.

Inheritance:

This field is not inherited by subtypes.

`PyObject.ob_type`

This is the type's type, in other words its metatype. It is initialized by the argument to the `PyObject_HEAD_INIT` macro, and its value should normally be `&PyType_Type`. However, for dynamically loadable extension modules that must be usable on Windows (at least), the compiler complains that this is not a valid initializer. Therefore, the convention is to pass `NULL` to the `PyObject_HEAD_INIT` macro and to initialize this field explicitly at the start of the module's initialization function, before doing anything else. This is typically done like this:

```
Foo_Type.ob_type = &PyType_Type;
```

This should be done before any instances of the type are created. **`PyType_Ready()`** checks if **`ob_type`** is `NULL`, and if so, initializes it to the **`ob_type`** field of the base class. **`PyType_Ready()`** will not change this field if it is non-zero.

Inheritance:

This field is inherited by subtypes.

PyVarObject Slots

`PyVarObject.ob_size`

For statically allocated type objects, this should be initialized to zero. For dynamically allocated type objects, this field has a special internal meaning.

This field should be accessed using the **`Py_SIZE()`** macro.

Inheritance:

This field is not inherited by subtypes.

PyTypeObject Slots

Each slot has a section describing inheritance. If **`PyType_Ready()`** may set a value when the field is set to `NULL` then there will also be a “Default” section. (Note that many fields set on **`PyBaseObject_Type`** and **`PyType_Type`** effectively act as defaults.)

const char *PyTypeObject.tp_name

Pointer to a NUL-terminated string containing the name of the type. For types that are accessible as module globals, the string should be the full module name, followed by a dot, followed by the type name; for built-in types, it should be just the type name. If the module is a submodule of a package, the full package name is part of the full module name. For example, a type named `T` defined in module `M` in subpackage `Q` in package `P` should have the `tp_name` initializer `"P.Q.M.T"`.

For dynamically allocated type objects, this should just be the type name, and the module name explicitly stored in the type dict as the value for key `'__module__'`.

For statically allocated type objects, the *tp_name* field should contain a dot. Everything before the last dot is made accessible as the `__module__` attribute, and everything after the last dot is made accessible as the `__name__` attribute.

If no dot is present, the entire `tp_name` field is made accessible as the `__name__` attribute, and the `__module__` attribute is undefined (unless explicitly set in the dictionary, as explained above). This means your type will be impossible to pickle. Additionally, it will not be listed in module documentations created with pydoc.

This field must not be `NULL`. It is the only required field in `PyTypeObject()` (other than potentially `tp_itemsize`).

Inheritance:

This field is not inherited by subtypes.

Py_ssize_t PyTypeObject.tp_basicsize
Py_ssize_t PyTypeObject.tp_itemsize

These fields allow calculating the size in bytes of instances of the type.

There are two kinds of types: types with fixed-length instances have a zero `tp_itemsize` field, types with variable-length instances have a non-zero `tp_itemsize` field. For a type with fixed-length instances, all instances have the same size, given in `tp_basicsize`. (Exceptions to this rule can be made using `PyUnstable_Object_GC_NewWithExtraData()`.)

For a type with variable-length instances, the instances must have an `ob_size` field, and the instance size is `tp_basicsize` plus N times `tp_itemsize`, where N is the “length” of the object.

Functions like `PyObject_NewVar()` will take the value of N as an argument, and store in the instance's `ob_size` field. Note that the `ob_size` field may later be used for other purposes. For example, `int` instances use the bits of `ob_size` in an implementation-defined way; the underlying storage and its size should be accessed using `PyLong_Export()`.

Note

The `ob_size` field should be accessed using the `Py_SIZE()` and `Py_SET_SIZE()` macros.

Also, the presence of an `ob_size` field in the instance layout doesn't mean that the instance structure is variable-length. For example, the `list` type has fixed-length instances, yet those instances have a `ob_size` field. (As with `int`, avoid reading lists' **`ob_size`** directly. Call `PyList_Size()` instead.)

The **`tp_basicsize`** includes size needed for data of the type's `tp_base`, plus any extra data needed by each instance.

The correct way to set **`tp_basicsize`** is to use the `sizeof` operator on the struct used to declare the instance layout. This struct must include the struct used to declare the base type. In other words, **`tp_basicsize`** must be greater than or equal to the base's **`tp_basicsize`**.

Since every type is a subtype of `object`, this struct must include `PyObject` or `PyVarObject` (depending on whether `ob_size` should be included). These are usually defined by the macro `PyObject_HEAD` or `PyObject_VAR_HEAD`, respectively.

The basic size does not include the GC header size, as that header is not part of `PyObject_HEAD`.

For cases where struct used to declare the base type is unknown, see `PyType_Spec.basicsize` and `PyType_FromMetaclass()`.

Notes about alignment:

- **`tp_basicsize`** must be a multiple of `_Alignof(PyObject)`. When using `sizeof` on a `struct` that includes **`PyObject_HEAD`**, as recommended, the compiler ensures this. When not using a C `struct`, or when using compiler extensions like `__attribute__((packed))`, it is up to you.
- If the variable items require a particular alignment, **`tp_basicsize`** and **`tp_itemsize`** must each be a multiple of that alignment. For example, if a type's variable part stores a `double`, it is your responsibility that both fields are a multiple of `_Alignof(double)`.

Inheritance:

These fields are inherited separately by subtypes. (That is, if the field is set to zero, **`PyType_Ready()`** will copy the value from the base type, indicating that the instances do not need additional storage.)

If the base type has a non-zero **`tp_itemsize`**, it is generally not safe to set **`tp_itemsize`** to a different non-zero value in a subtype (though this depends on the implementation of the base type).

destructor PyTypeObject.tp_dealloc

The corresponding slot ID `Py_tp_dealloc` is part of the Stable ABI.

A pointer to the instance destructor function. The function signature is:

```
void tp_dealloc(PyObject *self);
```

The destructor function should remove all references which the instance owns (e.g., call **`Py_CLEAR()`**), free all memory buffers owned by the instance, and call the type's **`tp_free`** function to free the object itself.

If you may call functions that may set the error indicator, you must use **`PyErr_GetRaisedException()`** and **`PyErr_SetRaisedException()`** to ensure you don't clobber a preexisting error indicator (the deallocation could have occurred while processing a different error):

```
static void
foo_dealloc(foo_object *self)
{
    PyObject *et, *ev, *etb;
    PyObject *exc = PyErr_GetRaisedException();
    ...
    PyErr_SetRaisedException(exc);
}
```

The dealloc handler itself must not raise an exception; if it hits an error case it should call `PyErr_FormatUnraisable()` to log (and clear) an unraisable exception.

No guarantees are made about when an object is destroyed, except:

- Python will destroy an object immediately or some time after the final reference to the object is deleted, unless its finalizer (`tp_finalize`) subsequently resurrects the object.
- An object will not be destroyed while it is being automatically finalized (`tp_finalize`) or automatically cleared (`tp_clear`).

CPython currently destroys an object immediately from `Py_DECREF()` when the new reference count is zero, but this may change in a future version.

It is recommended to call `PyObject_CallFinalizerFromDealloc()` at the beginning of **`tp_dealloc`** to guarantee that the object is always finalized before destruction.

If the type supports garbage collection (the `Py_TPFLAGS_HAVE_GC` flag is set), the destructor should call `PyObject_GC_UnTrack()` before clearing any member fields.

It is permissible to call `tp_clear` from **`tp_dealloc`** to reduce code duplication and to guarantee that the object is always cleared before destruction. Beware that **`tp_clear`** might have already been called.

If the type is heap allocated (`Py_TPFLAGS_HEAPTYPE`), the deallocator should release the owned reference to its type object (via `Py_DECREF()`) after calling the type deallocator. See the example code below.:

```
static void
foo_dealloc(PyObject *op)
{
   foo_object *self = (foo_object *) op;
   PyObject_GC_UnTrack(self);
   Py_CLEAR(self->ref);
   Py_TYPE(self)->tp_free(self);
}
```

`tp_dealloc` must leave the exception status unchanged. If it needs to call something that might raise an exception, the exception state must be backed up first and restored later (after logging any exceptions with `PyErr_WriteUnraisable()`).

Example:

```
static void
foo_dealloc(PyObject *self)
{
    PyObject *exc = PyErr_GetRaisedException();

    if (PyObject_CallFinalizerFromDealloc(self) < 0) {
        // self was resurrected.
        goto done;
    }

    PyTypeObject *tp = Py_TYPE(self);

    if (tp->tp_flags & Py_TPFLAGS_HAVE_GC) {
        PyObject_GC_UnTrack(self);
    }

    // Optional, but convenient to avoid code duplication.
    if (tp->tp_clear && tp->tp_clear(self) < 0) {
        PyErr_WriteUnraisable(self);
    }

    // Any additional destruction goes here.

    tp->tp_free(self);
    self = NULL;  // In case PyErr_WriteUnraisable() is called
below.
```

```
    if (tp->tp_flags & Py_TPFLAGS_HEAPTYPE) {
        Py_CLEAR(tp);
    }

done:
    // Optional, if something was called that might have raised an
    // exception.
    if (PyErr_Occurred()) {
        PyErr_WriteUnraisable(self);
    }
    PyErr_SetRaisedException(exc);
}
```

`tp_dealloc` may be called from any Python thread, not just the thread which created the object (if the object becomes part of a refcount cycle, that cycle might be collected by a garbage collection on any thread). This is not a problem for Python API calls, since the thread on which **`tp_dealloc`** is called with an attached thread state. However, if the object being destroyed in turn destroys objects from some other C library, care should be taken to ensure that destroying those objects on the thread which called **`tp_dealloc`** will not violate any assumptions of the library.

Inheritance:

This field is inherited by subtypes.

See also

Object Life Cycle for details about how this slot relates to other slots.

Py_ssize_t PyTypeObject.tp_vectorcall_offset

An optional offset to a per-instance function that implements calling the object using the vectorcall protocol, a more efficient alternative of the simpler **`tp_call`**.

This field is only used if the flag **`Py_TPFLAGS_HAVE_VECTORCALL`** is set. If so, this must be a positive integer containing the offset in the instance of a **`vectorcallfunc`** pointer.

The *vectorcallfunc* pointer may be `NULL`, in which case the instance behaves as if **`Py_TPFLAGS_HAVE_VECTORCALL`** was not set: calling the instance falls back to **`tp_call`**.

Any class that sets `Py_TPFLAGS_HAVE_VECTORCALL` must also set **`tp_call`** and make sure its behaviour is consistent with the *vectorcallfunc* function. This can be done by setting *tp_call* to **`PyVectorcall_Call()`**.

Changed in version 3.8: Before version 3.8, this slot was named `tp_print`. In Python 2.x, it was used for printing to a file. In Python 3.0 to 3.7, it was unused.

Changed in version 3.12: Before version 3.12, it was not recommended for mutable heap types to implement the vectorcall protocol. When a user sets **`__call__`** in Python code, only *tp_call* is updated, likely making it inconsistent with the vectorcall function. Since 3.12, setting `__call__` will disable vectorcall optimization by clearing the **`Py_TPFLAGS_HAVE_VECTORCALL`** flag.

Inheritance:

This field is always inherited. However, the **`Py_TPFLAGS_HAVE_VECTORCALL`** flag is not always inherited. If it's not set, then the subclass won't use vectorcall, except when **`PyVectorcall_Call()`** is explicitly called.

getattrfunc PyTypeObject.tp_getattr

The corresponding slot ID `Py_tp_getattr` is part of the Stable ABI.

An optional pointer to the get-attribute-string function.

This field is deprecated. When it is defined, it should point to a function that acts the same as the **`tp_getattro`** function, but taking a C string instead of a Python string object to give the attribute name.

Inheritance:

Group: **`tp_getattr`**, **`tp_getattro`**

This field is inherited by subtypes together with **`tp_getattro`**: a subtype inherits both **`tp_getattr`** and **`tp_getattro`** from its base type when the subtype's **`tp_getattr`** and **`tp_getattro`** are both `NULL`.

setattrfunc PyTypeObject.tp_setattr

The corresponding slot ID `Py_tp_setattr` is part of the Stable ABI.

An optional pointer to the function for setting and deleting attributes.

This field is deprecated. When it is defined, it should point to a function that acts the same as the **`tp_setattro`** function, but taking a C string instead of a Python string object to give the attribute name.

Inheritance:

Group: **`tp_setattr`**, **`tp_setattro`**

This field is inherited by subtypes together with **`tp_setattro`**: a subtype inherits both **`tp_setattr`** and **`tp_setattro`** from its base type when the subtype's **`tp_setattr`** and **`tp_setattro`** are both `NULL`.

PyAsyncMethods *PyTypeObject.tp_as_async

Pointer to an additional structure that contains fields relevant only to objects which implement awaitable and asynchronous iterator protocols at the C-level. See Async Object Structures for details.

Added in version 3.5: Formerly known as `tp_compare` and `tp_reserved`.

Inheritance:

The **`tp_as_async`** field is not inherited, but the contained fields are inherited individually.

reprfunc PyTypeObject.tp_repr

The corresponding slot ID `Py_tp_repr` is part of the Stable ABI.

An optional pointer to a function that implements the built-in function `repr()`.

The signature is the same as for `PyObject_Repr()`:

```
PyObject *tp_repr(PyObject *self);
```

The function must return a string or a Unicode object. Ideally, this function should return a string that, when passed to `eval()`, given a suitable environment, returns an object with the same value. If this is not feasible, it should return a string starting with `'<'` and ending with `'>'` from which both the type and the value of the object can be deduced.

Inheritance:

This field is inherited by subtypes.

Default:

When this field is not set, a string of the form `<%s object at %p>` is returned, where `%s` is replaced by the type name, and `%p` by the object’s memory address.

PyNumberMethods *PyTypeObject.tp_as_number

Pointer to an additional structure that contains fields relevant only to objects which implement the number protocol. These fields are documented in Number Object Structures.

Inheritance:

The `tp_as_number` field is not inherited, but the contained fields are inherited individually.

PySequenceMethods *PyTypeObject.tp_as_sequence

Pointer to an additional structure that contains fields relevant only to objects which implement the sequence protocol. These fields are documented in Sequence Object Structures.

Inheritance:

The `tp_as_sequence` field is not inherited, but the contained fields are inherited individually.

PyMappingMethods *PyTypeObject.tp_as_mapping

Pointer to an additional structure that contains fields relevant only to objects which implement the mapping protocol. These fields are documented in Mapping Object Structures.

Inheritance:

The `tp_as_mapping` field is not inherited, but the contained fields are inherited individually.

hashfunc PyTypeObject.tp_hash

The corresponding slot ID `Py_tp_hash` *is part of the Stable ABI.*

An optional pointer to a function that implements the built-in function `hash()`.

The signature is the same as for `PyObject_Hash()`:

```
Py_hash_t tp_hash(PyObject *);
```

The value `-1` should not be returned as a normal return value; when an error occurs during the computation of the hash value, the function should set an exception and return `-1`.

When this field is not set (*and* `tp_richcompare` is not set), an attempt to take the hash of the object raises `TypeError`. This is the same as setting it to `PyObject_HashNotImplemented()`.

This field can be set explicitly to `PyObject_HashNotImplemented()` to block inheritance of the hash method from a parent type. This is interpreted as the equivalent of `__hash__ = None` at the Python level, causing `isinstance(o, collections.Hashable)` to correctly return `False`. Note that the converse is also true - setting `__hash__ = None` on a class at the Python level will result in the `tp_hash` slot being set to `PyObject_HashNotImplemented()`.

Inheritance:

Group: `tp_hash`, `tp_richcompare`

This field is inherited by subtypes together with `tp_richcompare`: a subtype inherits both of `tp_richcompare` and `tp_hash`, when the subtype's `tp_richcompare` and `tp_hash` are both `NULL`.

Default:

`PyBaseObject_Type` uses `PyObject_GenericHash()`.

ternaryfunc PyTypeObject.tp_call

The corresponding slot ID `Py_tp_call` is part of the Stable ABI.

An optional pointer to a function that implements calling the object. This should be `NULL` if the object is not callable. The signature is the same as for `PyObject_Call()`:

```
PyObject *tp_call(PyObject *self, PyObject *args, PyObject
*kwargs);
```

Inheritance:

This field is inherited by subtypes.

reprfunc PyTypeObject.tp_str

The corresponding slot ID `Py_tp_str` is part of the Stable ABI.

An optional pointer to a function that implements the built-in operation `str()`. (Note that `str` is a type now, and `str()` calls the constructor for that type. This constructor calls `PyObject_Str()` to do the actual work, and `PyObject_Str()` will call this handler.)

The signature is the same as for `PyObject_Str()`:

```
PyObject *tp_str(PyObject *self);
```

The function must return a string or a Unicode object. It should be a “friendly” string representation of the object, as this is the representation that will be used, among other things, by the `print()` function.

Inheritance:

This field is inherited by subtypes.

Default:

When this field is not set, **`PyObject_Repr()`** is called to return a string representation.

getattrofunc PyTypeObject.tp_getattro

The corresponding slot ID `Py_tp_getattro` is part of the Stable ABI.

An optional pointer to the get-attribute function.

The signature is the same as for **`PyObject_GetAttr()`**:

```
PyObject *tp_getattro(PyObject *self, PyObject *attr);
```

It is usually convenient to set this field to **`PyObject_GenericGetAttr()`**, which implements the normal way of looking for object attributes.

Inheritance:

Group: **`tp_getattr`**, **`tp_getattro`**

This field is inherited by subtypes together with **`tp_getattr`**: a subtype inherits both **`tp_getattr`** and **`tp_getattro`** from its base type when the subtype's **`tp_getattr`** and **`tp_getattro`** are both `NULL`.

Default:

`PyBaseObject_Type` uses **`PyObject_GenericGetAttr()`**.

setattrofunc PyTypeObject.tp_setattro

The corresponding slot ID `Py_tp_setattro` is part of the Stable ABI.

An optional pointer to the function for setting and deleting attributes.

The signature is the same as for **`PyObject_SetAttr()`**:

```
int tp_setattro(PyObject *self, PyObject *attr, PyObject *value);
```

In addition, setting *value* to `NULL` to delete an attribute must be supported. It is usually convenient to set this field to `PyObject_GenericSetAttr()`, which implements the normal way of setting object attributes.

Inheritance:

Group: `tp_setattr`, `tp_setattro`

This field is inherited by subtypes together with `tp_setattr`: a subtype inherits both `tp_setattr` and `tp_setattro` from its base type when the subtype's `tp_setattr` and `tp_setattro` are both `NULL`.

Default:

`PyBaseObject_Type` uses `PyObject_GenericSetAttr()`.

PyBufferProcs *PyTypeObject.tp_as_buffer

Pointer to an additional structure that contains fields relevant only to objects which implement the buffer interface. These fields are documented in Buffer Object Structures.

Inheritance:

The `tp_as_buffer` field is not inherited, but the contained fields are inherited individually.

unsigned long PyTypeObject.tp_flags

This field is a bit mask of various flags. Some flags indicate variant semantics for certain situations; others are used to indicate that certain fields in the type object (or in the extension structures referenced via `tp_as_number`, `tp_as_sequence`, `tp_as_mapping`, and `tp_as_buffer`) that were historically not always present are valid; if such a flag bit is clear, the type fields it guards must not be accessed and must be considered to have a zero or `NULL` value instead.

Inheritance:

Inheritance of this field is complicated. Most flag bits are inherited individually, i.e. if the base type has a flag bit set, the subtype inherits this flag bit. The flag bits that pertain to extension structures are strictly inherited if the extension structure is inherited, i.e. the base type's value of the flag bit is copied into the subtype together with a pointer to the extension structure. The `Py_TPFLAGS_HAVE_GC` flag bit is inherited together with the `tp_traverse` and `tp_clear` fields, i.e. if the `Py_TPFLAGS_HAVE_GC` flag bit is clear in the subtype and the `tp_traverse` and `tp_clear` fields in the subtype exist and have `NULL` values.

Default:

`PyBaseObject_Type` uses `Py_TPFLAGS_DEFAULT | Py_TPFLAGS_BASETYPE`.

Bit Masks:

The following bit masks are currently defined; these can be ORed together using the `|` operator to form the value of the `tp_flags` field. The macro `PyType_HasFeature()` takes a type and a flags value, *tp* and *f*, and checks whether `tp->tp_flags & f` is non-zero.

Py_TPFLAGS_HEAPTYPE

This bit is set when the type object itself is allocated on the heap, for example, types created dynamically using `PyType_FromSpec()`. In this case, the `ob_type` field of its instances is considered a reference to the type, and the type object is INCREF'ed when a new instance is created, and DECREF'ed when an instance is destroyed (this does not apply to instances of subtypes; only the type referenced by the instance's ob_type gets INCREF'ed or DECREF'ed). Heap types should also support garbage collection as they can form a reference cycle with their own module object.

Inheritance:

???

Py_TPFLAGS_BASETYPE

Part of the Stable ABI.

This bit is set when the type can be used as the base type of another type. If this bit is clear, the type cannot be subtyped (similar to a “final” class in Java).

Inheritance:

???

Py_TPFLAGS_READY

This bit is set when the type object has been fully initialized by `PyType_Ready()`.

Inheritance:

???

Py_TPFLAGS_READYING

This bit is set while `PyType_Ready()` is in the process of initializing the type object.

Inheritance:

???

Py_TPFLAGS_HAVE_GC

Part of the Stable ABI.

This bit is set when the object supports garbage collection. If this bit is set, memory for new instances (see `tp_alloc`) must be allocated using `PyObject_GC_New` or `PyType_GenericAlloc()` and deallocated (see `tp_free`) using `PyObject_GC_Del()`. More information in section Supporting Cyclic Garbage Collection.

Inheritance:

Group: `Py_TPFLAGS_HAVE_GC`, `tp_traverse`, `tp_clear`

The `Py_TPFLAGS_HAVE_GC` flag bit is inherited together with the `tp_traverse` and `tp_clear` fields, i.e. if the `Py_TPFLAGS_HAVE_GC` flag bit is clear in the subtype and the **`tp_traverse`** and **`tp_clear`** fields in the subtype exist and have `NULL` values.

Py_TPFLAGS_DEFAULT

Part of the Stable ABI.

This is a bitmask of all the bits that pertain to the existence of certain fields in the type object and its extension structures. Currently, it includes the following bits: **`Py_TPFLAGS_HAVE_STACKLESS_EXTENSION`**.

Inheritance:

???

Py_TPFLAGS_METHOD_DESCRIPTOR

Part of the Stable ABI since version 3.8.

This bit indicates that objects behave like unbound methods.

If this flag is set for `type(meth)`, then:

- `meth.__get__(obj, cls)(*args, **kwds)` (with `obj` not None) must be equivalent to `meth(obj, *args, **kwds)`.
- `meth.__get__(None, cls)(*args, **kwds)` must be equivalent to `meth(*args, **kwds)`.

This flag enables an optimization for typical method calls like `obj.meth()`: it avoids creating a temporary “bound method” object for `obj.meth`.

Added in version 3.8.

Inheritance:

This flag is never inherited by types without the **`Py_TPFLAGS_IMMUTABLETYPE`** flag set. For extension types, it is inherited whenever **`tp_descr_get`** is inherited.

Py_TPFLAGS_MANAGED_DICT

This bit indicates that instances of the class have a **`__dict__`** attribute, and that the space for the dictionary is managed by the VM.

If this flag is set, `Py_TPFLAGS_HAVE_GC` should also be set.

The type traverse function must call `PyObject_VisitManagedDict()` and its clear function must call `PyObject_ClearManagedDict()`.

Added in version 3.12.

Inheritance:

This flag is inherited unless the `tp_dictoffset` field is set in a superclass.

Py_TPFLAGS_MANAGED_WEAKREF

This bit indicates that instances of the class should be weakly referenceable.

Added in version 3.12.

Inheritance:

This flag is inherited unless the `tp_weaklistoffset` field is set in a superclass.

Py_TPFLAGS_ITEMS_AT_END

Part of the Stable ABI since version 3.12.
Only usable with variable-size types, i.e. ones with non-zero `tp_itemsize`.

Indicates that the variable-sized portion of an instance of this type is at the end of the instance’s memory area, at an offset of `Py_TYPE(obj)->tp_basicsize` (which may be different in each subclass).

When setting this flag, be sure that all superclasses either use this memory layout, or are not variable-sized. Python does not check this.

Added in version 3.12.

Inheritance:

This flag is inherited.

Py_TPFLAGS_LONG_SUBCLASS

Py_TPFLAGS_LIST_SUBCLASS

Py_TPFLAGS_TUPLE_SUBCLASS

Py_TPFLAGS_BYTES_SUBCLASS

Py_TPFLAGS_UNICODE_SUBCLASS

Py_TPFLAGS_DICT_SUBCLASS

Py_TPFLAGS_BASE_EXC_SUBCLASS

Py_TPFLAGS_TYPE_SUBCLASS

Functions such as `PyLong_Check()` will call `PyType_FastSubclass()` with one of these flags to quickly determine if a type is a subclass of a built-in type; such specific checks are faster than a generic check, like `PyObject_IsInstance()`. Custom types that inherit from built-ins should have their `tp_flags` set appropriately, or the code that interacts with such types will behave differently depending on what kind of check is used.

Py_TPFLAGS_HAVE_FINALIZE

This bit is set when the `tp_finalize` slot is present in the type structure.

Added in version 3.4.

Deprecated since version 3.8: This flag isn't necessary anymore, as the interpreter assumes the `tp_finalize` slot is always present in the type structure.

Py_TPFLAGS_HAVE_VECTORCALL

Part of the Stable ABI since version 3.12.

This bit is set when the class implements the vectorcall protocol. See `tp_vectorcall_offset` for details.

Inheritance:

This bit is inherited if `tp_call` is also inherited.

Added in version 3.8: as `_Py_TPFLAGS_HAVE_VECTORCALL`

Changed in version 3.9.

Renamed to the current name, without the leading underscore. The old provisional name is soft deprecated.

Changed in version 3.12: This flag is now removed from a class when the class's `__call__()` method is reassigned.

This flag can now be inherited by mutable classes.

Py_TPFLAGS_IMMUTABLETYPE

This bit is set for type objects that are immutable: type attributes cannot be set nor deleted.

`PyType_Ready()` automatically applies this flag to static types.

Inheritance:

This flag is not inherited.

Added in version 3.10.

Py_TPFLAGS_DISALLOW_INSTANTIATION

Disallow creating instances of the type: set `tp_new` to NULL and don't create the `__new__` key in the type dictionary.

The flag must be set before creating the type, not after. For example, it must be set before `PyType_Ready()` is called on the type.

The flag is set automatically on static types if `tp_base` is NULL or `&PyBaseObject_Type` and `tp_new` is NULL.

Inheritance:

This flag is not inherited. However, subclasses will not be instantiable unless they provide a non-NULL `tp_new` (which is only possible via the C API).

Note

To disallow instantiating a class directly but allow instantiating its subclasses (e.g. for an abstract base class), do not use this flag. Instead, make `tp_new` only succeed for subclasses.

Added in version 3.10.

Py_TPFLAGS_MAPPING

This bit indicates that instances of the class may match mapping patterns when used as the subject of a `match` block. It is automatically set when registering or subclassing `collections.abc.Mapping`, and unset when registering `collections.abc.Sequence`.

Note

`Py_TPFLAGS_MAPPING` and `Py_TPFLAGS_SEQUENCE` are mutually exclusive; it is an error to enable both flags simultaneously.

Inheritance:

This flag is inherited by types that do not already set `Py_TPFLAGS_SEQUENCE`.

See also

PEP 634 [https://peps.python.org/pep-0634/] – Structural Pattern Matching: Specification

Added in version 3.10.

Py_TPFLAGS_SEQUENCE

This bit indicates that instances of the class may match sequence patterns when used as the subject of a `match` block. It is automatically set when registering or subclassing `collections.abc.Sequence`, and unset when registering `collections.abc.Mapping`.

Note

`Py_TPFLAGS_MAPPING` and `Py_TPFLAGS_SEQUENCE` are mutually exclusive; it is an error to enable both flags simultaneously.

Inheritance:

This flag is inherited by types that do not already set `Py_TPFLAGS_MAPPING`.

See also

PEP 634 [https://peps.python.org/pep-0634/] – Structural Pattern Matching: Specification

Added in version 3.10.

Py_TPFLAGS_VALID_VERSION_TAG

Internal. Do not set or unset this flag. To indicate that a class has changed call `PyType_Modified()`

Warning

This flag is present in header files, but is not be used. It will be removed in a future version of CPython

const char *PyTypeObject.tp_doc

The corresponding slot ID `Py_tp_doc` is part of the Stable ABI.

An optional pointer to a NUL-terminated C string giving the docstring for this type object. This is exposed as the `__doc__` attribute on the type and instances of the type.

Inheritance:

This field is *not* inherited by subtypes.

traverseproc PyTypeObject.tp_traverse

The corresponding slot ID `Py_tp_traverse` is part of the Stable ABI.

An optional pointer to a traversal function for the garbage collector. This is only used if the **`Py_TPFLAGS_HAVE_GC`** flag bit is set. The signature is:

```
int tp_traverse(PyObject *self, visitproc visit, void *arg);
```

More information about Python's garbage collection scheme can be found in section Supporting Cyclic Garbage Collection.

The **`tp_traverse`** pointer is used by the garbage collector to detect reference cycles. A typical implementation of a **`tp_traverse`** function simply calls **`Py_VISIT()`** on each of the instance's members that are Python objects that the instance owns. For example, this is function **`local_traverse()`** from the **`_thread`** extension module:

```
static int
local_traverse(PyObject *op, visitproc visit, void *arg)
{
    localobject *self = (localobject *) op;
    Py_VISIT(self->args);
    Py_VISIT(self->kw);
    Py_VISIT(self->dict);
    return 0;
}
```

Note that **`Py_VISIT()`** is called only on those members that can participate in reference cycles. Although there is also a `self->key` member, it can only be `NULL` or a Python string and therefore cannot be part of a reference cycle.

On the other hand, even if you know a member can never be part of a cycle, as a debugging aid you may want to visit it anyway just so the **`gc`** module's **`get_referents()`** function will include it.

Heap types (**`Py_TPFLAGS_HEAPTYPE`**) must visit their type with:

```
Py_VISIT(Py_TYPE(self));
```

It is only needed since Python 3.9. To support Python 3.8 and older, this line must be conditional:

```
#if PY_VERSION_HEX >= 0x03090000
    Py_VISIT(Py_TYPE(self));
#endif
```

If the **`Py_TPFLAGS_MANAGED_DICT`** bit is set in the **`tp_flags`** field, the traverse function must call **`PyObject_VisitManagedDict()`** like this:

```
PyObject_VisitManagedDict((PyObject*)self, visit, arg);
```

Warning

When implementing **`tp_traverse`**, only the members that the instance *owns* (by having strong references to them) must be visited. For instance, if an object supports weak references via the **`tp_weaklist`** slot, the pointer supporting the linked list (what *tp_weaklist* points to) must **not** be visited as the instance does not directly own the weak references to itself (the weakreference list is there to support the weak reference machinery, but the instance has no strong reference to the elements inside it, as they are allowed to be removed even if the instance is still alive).

Warning

The traversal function must not have any side effects. It must not modify the reference counts of any Python objects nor create or destroy any Python objects.

Note that **`Py_VISIT()`** requires the *visit* and *arg* parameters to **`local_traverse()`** to have these specific names; don't name them just anything.

Instances of heap-allocated types hold a reference to their type. Their traversal function must therefore either visit **`Py_TYPE(self)`**, or delegate this responsibility by calling `tp_traverse` of another heap-allocated type (such as a heap-allocated superclass). If they do not, the type object may not be garbage-collected.

Note

The **`tp_traverse`** function can be called from any thread.

Changed in version 3.9: Heap-allocated types are expected to visit `Py_TYPE(self)` in `tp_traverse`. In earlier versions of Python, due to bug 40217 [https://bugs.python.org/issue40217], doing this may lead to crashes in subclasses.

Inheritance:

Group: **`Py_TPFLAGS_HAVE_GC`**, **`tp_traverse`**, **`tp_clear`**

This field is inherited by subtypes together with **`tp_clear`** and the **`Py_TPFLAGS_HAVE_GC`** flag bit: the flag bit, **`tp_traverse`**, and **`tp_clear`** are all inherited from the base type if they are all zero in the subtype.

inquiry PyTypeObject.tp_clear

The corresponding slot ID `Py_tp_clear` is part of the Stable ABI.

An optional pointer to a clear function. The signature is:

```
int tp_clear(PyObject *);
```

The purpose of this function is to break reference cycles that are causing a cyclic isolate so that the objects can be safely destroyed. A cleared object is a partially destroyed object; the object is not obligated to satisfy design invariants held during normal use.

`tp_clear` does not need to delete references to objects that can’t participate in reference cycles, such as Python strings or Python integers. However, it may be convenient to clear all references, and write the type’s **`tp_dealloc`** function to invoke **`tp_clear`** to avoid code duplication. (Beware that **`tp_clear`** might have already been called. Prefer calling idempotent functions like **`Py_CLEAR()`**.)

Any non-trivial cleanup should be performed in **`tp_finalize`** instead of **`tp_clear`**.

Note

If `tp_clear` fails to break a reference cycle then the objects in the cyclic isolate may remain indefinitely uncollectable (“leak”). See `gc.garbage`.

Note

Referents (direct and indirect) might have already been cleared; they are not guaranteed to be in a consistent state.

Note

The `tp_clear` function can be called from any thread.

Note

An object is not guaranteed to be automatically cleared before its destructor (`tp_dealloc`) is called.

This function differs from the destructor (`tp_dealloc`) in the following ways:

- The purpose of clearing an object is to remove references to other objects that might participate in a reference cycle. The purpose of the destructor, on the other hand, is a superset: it must release *all* resources it owns, including references to objects that cannot participate in a reference cycle (e.g., integers) as well as the object’s own memory (by calling `tp_free`).
- When `tp_clear` is called, other objects might still hold references to the object being cleared. Because of this, `tp_clear` must not deallocate the object’s own memory (`tp_free`). The destructor, on the other hand, is only called when no (strong) references exist, and as such, must safely destroy the object itself by deallocating it.
- `tp_clear` might never be automatically called. An object’s destructor, on the other hand, will be automatically called some time after the object becomes unreachable (i.e.,

either there are no references to the object or the object is a member of a cyclic isolate).

No guarantees are made about when, if, or how often Python automatically clears an object, except:

- Python will not automatically clear an object if it is reachable, i.e., there is a reference to it and it is not a member of a cyclic isolate.
- Python will not automatically clear an object if it has not been automatically finalized (see **`tp_finalize`**). (If the finalizer resurrected the object, the object may or may not be automatically finalized again before it is cleared.)
- If an object is a member of a cyclic isolate, Python will not automatically clear it if any member of the cyclic isolate has not yet been automatically finalized (**`tp_finalize`**).
- Python will not destroy an object until after any automatic calls to its **`tp_clear`** function have returned. This ensures that the act of breaking a reference cycle does not invalidate the `self` pointer while **`tp_clear`** is still executing.
- Python will not automatically call **`tp_clear`** multiple times concurrently.

CPython currently only automatically clears objects as needed to break reference cycles in a cyclic isolate, but future versions might clear objects regularly before their destruction.

Taken together, all **`tp_clear`** functions in the system must combine to break all reference cycles. This is subtle, and if in any doubt supply a **`tp_clear`** function. For example, the tuple type does not implement a **`tp_clear`** function, because it's possible to prove that no reference cycle can be composed entirely of tuples. Therefore the **`tp_clear`** functions of other types are responsible for breaking any cycle containing a tuple. This isn't immediately obvious, and there's rarely a good reason to avoid implementing **`tp_clear`**.

Implementations of **`tp_clear`** should drop the instance's references to those of its members that may be Python objects, and set its pointers to those members to `NULL`, as in the following example:

```
static int
local_clear(PyObject *op)
{
    localobject *self = (localobject *) op;
    Py_CLEAR(self->key);
    Py_CLEAR(self->args);
    Py_CLEAR(self->kw);
    Py_CLEAR(self->dict);
    return 0;
}
```

The `Py_CLEAR()` macro should be used, because clearing references is delicate: the reference to the contained object must not be released (via `Py_DECREF()`) until after the pointer to the contained object is set to `NULL`. This is because releasing the reference may cause the contained object to become trash, triggering a chain of reclamation activity that may include invoking arbitrary Python code (due to finalizers, or weakref callbacks, associated with the contained object). If it's possible for such code to reference *self* again, it's important that the pointer to the contained object be `NULL` at that time, so that *self* knows the contained object can no longer be used. The `Py_CLEAR()` macro performs the operations in a safe order.

If the `Py_TPFLAGS_MANAGED_DICT` bit is set in the `tp_flags` field, the clear function must call `PyObject_ClearManagedDict()` like this:

```
PyObject_ClearManagedDict((PyObject*)self);
```

More information about Python's garbage collection scheme can be found in section Supporting Cyclic Garbage Collection.

Inheritance:

Group: `Py_TPFLAGS_HAVE_GC`, `tp_traverse`, `tp_clear`

This field is inherited by subtypes together with `tp_traverse` and the `Py_TPFLAGS_HAVE_GC` flag bit: the flag bit, `tp_traverse`, and `tp_clear` are all inherited from the base type if they are all zero in the subtype.

See also

Object Life Cycle for details about how this slot relates to other slots.

richcmpfunc PyTypeObject.tp_richcompare

The corresponding slot ID `Py_tp_richcompare` *is part of the Stable ABI.*

An optional pointer to the rich comparison function, whose signature is:

```
PyObject *tp_richcompare(PyObject *self, PyObject *other, int op);
```

The first parameter is guaranteed to be an instance of the type that is defined by **`PyTypeObject`**.

The function should return the result of the comparison (usually `Py_True` or `Py_False`). If the comparison is undefined, it must return `Py_NotImplemented`, if another error occurred it must return `NULL` and set an exception condition.

The following constants are defined to be used as the third argument for **`tp_richcompare`** and for **`PyObject_RichCompare()`**:

Constant	Comparison
Py_LT	`<`
Py_LE	`<=`
Py_EQ	`==`
Py_NE	`!=`
Py_GT	`>`
Py_GE	`>=`

The following macro is defined to ease writing rich comparison functions:

Py_RETURN_RICHCOMPARE(VAL_A, VAL_B, op)

Return `Py_True` or `Py_False` from the function, depending on the result of a comparison. VAL_A and VAL_B must be orderable by C comparison operators (for example, they may be C ints or floats). The third argument specifies the requested operation, as for **`PyObject_RichCompare()`**.

The returned value is a new strong reference.

On error, sets an exception and returns `NULL` from the function.

Added in version 3.7.

Inheritance:

Group: **`tp_hash`**, **`tp_richcompare`**

This field is inherited by subtypes together with **`tp_hash`**: a subtype inherits **`tp_richcompare`** and **`tp_hash`** when the subtype's **`tp_richcompare`** and **`tp_hash`** are both `NULL`.

Default:

`PyBaseObject_Type` provides a **`tp_richcompare`** implementation, which may be inherited. However, if only **`tp_hash`** is defined, not even the inherited function is used and instances of the type will not be able to participate in any comparisons.

Py_ssize_t PyTypeObject.tp_weaklistoffset

While this field is still supported, **`Py_TPFLAGS_MANAGED_WEAKREF`** should be used instead, if at all possible.

If the instances of this type are weakly referenceable, this field is greater than zero and contains the offset in the instance structure of the weak reference list head (ignoring the GC header, if present); this offset is used by **`PyObject_ClearWeakRefs()`** and the `PyWeakref_*` functions. The instance structure needs to include a field of type PyObject* which is initialized to `NULL`.

Do not confuse this field with **`tp_weaklist`**; that is the list head for weak references to the type object itself.

It is an error to set both the **`Py_TPFLAGS_MANAGED_WEAKREF`** bit and **`tp_weaklistoffset`**.

Inheritance:

This field is inherited by subtypes, but see the rules listed below. A subtype may override this offset; this means that the subtype uses a different weak reference list head than the base type. Since the list head is always found via **`tp_weaklistoffset`**, this should not be a problem.

Default:

If the **`Py_TPFLAGS_MANAGED_WEAKREF`** bit is set in the **`tp_flags`** field, then **`tp_weaklistoffset`** will be set to a negative value, to indicate that it is unsafe to use this field.

getiterfunc PyTypeObject.tp_iter

The corresponding slot ID `Py_tp_iter` is part of the Stable ABI.

An optional pointer to a function that returns an iterator for the object. Its presence normally signals that the instances of this type are iterable (although sequences may be iterable without this function).

This function has the same signature as **`PyObject_GetIter()`**:

```
PyObject *tp_iter(PyObject *self);
```

Inheritance:

This field is inherited by subtypes.

iternextfunc PyTypeObject.tp_iternext

The corresponding slot ID `Py_tp_iternext` is part of the Stable ABI.

An optional pointer to a function that returns the next item in an iterator. The signature is:

```
PyObject *tp_iternext(PyObject *self);
```

When the iterator is exhausted, it must return `NULL`; a **`StopIteration`** exception may or may not be set. When another error occurs, it must return `NULL` too. Its presence signals that the instances of this type are iterators.

Iterator types should also define the **`tp_iter`** function, and that function should return the iterator instance itself (not a new iterator instance).

This function has the same signature as **`PyIter_Next()`**.

Inheritance:

This field is inherited by subtypes.

struct PyMethodDef *PyTypeObject.tp_methods

The corresponding slot ID `Py_tp_methods` is part of the Stable ABI.

An optional pointer to a static `NULL`-terminated array of **`PyMethodDef`** structures, declaring regular methods of this type.

For each entry in the array, an entry is added to the type's dictionary (see **`tp_dict`** below) containing a method descriptor.

Inheritance:

This field is not inherited by subtypes (methods are inherited through a different mechanism).

struct PyMemberDef *PyTypeObject.tp_members

The corresponding slot ID `Py_tp_members` is part of the Stable ABI.

An optional pointer to a static `NULL`-terminated array of **`PyMemberDef`** structures, declaring regular data members (fields or slots) of instances of this type.

For each entry in the array, an entry is added to the type's dictionary (see `tp_dict` below) containing a member descriptor.

Inheritance:

This field is not inherited by subtypes (members are inherited through a different mechanism).

struct PyGetSetDef *PyTypeObject.tp_getset

The corresponding slot ID `Py_tp_getset` is part of the Stable ABI.

An optional pointer to a static `NULL`-terminated array of **`PyGetSetDef`** structures, declaring computed attributes of instances of this type.

For each entry in the array, an entry is added to the type's dictionary (see `tp_dict` below) containing a getset descriptor.

Inheritance:

This field is not inherited by subtypes (computed attributes are inherited through a different mechanism).

PyTypeObject *PyTypeObject.tp_base

The corresponding slot ID `Py_tp_base` is part of the Stable ABI.

An optional pointer to a base type from which type properties are inherited. At this level, only single inheritance is supported; multiple inheritance require dynamically creating a type object by calling the metatype.

Note

Slot initialization is subject to the rules of initializing globals. C99 requires the initializers to be "address constants". Function designators like `PyType_GenericNew()`, with implicit conversion to a pointer, are valid C99 address constants.

However, the unary '&' operator applied to a non-static variable like `PyBaseObject_Type` is not required to produce an address constant. Compilers may support this (gcc does), MSVC does not. Both compilers are strictly standard conforming in this particular behavior.

Consequently, `tp_base` should be set in the extension module's init function.

Inheritance:

This field is not inherited by subtypes (obviously).

Default:

This field defaults to `&PyBaseObject_Type` (which to Python programmers is known as the type `object`).

PyObject *PyTypeObject.tp_dict

The type's dictionary is stored here by `PyType_Ready()`.

This field should normally be initialized to `NULL` before PyType_Ready is called; it may also be initialized to a dictionary containing initial attributes for the type. Once `PyType_Ready()` has initialized the type, extra attributes for the type may be added to this dictionary only if they don't correspond to overloaded operations (like `__add__()`). Once initialization for the type has finished, this field should be treated as read-only.

Some types may not store their dictionary in this slot. Use `PyType_GetDict()` to retrieve the dictionary for an arbitrary type.

Changed in version 3.12: Internals detail: For static builtin types, this is always `NULL`. Instead, the dict for such types is stored on `PyInterpreterState`. Use `PyType_GetDict()` to get the dict for an arbitrary type.

Inheritance:

This field is not inherited by subtypes (though the attributes defined in here are inherited through a different mechanism).

Default:

If this field is `NULL`, **`PyType_Ready()`** will assign a new dictionary to it.

> **Warning**
>
> It is not safe to use **`PyDict_SetItem()`** on or otherwise modify **`tp_dict`** with the dictionary C-API.

descrgetfunc PyTypeObject.tp_descr_get

The corresponding slot ID `Py_tp_descr_get` is part of the Stable ABI.

An optional pointer to a “descriptor get” function.

The function signature is:

```
PyObject * tp_descr_get(PyObject *self, PyObject *obj, PyObject
*type);
```

Inheritance:

This field is inherited by subtypes.

descrsetfunc PyTypeObject.tp_descr_set

The corresponding slot ID `Py_tp_descr_set` is part of the Stable ABI.

An optional pointer to a function for setting and deleting a descriptor’s value.

The function signature is:

```
int tp_descr_set(PyObject *self, PyObject *obj, PyObject *value);
```

The *value* argument is set to `NULL` to delete the value.

Inheritance:

This field is inherited by subtypes.

Py_ssize_t PyTypeObject.tp_dictoffset

While this field is still supported, `Py_TPFLAGS_MANAGED_DICT` should be used instead, if at all possible.

If the instances of this type have a dictionary containing instance variables, this field is non-zero and contains the offset in the instances of the type of the instance variable dictionary; this offset is used by `PyObject_GenericGetAttr()`.

Do not confuse this field with `tp_dict`; that is the dictionary for attributes of the type object itself.

The value specifies the offset of the dictionary from the start of the instance structure.

The `tp_dictoffset` should be regarded as write-only. To get the pointer to the dictionary call `PyObject_GenericGetDict()`. Calling `PyObject_GenericGetDict()` may need to allocate memory for the dictionary, so it is may be more efficient to call `PyObject_GetAttr()` when accessing an attribute on the object.

It is an error to set both the `Py_TPFLAGS_MANAGED_DICT` bit and `tp_dictoffset`.

Inheritance:

This field is inherited by subtypes. A subtype should not override this offset; doing so could be unsafe, if C code tries to access the dictionary at the previous offset. To properly support inheritance, use `Py_TPFLAGS_MANAGED_DICT`.

Default:

This slot has no default. For static types, if the field is `NULL` then no `__dict__` gets created for instances.

If the `Py_TPFLAGS_MANAGED_DICT` bit is set in the `tp_flags` field, then `tp_dictoffset` will be set to `-1`, to indicate that it is unsafe to use this field.

initproc PyTypeObject.tp_init

The corresponding slot ID `Py_tp_init` *is part of the Stable ABI.*

An optional pointer to an instance initialization function.

This function corresponds to the `__init__()` method of classes. Like `__init__()`, it is possible to create an instance without calling `__init__()`, and it is possible to reinitialize an instance by calling its `__init__()` method again.

The function signature is:

```
int tp_init(PyObject *self, PyObject *args, PyObject *kwds);
```

The self argument is the instance to be initialized; the *args* and *kwds* arguments represent positional and keyword arguments of the call to `__init__()`.

The `tp_init` function, if not `NULL`, is called when an instance is created normally by calling its type, after the type's `tp_new` function has returned an instance of the type. If the `tp_new` function returns an instance of some other type that is not a subtype of the original type, no `tp_init` function is called; if `tp_new` returns an instance of a subtype of the original type, the subtype's `tp_init` is called.

Returns `0` on success, `-1` and sets an exception on error.

Inheritance:

This field is inherited by subtypes.

Default:

For static types this field does not have a default.

allocfunc PyTypeObject.tp_alloc

The corresponding slot ID `Py_tp_alloc` is part of the Stable ABI.

An optional pointer to an instance allocation function.

The function signature is:

```
PyObject *tp_alloc(PyTypeObject *self, Py_ssize_t nitems);
```

Inheritance:

Static subtypes inherit this slot, which will be `PyType_GenericAlloc()` if inherited from `object`.

Heap subtypes do not inherit this slot.

Default:

For heap subtypes, this field is always set to `PyType_GenericAlloc()`.

For static subtypes, this slot is inherited (see above).

newfunc PyTypeObject.tp_new

The corresponding slot ID `Py_tp_new` *is part of the Stable ABI.*

An optional pointer to an instance creation function.

The function signature is:

```
PyObject *tp_new(PyTypeObject *subtype, PyObject *args, PyObject
*kwds);
```

The *subtype* argument is the type of the object being created; the *args* and *kwds* arguments represent positional and keyword arguments of the call to the type. Note that *subtype* doesn't have to equal the type whose `tp_new` function is called; it may be a subtype of that type (but not an unrelated type).

The `tp_new` function should call `subtype->tp_alloc(subtype, nitems)` to allocate space for the object, and then do only as much further initialization as is absolutely necessary. Initialization that can safely be ignored or repeated should be placed in the `tp_init` handler. A good rule of thumb is that for immutable types, all initialization should take place in `tp_new`, while for mutable types, most initialization should be deferred to `tp_init`.

Set the `Py_TPFLAGS_DISALLOW_INSTANTIATION` flag to disallow creating instances of the type in Python.

Inheritance:

This field is inherited by subtypes, except it is not inherited by static types whose **`tp_base`** is `NULL` or `&PyBaseObject_Type`.

Default:

For static types this field has no default. This means if the slot is defined as `NULL`, the type cannot be called to create new instances; presumably there is some other way to create instances, like a factory function.

freefunc PyTypeObject.tp_free

The corresponding slot ID `Py_tp_free` is part of the Stable ABI.

An optional pointer to an instance deallocation function. Its signature is:

```
void tp_free(void *self);
```

This function must free the memory allocated by **`tp_alloc`**.

Inheritance:

Static subtypes inherit this slot, which will be **`PyObject_Free()`** if inherited from **`object`**. Exception: If the type supports garbage collection (i.e., the **`Py_TPFLAGS_HAVE_GC`** flag is set in **`tp_flags`**) and it would inherit **`PyObject_Free()`**, then this slot is not inherited but instead defaults to **`PyObject_GC_Del()`**.

Heap subtypes do not inherit this slot.

Default:

For heap subtypes, this slot defaults to a deallocator suitable to match **`PyType_GenericAlloc()`** and the value of the **`Py_TPFLAGS_HAVE_GC`** flag.

For static subtypes, this slot is inherited (see above).

inquiry PyTypeObject.tp_is_gc

The corresponding slot ID `Py_tp_is_gc` is part of the Stable ABI.

An optional pointer to a function called by the garbage collector.

The garbage collector needs to know whether a particular object is collectible or not. Normally, it is sufficient to look at the object's type's **`tp_flags`** field, and check the **`Py_TPFLAGS_HAVE_GC`** flag bit. But some types have a mixture of statically and dynamically allocated instances, and the statically allocated instances are not collectible. Such types should define this function; it should return `1` for a collectible instance, and `0` for a non-collectible instance. The signature is:

```
int tp_is_gc(PyObject *self);
```

(The only example of this are types themselves. The metatype, **`PyType_Type`**, defines this function to distinguish between statically and dynamically allocated types.)

Inheritance:

This field is inherited by subtypes.

Default:

This slot has no default. If this field is `NULL`, **`Py_TPFLAGS_HAVE_GC`** is used as the functional equivalent.

PyObject *PyTypeObject.tp_bases

The corresponding slot ID `Py_tp_bases` is part of the Stable ABI.

Tuple of base types.

This field should be set to `NULL` and treated as read-only. Python will fill it in when the type is **`initialized`**.

For dynamically created classes, the **`Py_tp_bases`** **`slot`** can be used instead of the *bases* argument of **`PyType_FromSpecWithBases()`**. The argument form is preferred.

Warning

Multiple inheritance does not work well for statically defined types. If you set `tp_bases` to a tuple, Python will not raise an error, but some slots will only be inherited from the first base.

Inheritance:

This field is not inherited.

PyObject *PyTypeObject.tp_mro

Tuple containing the expanded set of base types, starting with the type itself and ending with **`object`**, in Method Resolution Order.

This field should be set to `NULL` and treated as read-only. Python will fill it in when the type is **`initialized`**.

Inheritance:

This field is not inherited; it is calculated fresh by **`PyType_Ready()`**.

PyObject *PyTypeObject.tp_cache

Unused. Internal use only.

Inheritance:

This field is not inherited.

void *PyTypeObject.tp_subclasses

A collection of subclasses. Internal use only. May be an invalid pointer.

To get a list of subclasses, call the Python method **`__subclasses__()`**.

Changed in version 3.12: For some types, this field does not hold a valid PyObject*. The type was changed to void* to indicate this.

Inheritance:

This field is not inherited.

PyObject *PyTypeObject.tp_weaklist

Weak reference list head, for weak references to this type object. Not inherited. Internal use only.

Changed in version 3.12: Internals detail: For the static builtin types this is always `NULL`, even if weakrefs are added. Instead, the weakrefs for each are stored on `PyInterpreterState`. Use the public C-API or the internal `_PyObject_GET_WEAKREFS_LISTPTR()` macro to avoid the distinction.

Inheritance:

This field is not inherited.

destructor PyTypeObject.tp_del

The corresponding slot ID `Py_tp_del` *is part of the Stable ABI.*

This field is deprecated. Use **`tp_finalize`** instead.

unsigned int PyTypeObject.tp_version_tag

Used to index into the method cache. Internal use only.

Inheritance:

This field is not inherited.

destructor PyTypeObject.tp_finalize

The corresponding slot ID `Py_tp_finalize` *is part of the Stable ABI since version 3.5.*

An optional pointer to an instance finalization function. This is the C implementation of the **`__del__()`** special method. Its signature is:

```
void tp_finalize(PyObject *self);
```

The primary purpose of finalization is to perform any non-trivial cleanup that must be performed before the object is destroyed, while the object and any other objects it directly or indirectly references are still in a consistent state. The finalizer is allowed to execute arbitrary Python code.

Before Python automatically finalizes an object, some of the object's direct or indirect referents might have themselves been automatically finalized. However, none of the referents will have been automatically cleared (`tp_clear`) yet.

Other non-finalized objects might still be using a finalized object, so the finalizer must leave the object in a sane state (e.g., invariants are still met).

Note

After Python automatically finalizes an object, Python might start automatically clearing (`tp_clear`) the object and its referents (direct and indirect). Cleared objects are not guaranteed to be in a consistent state; a finalized object must be able to tolerate cleared referents.

Note

An object is not guaranteed to be automatically finalized before its destructor (`tp_dealloc`) is called. It is recommended to call `PyObject_CallFinalizerFromDealloc()` at the beginning of **`tp_dealloc`** to guarantee that the object is always finalized before destruction.

Note

The `tp_finalize` function can be called from any thread, although the GIL will be held.

Note

The **`tp_finalize`** function can be called during shutdown, after some global variables have been deleted. See the documentation of the `__del__()` method for details.

When Python finalizes an object, it behaves like the following algorithm:

1. Python might mark the object as *finalized*. Currently, Python always marks objects whose type supports garbage collection (i.e., the `Py_TPFLAGS_HAVE_GC` flag is set in `tp_flags`) and never marks other types of objects; this might change in a future version.
2. If the object is not marked as *finalized* and its **`tp_finalize`** finalizer function is non-`NULL`, the finalizer function is called.
3. If the finalizer function was called and the finalizer made the object reachable (i.e., there is a reference to the object and it is not a member of a cyclic isolate), then the finalizer is said to have *resurrected* the object. It is unspecified whether the finalizer can also resurrect the object by adding a new reference to the object that does not make it reachable, i.e., the object is (still) a member of a cyclic isolate.
4. If the finalizer resurrected the object, the object's pending destruction is canceled and the object's *finalized* mark might be removed if present. Currently, Python never removes the *finalized* mark; this might change in a future version.

Automatic finalization refers to any finalization performed by Python except via calls to `PyObject_CallFinalizer()` or `PyObject_CallFinalizerFromDealloc()`. No guarantees are made about when, if, or how often an object is automatically finalized, except:

- Python will not automatically finalize an object if it is reachable, i.e., there is a reference to it and it is not a member of a cyclic isolate.
- Python will not automatically finalize an object if finalizing it would not mark the object as *finalized*. Currently, this applies to objects whose type does not support garbage collection, i.e., the `Py_TPFLAGS_HAVE_GC` flag is not set. Such objects can still be manually finalized by calling `PyObject_CallFinalizer()` or `PyObject_CallFinalizerFromDealloc()`.

- Python will not automatically finalize any two members of a cyclic isolate concurrently.
- Python will not automatically finalize an object after it has automatically cleared (`tp_clear`) the object.
- If an object is a member of a cyclic isolate, Python will not automatically finalize it after automatically clearing (see `tp_clear`) any other member.
- Python will automatically finalize every member of a cyclic isolate before it automatically clears (see `tp_clear`) any of them.
- If Python is going to automatically clear an object (`tp_clear`), it will automatically finalize the object first.

Python currently only automatically finalizes objects that are members of a cyclic isolate, but future versions might finalize objects regularly before their destruction.

To manually finalize an object, do not call this function directly; call `PyObject_CallFinalizer()` or `PyObject_CallFinalizerFromDealloc()` instead.

`tp_finalize` should leave the current exception status unchanged. The recommended way to write a non-trivial finalizer is to back up the exception at the beginning by calling `PyErr_GetRaisedException()` and restore the exception at the end by calling `PyErr_SetRaisedException()`. If an exception is encountered in the middle of the finalizer, log and clear it with `PyErr_WriteUnraisable()` or `PyErr_FormatUnraisable()`. For example:

```
static void
foo_finalize(PyObject *self)
{
    // Save the current exception, if any.
    PyObject *exc = PyErr_GetRaisedException();

    // ...

    if (do_something_that_might_raise() != success_indicator) {
        PyErr_WriteUnraisable(self);
        goto done;
    }

done:
    // Restore the saved exception.  This silently discards any
exception
    // raised above, so be sure to call PyErr_WriteUnraisable
first if
    // necessary.
    PyErr_SetRaisedException(exc);
}
```

Inheritance:

This field is inherited by subtypes.

Added in version 3.4.

Changed in version 3.8: Before version 3.8 it was necessary to set the **`Py_TPFLAGS_HAVE_FINALIZE`** flags bit in order for this field to be used. This is no longer required.

- **`PyObject_CallFinalizerFromDealloc()`**

vectorcallfunc PyTypeObject.tp_vectorcall

The corresponding slot ID `Py_tp_vectorcall` is part of the Stable ABI since version 3.14.

A vectorcall function to use for calls of this type object (rather than instances). In other words, `tp_vectorcall` can be used to optimize `type.__call__`, which typically returns a new instance of *type*.

As with any vectorcall function, if `tp_vectorcall` is `NULL`, the *tp_call* protocol (`Py_TYPE(type)->tp_call`) is used instead.

Note

The vectorcall protocol requires that the vectorcall function has the same behavior as the corresponding `tp_call`. This means that `type->tp_vectorcall` must match the behavior of `Py_TYPE(type)->tp_call`.

Specifically, if *type* uses the default metaclass, `type->tp_vectorcall` must behave the same as PyType_Type->tp_call, which:

- calls `type->tp_new`,
- if the result is a subclass of *type*, calls `type->tp_init` on the result of `tp_new`, and
- returns the result of `tp_new`.

Typically, `tp_vectorcall` is overridden to optimize this process for specific **`tp_new`** and **`tp_init`**. When doing this for user-subclassable types, note that both can be overridden (using **`__new__()`** and **`__init__()`**, respectively).

Inheritance:

This field is never inherited.

Added in version 3.9: (the field exists since 3.8 but it’s only used since 3.9)

unsigned char PyTypeObject.tp_watched

Internal. Do not use.

Added in version 3.12.

Static Types

Traditionally, types defined in C code are *static*, that is, a static **`PyTypeObject`** structure is defined directly in code and initialized using **`PyType_Ready()`**.

This results in types that are limited relative to types defined in Python:

- Static types are limited to one base, i.e. they cannot use multiple inheritance.

- Static type objects (but not necessarily their instances) are immutable. It is not possible to add or modify the type object’s attributes from Python.
- Static type objects are shared across sub-interpreters, so they should not include any subinterpreter-specific state.

Also, since **`PyTypeObject`** is only part of the Limited API as an opaque struct, any extension modules using static types must be compiled for a specific Python minor version.

Heap Types

An alternative to static types is *heap-allocated types*, or *heap types* for short, which correspond closely to classes created by Python’s `class` statement. Heap types have the **`Py_TPFLAGS_HEAPTYPE`** flag set.

This is done by filling a **`PyType_Spec`** structure and calling **`PyType_FromSpec()`**, **`PyType_FromSpecWithBases()`**, **`PyType_FromModuleAndSpec()`**, or **`PyType_FromMetaclass()`**.

Number Object Structures

type PyNumberMethods

This structure holds pointers to the functions which an object uses to implement the number protocol. Each function is used by the function of similar name documented in the Number Protocol section.

Here is the structure definition:

```
typedef struct {
     binaryfunc nb_add;
     binaryfunc nb_subtract;
     binaryfunc nb_multiply;
     binaryfunc nb_remainder;
     binaryfunc nb_divmod;
     ternaryfunc nb_power;
     unaryfunc nb_negative;
     unaryfunc nb_positive;
     unaryfunc nb_absolute;
```

```
    inquiry nb_bool;
    unaryfunc nb_invert;
    binaryfunc nb_lshift;
    binaryfunc nb_rshift;
    binaryfunc nb_and;
    binaryfunc nb_xor;
    binaryfunc nb_or;
    unaryfunc nb_int;
    void *nb_reserved;
    unaryfunc nb_float;

    binaryfunc nb_inplace_add;
    binaryfunc nb_inplace_subtract;
    binaryfunc nb_inplace_multiply;
    binaryfunc nb_inplace_remainder;
    ternaryfunc nb_inplace_power;
    binaryfunc nb_inplace_lshift;
    binaryfunc nb_inplace_rshift;
    binaryfunc nb_inplace_and;
    binaryfunc nb_inplace_xor;
    binaryfunc nb_inplace_or;

    binaryfunc nb_floor_divide;
    binaryfunc nb_true_divide;
    binaryfunc nb_inplace_floor_divide;
    binaryfunc nb_inplace_true_divide;

    unaryfunc nb_index;

    binaryfunc nb_matrix_multiply;
    binaryfunc nb_inplace_matrix_multiply;
} PyNumberMethods;
```

Note

Binary and ternary functions must check the type of all their operands, and implement the necessary conversions (at least one of the operands is an instance of the defined type). If the operation is not defined for the given operands, binary and ternary functions must return `Py_NotImplemented`, if another error occurred they must return `NULL` and set an exception.

Note

The **`nb_reserved`** field should always be `NULL`. It was previously called **`nb_long`**, and was renamed in Python 3.0.1.

binaryfunc PyNumberMethods.nb_add

The corresponding slot ID `Py_nb_add` is part of the Stable ABI.

binaryfunc PyNumberMethods.nb_subtract

The corresponding slot ID `Py_nb_subtract` is part of the Stable ABI.

binaryfunc PyNumberMethods.nb_multiply

The corresponding slot ID `Py_nb_multiply` is part of the Stable ABI.

binaryfunc PyNumberMethods.nb_remainder

The corresponding slot ID `Py_nb_remainder` is part of the Stable ABI.

binaryfunc PyNumberMethods.nb_divmod

The corresponding slot ID `Py_nb_divmod` is part of the Stable ABI.

ternaryfunc PyNumberMethods.nb_power

The corresponding slot ID `Py_nb_power` is part of the Stable ABI.

unaryfunc PyNumberMethods.nb_negative

The corresponding slot ID `Py_nb_negative` is part of the Stable ABI.

unaryfunc PyNumberMethods.nb_positive

The corresponding slot ID `Py_nb_positive` is part of the Stable ABI.

unaryfunc PyNumberMethods.nb_absolute

The corresponding slot ID `Py_nb_absolute` is part of the Stable ABI.

inquiry PyNumberMethods.nb_bool

The corresponding slot ID `Py_nb_bool` is part of the Stable ABI.

unaryfunc PyNumberMethods.nb_invert

The corresponding slot ID `Py_nb_invert` *is part of the Stable ABI.*

binaryfunc PyNumberMethods.nb_lshift

The corresponding slot ID `Py_nb_lshift` *is part of the Stable ABI.*

binaryfunc PyNumberMethods.nb_rshift

The corresponding slot ID `Py_nb_rshift` *is part of the Stable ABI.*

binaryfunc PyNumberMethods.nb_and

The corresponding slot ID `Py_nb_and` *is part of the Stable ABI.*

binaryfunc PyNumberMethods.nb_xor

The corresponding slot ID `Py_nb_xor` *is part of the Stable ABI.*

binaryfunc PyNumberMethods.nb_or

The corresponding slot ID `Py_nb_or` *is part of the Stable ABI.*

unaryfunc PyNumberMethods.nb_int

The corresponding slot ID `Py_nb_int` *is part of the Stable ABI.*

void *PyNumberMethods.nb_reserved

unaryfunc PyNumberMethods.nb_float

The corresponding slot ID `Py_nb_float` *is part of the Stable ABI.*

binaryfunc PyNumberMethods.nb_inplace_add

The corresponding slot ID `Py_nb_inplace_add` *is part of the Stable ABI.*

binaryfunc PyNumberMethods.nb_inplace_subtract

The corresponding slot ID `Py_nb_inplace_subtract` *is part of the Stable ABI.*

binaryfunc PyNumberMethods.nb_inplace_multiply

The corresponding slot ID `Py_nb_inplace_multiply` *is part of the Stable ABI.*

binaryfunc PyNumberMethods.nb_inplace_remainder

The corresponding slot ID `Py_nb_inplace_remainder` is part of the Stable ABI.

ternaryfunc PyNumberMethods.nb_inplace_power

The corresponding slot ID `Py_nb_inplace_power` is part of the Stable ABI.

binaryfunc PyNumberMethods.nb_inplace_lshift

The corresponding slot ID `Py_nb_inplace_lshift` is part of the Stable ABI.

binaryfunc PyNumberMethods.nb_inplace_rshift

The corresponding slot ID `Py_nb_inplace_rshift` is part of the Stable ABI.

binaryfunc PyNumberMethods.nb_inplace_and

The corresponding slot ID `Py_nb_inplace_and` is part of the Stable ABI.

binaryfunc PyNumberMethods.nb_inplace_xor

The corresponding slot ID `Py_nb_inplace_xor` is part of the Stable ABI.

binaryfunc PyNumberMethods.nb_inplace_or

The corresponding slot ID `Py_nb_inplace_or` is part of the Stable ABI.

binaryfunc PyNumberMethods.nb_floor_divide

The corresponding slot ID `Py_nb_floor_divide` is part of the Stable ABI.

binaryfunc PyNumberMethods.nb_true_divide

The corresponding slot ID `Py_nb_true_divide` is part of the Stable ABI.

binaryfunc PyNumberMethods.nb_inplace_floor_divide

The corresponding slot ID `Py_nb_inplace_floor_divide` is part of the Stable ABI.

binaryfunc PyNumberMethods.nb_inplace_true_divide

The corresponding slot ID `Py_nb_inplace_true_divide` is part of the Stable ABI.

unaryfunc PyNumberMethods.nb_index

The corresponding slot ID `Py_nb_index` is part of the Stable ABI.

binaryfunc PyNumberMethods.nb_matrix_multiply

The corresponding slot ID `Py_nb_matrix_multiply` is part of the Stable ABI since version 3.5.

binaryfunc PyNumberMethods.nb_inplace_matrix_multiply

The corresponding slot ID `Py_nb_inplace_matrix_multiply` is part of the Stable ABI since version 3.5.

Mapping Object Structures

type PyMappingMethods

This structure holds pointers to the functions which an object uses to implement the mapping protocol. It has three members:

lenfunc PyMappingMethods.mp_length

The corresponding slot ID `Py_mp_length` is part of the Stable ABI.

This function is used by **`PyMapping_Size()`** and **`PyObject_Size()`**, and has the same signature. This slot may be set to `NULL` if the object has no defined length.

binaryfunc PyMappingMethods.mp_subscript

The corresponding slot ID `Py_mp_subscript` is part of the Stable ABI.

This function is used by **`PyObject_GetItem()`** and **`PySequence_GetSlice()`**, and has the same signature as **`PyObject_GetItem()`**. This slot must be filled for the **`PyMapping_Check()`** function to return `1`, it can be `NULL` otherwise.

objobjargproc PyMappingMethods.mp_ass_subscript

The corresponding slot ID `Py_mp_ass_subscript` is part of the Stable ABI.

This function is used by **`PyObject_SetItem()`**, **`PyObject_DelItem()`**, **`PySequence_SetSlice()`** and **`PySequence_DelSlice()`**. It has the same signature as **`PyObject_SetItem()`**, but *v* can also be set to `NULL` to delete an item. If this slot is `NULL`, the object does not support item assignment and deletion.

Sequence Object Structures

type PySequenceMethods

This structure holds pointers to the functions which an object uses to implement the sequence protocol.

lenfunc PySequenceMethods.sq_length

The corresponding slot ID `Py_sq_length` is part of the Stable ABI.

This function is used by **`PySequence_Size()`** and **`PyObject_Size()`**, and has the same signature. It is also used for handling negative indices via the **`sq_item`** and the **`sq_ass_item`** slots.

binaryfunc PySequenceMethods.sq_concat

The corresponding slot ID `Py_sq_concat` is part of the Stable ABI.

This function is used by **`PySequence_Concat()`** and has the same signature. It is also used by the `+` operator, after trying the numeric addition via the **`nb_add`** slot.

ssizeargfunc PySequenceMethods.sq_repeat

The corresponding slot ID `Py_sq_repeat` is part of the Stable ABI.

This function is used by **`PySequence_Repeat()`** and has the same signature. It is also used by the `*` operator, after trying numeric multiplication via the **`nb_multiply`** slot.

ssizeargfunc PySequenceMethods.sq_item

The corresponding slot ID `Py_sq_item` is part of the Stable ABI.

This function is used by **`PySequence_GetItem()`** and has the same signature. It is also used by **`PyObject_GetItem()`**, after trying the subscription via the **`mp_subscript`** slot. This slot must be filled for the `PySequence_Check()` function to return `1`, it can be `NULL` otherwise.

Negative indexes are handled as follows: if the `sq_length` slot is filled, it is called and the sequence length is used to compute a positive index which is passed to `sq_item`. If **`sq_length`** is `NULL`, the index is passed as is to the function.

ssizeobjargproc PySequenceMethods.sq_ass_item

The corresponding slot ID `Py_sq_ass_item` is part of the Stable ABI.

This function is used by `PySequence_SetItem()` and has the same signature. It is also used by `PyObject_SetItem()` and `PyObject_DelItem()`, after trying the item assignment and deletion via the `mp_ass_subscript` slot. This slot may be left to `NULL` if the object does not support item assignment and deletion.

objobjproc PySequenceMethods.sq_contains

The corresponding slot ID `Py_sq_contains` is part of the Stable ABI.

This function may be used by `PySequence_Contains()` and has the same signature. This slot may be left to `NULL`, in this case **`PySequence_Contains()`** simply traverses the sequence until it finds a match.

binaryfunc PySequenceMethods.sq_inplace_concat

The corresponding slot ID `Py_sq_inplace_concat` is part of the Stable ABI.

This function is used by `PySequence_InPlaceConcat()` and has the same signature. It should modify its first operand, and return it. This slot may be left to `NULL`, in this case **`PySequence_InPlaceConcat()`** will fall back to `PySequence_Concat()`. It is also used by the augmented assignment `+=`, after trying numeric in-place addition via the `nb_inplace_add` slot.

ssizeargfunc PySequenceMethods.sq_inplace_repeat

The corresponding slot ID `Py_sq_inplace_repeat` is part of the Stable ABI.

This function is used by **`PySequence_InPlaceRepeat()`** and has the same signature. It should modify its first operand, and return it. This slot may be left to `NULL`, in this case **`PySequence_InPlaceRepeat()`** will fall back to **`PySequence_Repeat()`**. It is also used by the augmented assignment `*=`, after trying numeric in-place multiplication via the **`nb_inplace_multiply`** slot.

Buffer Object Structures

type PyBufferProcs

This structure holds pointers to the functions required by the Buffer protocol. The protocol defines how an exporter object can expose its internal data to consumer objects.

getbufferproc PyBufferProcs.bf_getbuffer

The corresponding slot ID `Py_bf_getbuffer` is part of the Stable ABI since version 3.11.

The signature of this function is:

```
int (PyObject *exporter, Py_buffer *view, int flags);
```

Handle a request to *exporter* to fill in *view* as specified by *flags*. Except for point (3), an implementation of this function MUST take these steps:

1. Check if the request can be met. If not, raise **`BufferError`**, set view->obj to `NULL` and return `-1`.
2. Fill in the requested fields.
3. Increment an internal counter for the number of exports.
4. Set view->obj to *exporter* and increment view->obj.
5. Return `0`.

If *exporter* is part of a chain or tree of buffer providers, two main schemes can be used:

- Re-export: Each member of the tree acts as the exporting object and sets view->obj to a new reference to itself.

- Redirect: The buffer request is redirected to the root object of the tree. Here, view->obj will be a new reference to the root object.

The individual fields of *view* are described in section Buffer structure, the rules how an exporter must react to specific requests are in section Buffer request types.

All memory pointed to in the **`Py_buffer`** structure belongs to the exporter and must remain valid until there are no consumers left. **`format`**, **`shape`**, **`strides`**, **`suboffsets`** and **`internal`** are read-only for the consumer.

`PyBuffer_FillInfo()` provides an easy way of exposing a simple bytes buffer while dealing correctly with all request types.

`PyObject_GetBuffer()` is the interface for the consumer that wraps this function.

releasebufferproc PyBufferProcs.bf_releasebuffer

The corresponding slot ID `Py_bf_releasebuffer` *is part of the Stable ABI since version 3.11.*

The signature of this function is:

```
void (PyObject *exporter, Py_buffer *view);
```

Handle a request to release the resources of the buffer. If no resources need to be released, **`PyBufferProcs.bf_releasebuffer`** may be `NULL`. Otherwise, a standard implementation of this function will take these optional steps:

1. Decrement an internal counter for the number of exports.
2. If the counter is `0`, free all memory associated with *view*.

The exporter MUST use the **`internal`** field to keep track of buffer-specific resources. This field is guaranteed to remain constant, while a consumer MAY pass a copy of the original buffer as the *view* argument.

This function MUST NOT decrement view->obj, since that is done automatically in **`PyBuffer_Release()`** (this scheme is useful for breaking reference cycles).

`PyBuffer_Release()` is the interface for the consumer that wraps this function.

Async Object Structures

Added in version 3.5.

type PyAsyncMethods

This structure holds pointers to the functions required to implement awaitable and asynchronous iterator objects.

Here is the structure definition:

```
typedef struct {
    unaryfunc am_await;
    unaryfunc am_aiter;
    unaryfunc am_anext;
    sendfunc am_send;
} PyAsyncMethods;
```

unaryfunc PyAsyncMethods.am_await

The corresponding slot ID `Py_am_await` *is part of the Stable ABI since version 3.5.*

The signature of this function is:

```
PyObject *am_await(PyObject *self);
```

The returned object must be an iterator, i.e. `PyIter_Check()` must return `1` for it.

This slot may be set to `NULL` if an object is not an awaitable.

unaryfunc PyAsyncMethods.am_aiter

The corresponding slot ID `Py_am_aiter` *is part of the Stable ABI since version 3.5.*

The signature of this function is:

```
PyObject *am_aiter(PyObject *self);
```

Must return an asynchronous iterator object. See **`__anext__()`** for details.

This slot may be set to `NULL` if an object does not implement asynchronous iteration protocol.

unaryfunc PyAsyncMethods.am_anext

The corresponding slot ID `Py_am_anext` is part of the Stable ABI since version 3.5.

The signature of this function is:

```
PyObject *am_anext(PyObject *self);
```

Must return an awaitable object. See **`__anext__()`** for details. This slot may be set to `NULL`.

sendfunc PyAsyncMethods.am_send

The corresponding slot ID `Py_am_send` is part of the Stable ABI since version 3.10.

The signature of this function is:

```
PySendResult am_send(PyObject *self, PyObject *arg, PyObject
**result);
```

See **`PyIter_Send()`** for details. This slot may be set to `NULL`.

Added in version 3.10.

Slot Type typedefs

typedef PyObject *(*allocfunc)(PyTypeObject *cls, Py_ssize_t nitems)

Part of the Stable ABI.

The purpose of this function is to separate memory allocation from memory initialization. It should return a pointer to a block of memory of adequate length for the instance, suitably aligned, and initialized to zeros, but with **`ob_refcnt`** set to `1` and **`ob_type`** set to the type argument. If the type's **`tp_itemsize`** is non-zero, the object's **`ob_size`** field should be initialized to *nitems* and the length of the allocated memory block should be `tp_basicsize + nitems*tp_itemsize`, rounded up to a multiple of `sizeof(void*)`; otherwise, *nitems* is not used and the length of the block should be **`tp_basicsize`**.

This function should not do any other instance initialization, not even to allocate additional memory; that should be done by **`tp_new`**.

typedef void (*destructor)(PyObject*)

Part of the Stable ABI.

typedef void (*freefunc)(void*)

See **`tp_free`**.

typedef PyObject *(*newfunc)(PyTypeObject*, PyObject*, PyObject*)

Part of the Stable ABI.
See **`tp_new`**.

typedef int (*initproc)(PyObject*, PyObject*, PyObject*)

Part of the Stable ABI.
See **`tp_init`**.

typedef PyObject *(*reprfunc)(PyObject*)

Part of the Stable ABI.
See **`tp_repr`**.

typedef PyObject *(*getattrfunc)(PyObject *self, char *attr)

Part of the Stable ABI.
Return the value of the named attribute for the object.

typedef int (*setattrfunc)(PyObject *self, char *attr, PyObject *value)

Part of the Stable ABI.
Set the value of the named attribute for the object. The value argument is set to `NULL` to delete the attribute.

typedef PyObject *(*getattrofunc)(PyObject *self, PyObject *attr)

Part of the Stable ABI.

Return the value of the named attribute for the object.

See **`tp_getattro`**.

typedef int (*setattrofunc)(PyObject *self, PyObject *attr, PyObject *value)

Part of the Stable ABI.
Set the value of the named attribute for the object. The value argument is set to `NULL` to delete the attribute.

See **`tp_setattro`**.

typedef PyObject *(*descrgetfunc)(PyObject*, PyObject*, PyObject*)

Part of the Stable ABI.
See **`tp_descr_get`**.

typedef int (*descrsetfunc)(PyObject*, PyObject*, PyObject*)

Part of the Stable ABI.
See **`tp_descr_set`**.

typedef Py_hash_t (*hashfunc)(PyObject*)

Part of the Stable ABI.
See **`tp_hash`**.

typedef PyObject *(*richcmpfunc)(PyObject*, PyObject*, int)

Part of the Stable ABI.
See **`tp_richcompare`**.

typedef PyObject *(*getiterfunc)(PyObject*)

Part of the Stable ABI.
See **`tp_iter`**.

typedef PyObject *(*iternextfunc)(PyObject*)

Part of the Stable ABI.
See **`tp_iternext`**.

typedef Py_ssize_t (*lenfunc)(PyObject*)

Part of the Stable ABI.

typedef int (*getbufferproc)(PyObject*, Py_buffer*, int)

Part of the Stable ABI since version 3.12.

typedef void (*releasebufferproc)(PyObject*, Py_buffer*)

Part of the Stable ABI since version 3.12.

typedef PyObject *(*unaryfunc)(PyObject*)

Part of the Stable ABI.

typedef PyObject *(*binaryfunc)(PyObject*, PyObject*)

Part of the Stable ABI.

typedef PySendResult (*sendfunc)(PyObject*, PyObject*, PyObject**)

See **`am_send`**.

typedef PyObject *(*ternaryfunc)(PyObject*, PyObject*, PyObject*)

Part of the Stable ABI.

typedef PyObject *(*ssizeargfunc)(PyObject*, Py_ssize_t)

Part of the Stable ABI.

typedef int (*ssizeobjargproc)(PyObject*, Py_ssize_t, PyObject*)

Part of the Stable ABI.

typedef int (*objobjproc)(PyObject*, PyObject*)

Part of the Stable ABI.

typedef int (*objobjargproc)(PyObject*, PyObject*, PyObject*)

Part of the Stable ABI.

Examples

The following are simple examples of Python type definitions. They include common usage you may encounter. Some demonstrate tricky corner cases. For more examples, practical info, and a tutorial, see Defining Extension Types: Tutorial and Defining Extension Types: Assorted Topics.

A basic static type:

```
typedef struct {
    PyObject_HEAD
    const char *data;
} MyObject;

static PyTypeObject MyObject_Type = {
    PyVarObject_HEAD_INIT(NULL, 0)
    .tp_name = "mymod.MyObject",
    .tp_basicsize = sizeof(MyObject),
    .tp_doc = PyDoc_STR("My objects"),
    .tp_new = myobj_new,
    .tp_dealloc = (destructor)myobj_dealloc,
    .tp_repr = (reprfunc)myobj_repr,
};
```

You may also find older code (especially in the CPython code base) with a more verbose initializer:

```
static PyTypeObject MyObject_Type = {
    PyVarObject_HEAD_INIT(NULL, 0)
    "mymod.MyObject",               /* tp_name */
    sizeof(MyObject),               /* tp_basicsize */
    0,                              /* tp_itemsize */
    (destructor)myobj_dealloc,      /* tp_dealloc */
    0,                              /* tp_vectorcall_offset */
    0,                              /* tp_getattr */
    0,                              /* tp_setattr */
    0,                              /* tp_as_async */
    (reprfunc)myobj_repr,           /* tp_repr */
    0,                              /* tp_as_number */
    0,                              /* tp_as_sequence */
    0,                              /* tp_as_mapping */
    0,                              /* tp_hash */
    0,                              /* tp_call */
    0,                              /* tp_str */
    0,                              /* tp_getattro */
    0,                              /* tp_setattro */
    0,                              /* tp_as_buffer */
    0,                              /* tp_flags */
    PyDoc_STR("My objects"),        /* tp_doc */
    0,                              /* tp_traverse */
    0,                              /* tp_clear */
    0,                              /* tp_richcompare */
    0,                              /* tp_weaklistoffset */
    0,                              /* tp_iter */
    0,                              /* tp_iternext */
    0,                              /* tp_methods */
    0,                              /* tp_members */
    0,                              /* tp_getset */
    0,                              /* tp_base */
    0,                              /* tp_dict */
    0,                              /* tp_descr_get */
    0,                              /* tp_descr_set */
    0,                              /* tp_dictoffset */
    0,                              /* tp_init */
    0,                              /* tp_alloc */
    myobj_new,                      /* tp_new */
};
```

A type that supports weakrefs, instance dicts, and hashing:

```
typedef struct {
    PyObject_HEAD
    const char *data;
} MyObject;

static PyTypeObject MyObject_Type = {
    PyVarObject_HEAD_INIT(NULL, 0)
    .tp_name = "mymod.MyObject",
    .tp_basicsize = sizeof(MyObject),
    .tp_doc = PyDoc_STR("My objects"),
    .tp_flags = Py_TPFLAGS_DEFAULT | Py_TPFLAGS_BASETYPE |
         Py_TPFLAGS_HAVE_GC | Py_TPFLAGS_MANAGED_DICT |
         Py_TPFLAGS_MANAGED_WEAKREF,
    .tp_new = myobj_new,
    .tp_traverse = (traverseproc)myobj_traverse,
    .tp_clear = (inquiry)myobj_clear,
    .tp_alloc = PyType_GenericNew,
    .tp_dealloc = (destructor)myobj_dealloc,
    .tp_repr = (reprfunc)myobj_repr,
    .tp_hash = (hashfunc)myobj_hash,
    .tp_richcompare = PyBaseObject_Type.tp_richcompare,
};
```

A str subclass that cannot be subclassed and cannot be called to create instances (e.g. uses a separate factory func) using `Py_TPFLAGS_DISALLOW_INSTANTIATION` flag:

```
typedef struct {
    PyUnicodeObject raw;
    char *extra;
} MyStr;

static PyTypeObject MyStr_Type = {
    PyVarObject_HEAD_INIT(NULL, 0)
    .tp_name = "mymod.MyStr",
    .tp_basicsize = sizeof(MyStr),
    .tp_base = NULL,  // set to &PyUnicode_Type in module init
    .tp_doc = PyDoc_STR("my custom str"),
    .tp_flags = Py_TPFLAGS_DEFAULT |
Py_TPFLAGS_DISALLOW_INSTANTIATION,
    .tp_repr = (reprfunc)myobj_repr,
};
```

The simplest static type with fixed-length instances:

```
typedef struct {
    PyObject_HEAD
} MyObject;

static PyTypeObject MyObject_Type = {
    PyVarObject_HEAD_INIT(NULL, 0)
    .tp_name = "mymod.MyObject",
};
```

The simplest static type with variable-length instances:

```
typedef struct {
    PyObject_VAR_HEAD
    const char *data[1];
} MyObject;

static PyTypeObject MyObject_Type = {
    PyVarObject_HEAD_INIT(NULL, 0)
    .tp_name = "mymod.MyObject",
    .tp_basicsize = sizeof(MyObject) - sizeof(char *),
    .tp_itemsize = sizeof(char *),
};
```

Supporting Cyclic Garbage Collection

Python’s support for detecting and collecting garbage which involves circular references requires support from object types which are “containers” for other objects which may also be containers. Types which do not store references to other objects, or which only store references to atomic types (such as numbers or strings), do not need to provide any explicit support for garbage collection.

To create a container type, the `tp_flags` field of the type object must include the `Py_TPFLAGS_HAVE_GC` and provide an implementation of the `tp_traverse` handler. If instances of the type are mutable, a `tp_clear` implementation must also be provided.

`Py_TPFLAGS_HAVE_GC`

Objects with a type with this flag set must conform with the rules documented here. For convenience these objects will be referred to as container objects.

Constructors for container types must conform to two rules:

1. The memory for the object must be allocated using `PyObject_GC_New` or `PyObject_GC_NewVar`.
2. Once all the fields which may contain references to other containers are initialized, it must call `PyObject_GC_Track()`.

Similarly, the deallocator for the object must conform to a similar pair of rules:

1. Before fields which refer to other containers are invalidated, `PyObject_GC_UnTrack()` must be called.

2. The object’s memory must be deallocated using `PyObject_GC_Del()`.

Warning

If a type adds the Py_TPFLAGS_HAVE_GC, then it *must* implement at least a `tp_traverse` handler or explicitly use one from its subclass or subclasses.

When calling `PyType_Ready()` or some of the APIs that indirectly call it like `PyType_FromSpecWithBases()` or `PyType_FromSpec()` the interpreter will automatically populate the `tp_flags`, `tp_traverse` and `tp_clear` fields if the type inherits from a class that implements the garbage collector protocol and the child class does *not* include the `Py_TPFLAGS_HAVE_GC` flag.

PyObject_GC_New(TYPE, typeobj)

Analogous to `PyObject_New` but for container objects with the `Py_TPFLAGS_HAVE_GC` flag set.

Do not call this directly to allocate memory for an object; call the type’s `tp_alloc` slot instead.

When populating a type’s `tp_alloc` slot, `PyType_GenericAlloc()` is preferred over a custom function that simply calls this macro.

Memory allocated by this macro must be freed with `PyObject_GC_Del()` (usually called via the object’s `tp_free` slot).

See also

- `PyObject_GC_Del()`
- `PyObject_New`
- `PyType_GenericAlloc()`
- `tp_alloc`

PyObject_GC_NewVar(TYPE, typeobj, size)

Analogous to `PyObject_NewVar` but for container objects with the `Py_TPFLAGS_HAVE_GC` flag set.

Do not call this directly to allocate memory for an object; call the type's `tp_alloc` slot instead.

When populating a type's `tp_alloc` slot, `PyType_GenericAlloc()` is preferred over a custom function that simply calls this macro.

Memory allocated by this macro must be freed with `PyObject_GC_Del()` (usually called via the object's `tp_free` slot).

See also

- `PyObject_GC_Del()`
- `PyObject_NewVar`
- `PyType_GenericAlloc()`
- `tp_alloc`

PyObject *PyUnstable_Object_GC_NewWithExtraData(PyTypeObject *type, size_t extra_size)

This is Unstable API. It may change without warning in minor releases.

Analogous to `PyObject_GC_New` but allocates *extra_size* bytes at the end of the object (at offset `tp_basicsize`). The allocated memory is initialized to zeros, except for the `Python object header`.

The extra data will be deallocated with the object, but otherwise it is not managed by Python.

Memory allocated by this function must be freed with `PyObject_GC_Del()` (usually called via the object's `tp_free` slot).

Warning

The function is marked as unstable because the final mechanism for reserving extra data after an instance is not yet decided. For allocating a variable number of fields, prefer using `PyVarObject` and `tp_itemsize` instead.

Added in version 3.12.

PyObject_GC_Resize(TYPE, op, newsize)

Resize an object allocated by `PyObject_NewVar`. Returns the resized object of type `TYPE*` (refers to any C type) or `NULL` on failure.

op must be of type PyVarObject* and must not be tracked by the collector yet. *newsize* must be of type `Py_ssize_t`.

void PyObject_GC_Track(PyObject *op)

Part of the Stable ABI.

Adds the object *op* to the set of container objects tracked by the collector. The collector can run at unexpected times so objects must be valid while being tracked. This should be called once all the fields followed by the `tp_traverse` handler become valid, usually near the end of the constructor.

int PyObject_IS_GC(PyObject *obj)

Returns non-zero if the object implements the garbage collector protocol, otherwise returns 0.

The object cannot be tracked by the garbage collector if this function returns 0.

int PyObject_GC_IsTracked(PyObject *op)

Part of the Stable ABI since version 3.9.
Returns 1 if the object type of *op* implements the GC protocol and *op* is being currently tracked by the garbage collector and 0 otherwise.

This is analogous to the Python function `gc.is_tracked()`.

Added in version 3.9.

int PyObject_GC_IsFinalized(PyObject *op)

Part of the Stable ABI since version 3.9.
Returns 1 if the object type of *op* implements the GC protocol and *op* has been already finalized by the garbage collector and 0 otherwise.

This is analogous to the Python function `gc.is_finalized()`.

Added in version 3.9.

void PyObject_GC_Del(void *op)

Part of the Stable ABI.
Releases memory allocated to an object using `PyObject_GC_New` or `PyObject_GC_NewVar`.

Do not call this directly to free an object’s memory; call the type’s `tp_free` slot instead.

Do not use this for memory allocated by `PyObject_New`, `PyObject_NewVar`, or related allocation functions; use `PyObject_Free()` instead.

See also

- `PyObject_Free()` is the non-GC equivalent of this function.
- `PyObject_GC_New`
- `PyObject_GC_NewVar`
- `PyType_GenericAlloc()`
- `tp_free`

void PyObject_GC_UnTrack(void *op)

Part of the Stable ABI.
Remove the object *op* from the set of container objects tracked by the collector. Note that `PyObject_GC_Track()` can be called again on this object to add it back to the set of tracked objects. The deallocator (`tp_dealloc` handler) should call this for the object before any of the fields used by the `tp_traverse` handler become invalid.

Changed in version 3.8: The `_PyObject_GC_TRACK()` and `_PyObject_GC_UNTRACK()` macros have been removed from the public C API.

The `tp_traverse` handler accepts a function parameter of this type:

typedef int (*visitproc)(PyObject *object, void *arg)

Part of the Stable ABI.
Type of the visitor function passed to the `tp_traverse` handler. The function should be called with an object to

traverse as *object* and the third parameter to the `tp_traverse` handler as *arg*. The Python core uses several visitor functions to implement cyclic garbage detection; it’s not expected that users will need to write their own visitor functions.

The `tp_traverse` handler must have the following type:

typedef int (*traverseproc)(PyObject *self, visitproc visit, void *arg)

Part of the Stable ABI.
Traversal function for a container object. Implementations must call the *visit* function for each object directly contained by *self*, with the parameters to *visit* being the contained object and the *arg* value passed to the handler. The *visit* function must not be called with a `NULL` object argument. If *visit* returns a non-zero value that value should be returned immediately.

The traversal function must not have any side effects. Implementations may not modify the reference counts of any Python objects nor create or destroy any Python objects.

To simplify writing `tp_traverse` handlers, a `Py_VISIT()` macro is provided. In order to use this macro, the `tp_traverse` implementation must name its arguments exactly *visit* and *arg*:

Py_VISIT(o)

If the PyObject* *o* is not `NULL`, call the *visit* callback, with arguments *o* and *arg*. If *visit* returns a non-zero value, then return it. Using this macro, `tp_traverse` handlers look like:

```
static int
my_traverse(Noddy *self, visitproc visit, void *arg)
{
    Py_VISIT(self->foo);
    Py_VISIT(self->bar);
    return 0;
}
```

The `tp_clear` handler must be of the `inquiry` type, or `NULL` if the object is immutable.

typedef int (*inquiry)(PyObject *self)

Part of the Stable ABI.
Drop references that may have created reference cycles. Immutable objects do not have to define this method since they can never directly create reference cycles. Note that the object must still be valid after calling this method (don’t just call `Py_DECREF()` on a reference). The collector will call this method if it detects that this object is involved in a reference cycle.

Controlling the Garbage Collector State

The C-API provides the following functions for controlling garbage collection runs.

Py_ssize_t PyGC_Collect(void)

Part of the Stable ABI.
Perform a full garbage collection, if the garbage collector is enabled. (Note that `gc.collect()` runs it unconditionally.)

Returns the number of collected + unreachable objects which cannot be collected. If the garbage collector is disabled or already collecting, returns `0` immediately. Errors during garbage collection are passed to `sys.unraisablehook`. This function does not raise exceptions.

int PyGC_Enable(void)

Part of the Stable ABI since version 3.10.
Enable the garbage collector: similar to `gc.enable()`. Returns the previous state, 0 for disabled and 1 for enabled.

Added in version 3.10.

int PyGC_Disable(void)

Part of the Stable ABI since version 3.10.
Disable the garbage collector: similar to `gc.disable()`. Returns the previous state, 0 for disabled and 1 for enabled.

Added in version 3.10.

int PyGC_IsEnabled(void)

Part of the Stable ABI since version 3.10.
Query the state of the garbage collector: similar to `gc.isenabled()`. Returns the current state, 0 for disabled and 1 for enabled.

Added in version 3.10.

Querying Garbage Collector State

The C-API provides the following interface for querying information about the garbage collector.

void PyUnstable_GC_VisitObjects(gcvisitobjects_t callback, void *arg)

This is Unstable API. It may change without warning in minor releases.

Run supplied *callback* on all live GC-capable objects. *arg* is passed through to all invocations of *callback*.

Warning

If new objects are (de)allocated by the callback it is undefined if they will be visited.

Garbage collection is disabled during operation. Explicitly running a collection in the callback may lead to undefined behaviour e.g. visiting the same objects multiple times or not at all.

Added in version 3.12.

typedef int (*gcvisitobjects_t)(PyObject *object, void *arg)

Type of the visitor function to be passed to **`PyUnstable_GC_VisitObjects()`**. *arg* is the same as the *arg* passed to `PyUnstable_GC_VisitObjects`. Return `1` to continue iteration, return `0` to stop iteration. Other return values are reserved for now so behavior on returning anything else is undefined.

Added in version 3.12.

API and ABI Versioning

Build-time version constants

CPython exposes its version number in the following macros. Note that these correspond to the version code is **built** with. See `Py_Version` for the version used at **run time**.

See C API Stability for a discussion of API and ABI stability across versions.

PY_MAJOR_VERSION

The `3` in `3.4.1a2`.

PY_MINOR_VERSION

The `4` in `3.4.1a2`.

PY_MICRO_VERSION

The `1` in `3.4.1a2`.

PY_RELEASE_LEVEL

The `a` in `3.4.1a2`. This can be `0xA` for alpha, `0xB` for beta, `0xC` for release candidate or `0xF` for final.

PY_RELEASE_SERIAL

The `2` in `3.4.1a2`. Zero for final releases.

PY_VERSION_HEX

The Python version number encoded in a single integer. See `Py_PACK_FULL_VERSION()` for the encoding details.

Use this for numeric comparisons, for example, `#if PY_VERSION_HEX >= ...`.

These macros are defined in Include/patchlevel.h [https://github.com/python/cpython/tree/3.14/Include/patchlevel.h].

Run-time version

const unsigned long Py_Version

Part of the Stable ABI since version 3.11.
The Python runtime version number encoded in a single constant integer. See **`Py_PACK_FULL_VERSION()`** for the encoding details. This contains the Python version used at run time.

Use this for numeric comparisons, for example, `if (Py_Version >= ...)`.

Added in version 3.11.

Bit-packing macros

uint32_t Py_PACK_FULL_VERSION(int major, int minor, int micro, int release_level, int release_serial)

Part of the Stable ABI since version 3.14.
Return the given version, encoded as a single 32-bit integer with the following structure:

Argument	**No. of bits**	**Bit mask**	**Bit shift**	**Example values**	
				`3.4.1a2`	**`3.10.0`**
major	8	`0xFF000000`	24	`0x03`	`0x03`
minor	8	`0x00FF0000`	16	`0x04`	`0x0A`
micro	8	`0x0000FF00`	8	`0x01`	`0x00`

Argument	**No. of bits**	**Bit mask**	**Bit shift**	**Example values**	
				`3.4.1a2`	**`3.10.0`**
release_level	4	`0x000000F0`	4	`0xA`	`0xF`
release_serial	4	`0x0000000F`	0	`0x2`	`0x0`

For example:

Version	**`Py_PACK_FULL_VERSION` arguments**	**Encoded version**
`3.4.1a2`	`(3, 4, 1, 0xA, 2)`	`0x030401a2`
`3.10.0`	`(3, 10, 0, 0xF, 0)`	`0x030a00f0`

Out-of range bits in the arguments are ignored. That is, the macro can be defined as:

```
#ifndef Py_PACK_FULL_VERSION
#define Py_PACK_FULL_VERSION(X, Y, Z, LEVEL, SERIAL) ( \
   (((X) & 0xff) << 24) |                              \
   (((Y) & 0xff) << 16) |                              \
   (((Z) & 0xff) << 8) |                               \
   (((LEVEL) & 0xf) << 4) |                            \
   (((SERIAL) & 0xf) << 0))
#endif
```

`Py_PACK_FULL_VERSION` is primarily a macro, intended for use in `#if` directives, but it is also available as an exported function.

Added in version 3.14.

uint32_t Py_PACK_VERSION(int major, int minor)

Part of the Stable ABI since version 3.14.
Equivalent to `Py_PACK_FULL_VERSION(major, minor, 0, 0, 0)`. The result does not correspond to any Python release, but is useful in numeric comparisons.

Added in version 3.14.

Monitoring C API

Added in version 3.13.

An extension may need to interact with the event monitoring system. Subscribing to events and registering callbacks can be done via the Python API exposed in `sys.monitoring`.

Generating Execution Events

The functions below make it possible for an extension to fire monitoring events as it emulates the execution of Python code. Each of these functions accepts a `PyMonitoringState` struct which contains concise information about the activation state of events, as well as the event arguments, which include a `PyObject*` representing the code object, the instruction offset and sometimes additional, event-specific arguments (see `sys.monitoring` for details about the signatures of the different event callbacks). The `codelike` argument should be an instance of `types.CodeType` or of a type that emulates it.

The VM disables tracing when firing an event, so there is no need for user code to do that.

Monitoring functions should not be called with an exception set, except those listed below as working with the current exception.

type PyMonitoringState

Representation of the state of an event type. It is allocated by the user while its contents are maintained by the monitoring API functions described below.

All of the functions below return 0 on success and -1 (with an exception set) on error.

See `sys.monitoring` for descriptions of the events.

int PyMonitoring_FirePyStartEvent(PyMonitoringState *state, PyObject *codelike, int32_t offset)

Fire a `PY_START` event.

int PyMonitoring_FirePyResumeEvent(PyMonitoringState *state, PyObject *codelike, int32_t offset)

Fire a `PY_RESUME` event.

int PyMonitoring_FirePyReturnEvent(PyMonitoringState *state, PyObject *codelike, int32_t offset, PyObject *retval)

Fire a `PY_RETURN` event.

int PyMonitoring_FirePyYieldEvent(PyMonitoringState *state, PyObject *codelike, int32_t offset, PyObject *retval)

Fire a `PY_YIELD` event.

int PyMonitoring_FireCallEvent(PyMonitoringState *state, PyObject *codelike, int32_t offset, PyObject *callable, PyObject *arg0)

Fire a `CALL` event.

int PyMonitoring_FireLineEvent(PyMonitoringState *state, PyObject *codelike, int32_t offset, int lineno)

Fire a `LINE` event.

int PyMonitoring_FireJumpEvent(PyMonitoringState *state, PyObject *codelike, int32_t offset, PyObject *target_offset)

Fire a `JUMP` event.

int PyMonitoring_FireBranchLeftEvent(PyMonitoringState *state, PyObject *codelike, int32_t offset, PyObject *target_offset)

Fire a `BRANCH_LEFT` event.

int PyMonitoring_FireBranchRightEvent(PyMonitoringState *state, PyObject *codelike, int32_t offset, PyObject *target_offset)

Fire a `BRANCH_RIGHT` event.

int PyMonitoring_FireCReturnEvent(PyMonitoringState *state, PyObject *codelike, int32_t offset, PyObject *retval)

Fire a `C_RETURN` event.

int PyMonitoring_FirePyThrowEvent(PyMonitoringState *state, PyObject *codelike, int32_t offset)

Fire a `PY_THROW` event with the current exception (as returned by **`PyErr_GetRaisedException()`**).

int PyMonitoring_FireRaiseEvent(PyMonitoringState *state, PyObject *codelike, int32_t offset)

Fire a `RAISE` event with the current exception (as returned by **`PyErr_GetRaisedException()`**).

int PyMonitoring_FireCRaiseEvent(PyMonitoringState *state, PyObject *codelike, int32_t offset)

Fire a `C_RAISE` event with the current exception (as returned by **`PyErr_GetRaisedException()`**).

int PyMonitoring_FireReraiseEvent(PyMonitoringState *state, PyObject *codelike, int32_t offset)

Fire a `RERAISE` event with the current exception (as returned by **`PyErr_GetRaisedException()`**).

int PyMonitoring_FireExceptionHandledEvent(PyMonitoringState *state, PyObject *codelike, int32_t offset)

Fire an `EXCEPTION_HANDLED` event with the current exception (as returned by **`PyErr_GetRaisedException()`**).

int PyMonitoring_FirePyUnwindEvent(PyMonitoringState *state, PyObject *codelike, int32_t offset)

Fire a `PY_UNWIND` event with the current exception (as returned by **`PyErr_GetRaisedException()`**).

int PyMonitoring_FireStopIterationEvent(PyMonitoringState *state, PyObject *codelike, int32_t offset, PyObject *value)

Fire a `STOP_ITERATION` event. If `value` is an instance of **`StopIteration`**, it is used. Otherwise, a new **`StopIteration`** instance is created with `value` as its argument.

Managing the Monitoring State

Monitoring states can be managed with the help of monitoring scopes. A scope would typically correspond to a Python function.

int PyMonitoring_EnterScope(PyMonitoringState *state_array, uint64_t *version, const uint8_t *event_types, Py_ssize_t length)

Enter a monitored scope. `event_types` is an array of the event IDs for events that may be fired from the scope. For example, the ID of a `PY_START` event is the value `PY_MONITORING_EVENT_PY_START`, which is numerically equal to the base-2 logarithm of `sys.monitoring.events.PY_START`. `state_array` is an array with a monitoring state entry for each event in `event_types`, it is allocated by the user but populated by **`PyMonitoring_EnterScope()`** with information about the activation state of the event. The size of `event_types` (and hence also of `state_array`) is given in `length`.

The `version` argument is a pointer to a value which should be allocated by the user together with `state_array` and initialized to 0, and then set only by **`PyMonitoring_EnterScope()`** itself. It allows this function to determine whether event states have changed since the previous call, and to return quickly if they have not.

The scopes referred to here are lexical scopes: a function, class or method. **`PyMonitoring_EnterScope()`** should be called whenever the lexical scope is entered. Scopes can be reentered, reusing the same *state_array* and *version*, in situations like when emulating a recursive Python function. When a code-like’s execution is paused, such as when emulating a generator, the scope needs to be exited and re-entered.

The macros for *event_types* are:

Macro	Event
PY_MONITORING_EVENT_BRANCH_LEFT	**`BRANCH_LEFT`**
PY_MONITORING_EVENT_BRANCH_RIGHT	**`BRANCH_RIGHT`**
PY_MONITORING_EVENT_CALL	**`CALL`**

Macro	**Event**
PY_MONITORING_EVENT_C_RAISE	`C_RAISE`
PY_MONITORING_EVENT_C_RETURN	`C_RETURN`
PY_MONITORING_EVENT_EXCEPTION_HANDLED	`EXCEPTION_HANDLED`
PY_MONITORING_EVENT_INSTRUCTION	`INSTRUCTION`
PY_MONITORING_EVENT_JUMP	`JUMP`
PY_MONITORING_EVENT_LINE	`LINE`
PY_MONITORING_EVENT_PY_RESUME	`PY_RESUME`
PY_MONITORING_EVENT_PY_RETURN	`PY_RETURN`
PY_MONITORING_EVENT_PY_START	`PY_START`
PY_MONITORING_EVENT_PY_THROW	`PY_THROW`
PY_MONITORING_EVENT_PY_UNWIND	`PY_UNWIND`
PY_MONITORING_EVENT_PY_YIELD	`PY_YIELD`
PY_MONITORING_EVENT_RAISE	`RAISE`
PY_MONITORING_EVENT_RERAISE	`RERAISE`
PY_MONITORING_EVENT_STOP_ITERATION	`STOP_ITERATION`

int PyMonitoring_ExitScope(void)

Exit the last scope that was entered with `PyMonitoring_EnterScope()`.

int PY_MONITORING_IS_INSTRUMENTED_EVENT(uint8_t ev)

Return true if the event corresponding to the event ID *ev* is a local event.

Added in version 3.13.

Deprecated since version 3.14: This function is soft deprecated.

Installing Python Modules

Email:: distutils-sig@python.org

As a popular open source development project, Python has an active supporting community of contributors and users that also make their software available for other Python developers to use under open source license terms.

This allows Python users to share and collaborate effectively, benefiting from the solutions others have already created to common (and sometimes even rare!) problems, as well as potentially contributing their own solutions to the common pool.

This guide covers the installation part of the process. For a guide to creating and sharing your own Python projects, refer to the Python packaging user guide [https://packaging.python.org/en/latest/tutorials/packaging-projects/].

Note

For corporate and other institutional users, be aware that many organisations have their own policies around using and contributing to open source software. Please take such policies into account when making use of the distribution and installation tools provided with Python.

Key terms

- `pip` is the preferred installer program. Starting with Python 3.4, it is included by default with the Python binary installers.

- A *virtual environment* is a semi-isolated Python environment that allows packages to be installed for use by a particular application, rather than being installed system wide.
- `venv` is the standard tool for creating virtual environments, and has been part of Python since Python 3.3. Starting with Python 3.4, it defaults to installing `pip` into all created virtual environments.
- `virtualenv` is a third party alternative (and predecessor) to `venv`. It allows virtual environments to be used on versions of Python prior to 3.4, which either don't provide `venv` at all, or aren't able to automatically install `pip` into created environments.
- The Python Package Index [https://pypi.org] is a public repository of open source licensed packages made available for use by other Python users.
- the Python Packaging Authority [https://www.pypa.io/] is the group of developers and documentation authors responsible for the maintenance and evolution of the standard packaging tools and the associated metadata and file format standards. They maintain a variety of tools, documentation, and issue trackers on GitHub [https://github.com/pypa].
- `distutils` is the original build and distribution system first added to the Python standard library in 1998. While direct use of `distutils` is being phased out, it still laid the foundation for the current packaging and distribution infrastructure, and it not only remains part of the standard library, but its name lives on in other ways (such as the name of the mailing list used to coordinate Python packaging standards development).

Changed in version 3.5: The use of `venv` is now recommended for creating virtual environments.

See also

Python Packaging User Guide: Creating and using virtual environments [https://packaging.python.org/installing/#creating-virtual-environments]

Basic usage

The standard packaging tools are all designed to be used from the command line.

The following command will install the latest version of a module and its dependencies from the Python Package Index:

```
python -m pip install SomePackage
```

Note

For POSIX users (including macOS and Linux users), the examples in this guide assume the use of a virtual environment.

For Windows users, the examples in this guide assume that the option to adjust the system PATH environment variable was selected when installing Python.

It’s also possible to specify an exact or minimum version directly on the command line. When using comparator operators such as `>`, `<` or some other special character which get interpreted by shell, the package name and the version should be enclosed within double quotes:

```
python -m pip install SomePackage==1.0.4    # specific version
python -m pip install "SomePackage>=1.0.4"  # minimum version
```

Normally, if a suitable module is already installed, attempting to install it again will have no effect. Upgrading existing modules must be requested explicitly:

```
python -m pip install --upgrade SomePackage
```

More information and resources regarding `pip` and its capabilities can be found in the Python Packaging User Guide [https://packaging.python.org].

Creation of virtual environments is done through the **`venv`** module. Installing packages into an active virtual environment uses the commands shown above.

Python Packaging User Guide: Installing Python Distribution Packages [https://packaging.python.org/installing/]

How do I …?

These are quick answers or links for some common tasks.

… install `pip` in versions of Python prior to Python 3.4?

Python only started bundling `pip` with Python 3.4. For earlier versions, `pip` needs to be “bootstrapped” as described in the Python Packaging User Guide.

See also

Python Packaging User Guide: Requirements for Installing Packages [https://packaging.python.org/installing/#requirements-for-installing-packages]

… install packages just for the current user?

Passing the `--user` option to `python -m pip install` will install a package just for the current user, rather than for all users of the system.

… install scientific Python packages?

A number of scientific Python packages have complex binary dependencies, and aren’t currently easy to install using `pip` directly. At this point in time, it will often be easier for users to install these packages by other means [https://packaging.python.org/science/] rather than attempting to install them with `pip`.

See also

Python Packaging User Guide: Installing Scientific Packages [https://packaging.python.org/science/]

… work with multiple versions of Python installed in parallel?

On Linux, macOS, and other POSIX systems, use the versioned Python commands in combination with the `-m` switch to run the appropriate copy of `pip`:

```
python2   -m pip install SomePackage  # default Python 2
python2.7 -m pip install SomePackage  # specifically Python 2.7
```

```
python3   -m pip install SomePackage  # default Python 3
python3.4 -m pip install SomePackage  # specifically Python 3.4
```

Appropriately versioned `pip` commands may also be available.

On Windows, use the `py` Python launcher in combination with the `-m` switch:

```
py -2   -m pip install SomePackage  # default Python 2
py -2.7 -m pip install SomePackage  # specifically Python 2.7
py -3   -m pip install SomePackage  # default Python 3
py -3.4 -m pip install SomePackage  # specifically Python 3.4
```

Common installation issues

Installing into the system Python on Linux

On Linux systems, a Python installation will typically be included as part of the distribution. Installing into this Python installation requires root access to the system, and may interfere with the operation of the system package manager and other components of the system if a component is unexpectedly upgraded using `pip`.

On such systems, it is often better to use a virtual environment or a per-user installation when installing packages with `pip`.

Pip not installed

It is possible that `pip` does not get installed by default. One potential fix is:

```
python -m ensurepip --default-pip
```

There are also additional resources for installing pip. [https://packaging.python.org/en/latest/tutorials/installing-packages/#ensure-pip-setuptools-and-wheel-are-up-to-date]

Installing binary extensions

Python has typically relied heavily on source based distribution, with end users being expected to compile extension modules from source as part of the installation process.

With the introduction of support for the binary `wheel` format, and the ability to publish wheels for at least Windows and macOS through the Python Package Index, this problem is expected to diminish over time, as users are more regularly able to install pre-built extensions rather than needing to build them themselves.

Some of the solutions for installing scientific software [https://packaging.python.org/science/] that are not yet available as pre-built `wheel` files may also help with obtaining other binary extensions without needing to build them locally.

Python HOWTOs

Python HOWTOs are documents that cover a specific topic in-depth. Modeled on the Linux Documentation Project's HOWTO collection, this collection is an effort to foster documentation that's more detailed than the Python Library Reference.

General:

- A Conceptual Overview of asyncio
- Annotations Best Practices
- Argparse Tutorial
- Descriptor Guide
- Enum HOWTO
- Functional Programming HOWTO
- An introduction to the ipaddress module
- Logging HOWTO
- Logging Cookbook
- Regular Expression HOWTO
- Sorting Techniques
- Unicode HOWTO
- HOWTO Fetch Internet Resources Using The urllib Package

Advanced development:

- Curses Programming with Python
- Python support for free threading
- C API Extension Support for Free Threading
- Isolating Extension Modules
- The Python 2.3 Method Resolution Order
- Socket Programming HOWTO
- timer file descriptor HOWTO

- Porting Extension Modules to Python 3

Debugging and profiling:

- Debugging C API extensions and CPython Internals with GDB
- Instrumenting CPython with DTrace and SystemTap
- Python support for the Linux perf profiler
- Remote debugging attachment protocol

A Conceptual Overview of `asyncio`

This HOWTO article seeks to help you build a sturdy mental model of how **`asyncio`** fundamentally works, helping you understand the how and why behind the recommended patterns.

You might be curious about some key **`asyncio`** concepts. By the end of this article, you'll be able to comfortably answer these questions:

- What's happening behind the scenes when an object is awaited?
- How does **`asyncio`** differentiate between a task which doesn't need CPU time (such as a network request or file read) as opposed to a task that does (such as computing n-factorial)?
- How to write an asynchronous variant of an operation, such as an async sleep or database request.

- This in-depth YouTube tutorial series [https://www.youtube.com/watch?v=Xbl7XjFYsN4&list=PLhNSoGM2ik6SIkVGXWBwerucXjgP1rHmB] on `asyncio` created by Python core team member, Łukasz Langa.
- 500 Lines or Less: A Web Crawler With asyncio Coroutines [https://aosabook.org/en/500L/a-web-crawler-with-asyncio-

coroutines.html] by A. Jesse Jiryu Davis and Guido van Rossum.

A conceptual overview part 1: the high-level

In part 1, we’ll cover the main, high-level building blocks of **`asyncio`**: the event loop, coroutine functions, coroutine objects, tasks, and `await`.

Event Loop

Everything in **`asyncio`** happens relative to the event loop. It’s the star of the show. It’s like an orchestra conductor. It’s behind the scenes managing resources. Some power is explicitly granted to it, but a lot of its ability to get things done comes from the respect and cooperation of its worker bees.

In more technical terms, the event loop contains a collection of jobs to be run. Some jobs are added directly by you, and some indirectly by **`asyncio`**. The event loop takes a job from its backlog of work and invokes it (or “gives it control”), similar to calling a function, and then that job runs. Once it pauses or completes, it returns control to the event loop. The event loop will then select another job from its pool and invoke it. You can *roughly* think of the collection of jobs as a queue: jobs are added and then processed one at a time, generally (but not always) in order. This process repeats indefinitely, with the event loop cycling endlessly onwards. If there are no more jobs pending execution, the event loop is smart enough to rest and avoid needlessly wasting CPU cycles, and will come back when there’s more work to be done.

Effective execution relies on jobs sharing well and cooperating; a greedy job could hog control and leave the other jobs to starve, rendering the overall event loop approach rather useless.

```
import asyncio

# This creates an event loop and indefinitely cycles through
# its collection of jobs.
event_loop = asyncio.new_event_loop()
event_loop.run_forever()
```

Asynchronous functions and coroutines

This is a basic, boring Python function:

```
def hello_printer():
    print(
        "Hi, I am a lowly, simple printer, though I have all I
"
        "need in life -- \nfresh paper and my dearly beloved
octopus "
        "partner in crime."
    )
```

Calling a regular function invokes its logic or body:

```
>>> hello_printer()
Hi, I am a lowly, simple printer, though I have all I need in
life --
fresh paper and my dearly beloved octopus partner in crime.
```

The async def, as opposed to just a plain `def`, makes this an asynchronous function (or “coroutine function”). Calling it creates and returns a coroutine object.

```
async def loudmouth_penguin(magic_number: int):
    print(
     "I am a super special talking penguin. Far cooler than
that printer. "
     f"By the way, my lucky number is: {magic_number}."
    )
```

Calling the async function, `loudmouth_penguin`, does not execute the print statement; instead, it creates a coroutine object:

```
>>> loudmouth_penguin(magic_number=3)
<coroutine object loudmouth_penguin at 0x104ed2740>
```

The terms “coroutine function” and “coroutine object” are often conflated as coroutine. That can be confusing! In this article, coroutine specifically refers to a coroutine object, or more precisely, an instance of **`types.CoroutineType`** (native coroutine). Note that coroutines can also exist as instances of **`collections.abc.Coroutine`** – a distinction that matters for type checking.

A coroutine represents the function’s body or logic. A coroutine has to be explicitly started; again, merely creating the coroutine does not start it. Notably, the coroutine can be paused and resumed at various points within the function’s body. That pausing and resuming ability is what allows for asynchronous behavior!

Coroutines and coroutine functions were built by leveraging the functionality of generators and generator functions. Recall, a generator function is a function that **`yield`**s, like this one:

```
def get_random_number():
    # This would be a bad random number generator!
    print("Hi")
    yield 1
    print("Hello")
    yield 7
    print("Howdy")
    yield 4
    ...
```

Similar to a coroutine function, calling a generator function does not run it. Instead, it creates a generator object:

```
>>> get_random_number()
<generator object get_random_number at 0x1048671c0>
```

You can proceed to the next `yield` of a generator by using the built-in function `next()`. In other words, the generator runs, then pauses. For example:

```
>>> generator = get_random_number()
>>> next(generator)
Hi
1
>>> next(generator)
Hello
7
```

Tasks

Roughly speaking, tasks are coroutines (not coroutine functions) tied to an event loop. A task also maintains a list of callback functions whose importance will become clear in a moment when we discuss `await`. The recommended way to create tasks is via `asyncio.create_task()`.

Creating a task automatically schedules it for execution (by adding a callback to run it in the event loop's to-do list, that is, collection of jobs).

`asyncio` automatically associates tasks with the event loop for you. This automatic association was purposely designed into **`asyncio`** for the sake of simplicity. Without it, you'd have to keep track of the event loop object and pass it to any coroutine function that wants to create tasks, adding redundant clutter to your code.

```
coroutine = loudmouth_penguin(magic_number=5)
# This creates a Task object and schedules its execution via
the event loop.
task = asyncio.create_task(coroutine)
```

Earlier, we manually created the event loop and set it to run forever. In practice, it’s recommended to use (and common to see) [`asyncio.run()`](), which takes care of managing the event loop and ensuring the provided coroutine finishes before advancing. For example, many async programs follow this setup:

```
import asyncio

async def main():
    # Perform all sorts of wacky, wild asynchronous things...
    ...

if __name__ == "__main__":
    asyncio.run(main())
    # The program will not reach the following print statement
until the
    # coroutine main() finishes.
    print("coroutine main() is done!")
```

It’s important to be aware that the task itself is not added to the event loop, only a callback to the task is. This matters if the task object you created is garbage collected before it’s called by the event loop. For example, consider this program:

```
async def hello():
    print("hello!")

async def main():
    asyncio.create_task(hello())
    # Other asynchronous instructions which run for a while
    # and cede control to the event loop...
    ...

asyncio.run(main())
```

Because there’s no reference to the task object created on line 5, it *might* be garbage collected before the event loop invokes it. Later instructions in the coroutine `main()` hand control back to the event loop so it can invoke other jobs. When the event loop eventually tries to run the task, it might fail and discover the task object does not exist! This can also happen even if a coroutine keeps a reference to a task but completes before that task finishes. When the coroutine exits, local variables go out of scope and may be subject to garbage collection. In practice, `asyncio` and Python’s garbage collector work pretty hard to ensure this sort of thing doesn’t happen. But that’s no reason to be reckless!

await

`await` is a Python keyword that’s commonly used in one of two different ways:

```
await task
await coroutine
```

In a crucial way, the behavior of `await` depends on the type of object being awaited.

Awaiting a task will cede control from the current task or coroutine to the event loop. In the process of relinquishing control, a few important things happen. We’ll use the following code example to illustrate:

```
async def plant_a_tree():
    dig_the_hole_task = asyncio.create_task(dig_the_hole())
    await dig_the_hole_task

    # Other instructions associated with planting a tree.
    ...
```

In this example, imagine the event loop has passed control to the start of the coroutine `plant_a_tree()`. As seen above, the coroutine creates a task and then awaits it. The `await dig_the_hole_task` instruction adds a callback (which will resume `plant_a_tree()`) to the `dig_the_hole_task` object's list of callbacks. And then, the instruction cedes control to the event loop. Some time later, the event loop will pass control to `dig_the_hole_task` and the task will finish whatever it needs to do. Once the task finishes, it will add its various callbacks to the event loop, in this case, a call to resume `plant_a_tree()`.

Generally speaking, when the awaited task finishes (`dig_the_hole_task`), the original task or coroutine (`plant_a_tree()`) is added back to the event loop's to-do list to be resumed.

This is a basic, yet reliable mental model. In practice, the control handoffs are slightly more complex, but not by much. In part 2, we'll walk through the details that make this possible.

Unlike tasks, awaiting a coroutine does not hand control back to the event loop! Wrapping a coroutine in a task first, then awaiting that would cede control. The behavior of `await coroutine` is effectively the same as invoking a regular, synchronous Python function. Consider this program:

```
import asyncio

async def coro_a():
   print("I am coro_a(). Hi!")

async def coro_b():
   print("I am coro_b(). I sure hope no one hogs the event
loop...")
```

```
async def main():
   task_b = asyncio.create_task(coro_b())
   num_repeats = 3
   for _ in range(num_repeats):
      await coro_a()
   await task_b

asyncio.run(main())
```

The first statement in the coroutine `main()` creates `task_b` and schedules it for execution via the event loop. Then, `coro_a()` is repeatedly awaited. Control never cedes to the event loop, which is why we see the output of all three `coro_a()` invocations before `coro_b()`'s output:

```
I am coro_a(). Hi!
I am coro_a(). Hi!
I am coro_a(). Hi!
I am coro_b(). I sure hope no one hogs the event loop...
```

If we change `await coro_a()` to `await asyncio.create_task(coro_a())`, the behavior changes. The coroutine `main()` cedes control to the event loop with that statement. The event loop then proceeds through its backlog of work, calling `task_b` and then the task which wraps `coro_a()` before resuming the coroutine `main()`.

```
I am coro_b(). I sure hope no one hogs the event loop...
I am coro_a(). Hi!
I am coro_a(). Hi!
I am coro_a(). Hi!
```

This behavior of `await coroutine` can trip a lot of people up! That example highlights how using only `await coroutine` could unintentionally hog control from other tasks and effectively stall the event loop. **`asyncio.run()`** can help you detect such occurrences via the `debug=True` flag, which enables debug mode. Among other things, it will log any coroutines that monopolize execution for 100ms or longer.

The design intentionally trades off some conceptual clarity around usage of `await` for improved performance. Each time a task is awaited, control needs to be passed all the way up the call stack to the event loop. That might sound minor, but in a large program with many `await` statements and a deep call stack, that overhead can add up to a meaningful performance drag.

A conceptual overview part 2: the nuts and bolts

Part 2 goes into detail on the mechanisms **`asyncio`** uses to manage control flow. This is where the magic happens. You’ll come away from this section knowing what `await` does behind the scenes and how to make your own asynchronous operators.

The inner workings of coroutines

`asyncio` leverages four components to pass around control.

`coroutine.send(arg)` is the method used to start or resume a coroutine. If the coroutine was paused and is now being resumed, the argument `arg` will be sent in as the return value of the `yield` statement which originally paused it. If the coroutine is being used for the first time (as opposed to being resumed), `arg` must be `None`.

```
class Rock:
    def __await__(self):
        value_sent_in = yield 7
        print(f"Rock.__await__ resuming with value: {value_sent_in}.")
        return value_sent_in

async def main():
    print("Beginning coroutine main().")
    rock = Rock()
    print("Awaiting rock...")
    value_from_rock = await rock
    print(f"Coroutine received value: {value_from_rock} from rock.")
    return 23

coroutine = main()
```

```
16 intermediate_result = coroutine.send(None)
17 print(f"Coroutine paused and returned intermediate value: {intermediate_result}.")
18
19 print(f"Resuming coroutine and sending in value: 42.")
20 try:
21     coroutine.send(42)
22 except StopIteration as e:
23     returned_value = e.value
24 print(f"Coroutine main() finished and provided value: {returned_value}.")
```

yield, as usual, pauses execution and returns control to the caller. In the example above, the `yield`, on line 3, is called by `... = await rock` on line 11. More broadly speaking, `await` calls the **`__await__()`** method of the given object. `await` also does one more very special thing: it propagates (or “passes along”) any `yield`s it receives up the call chain. In this case, that’s back to `... = coroutine.send(None)` on line 16.

The coroutine is resumed via the `coroutine.send(42)` call on line 21. The coroutine picks back up from where it `yield`ed (or paused) on line 3 and executes the remaining statements in its body. When a coroutine finishes, it raises a **`StopIteration`** exception with the return value attached in the **`value`** attribute.

That snippet produces this output:

```
Beginning coroutine main().
Awaiting rock...
Coroutine paused and returned intermediate value: 7.
Resuming coroutine and sending in value: 42.
Rock.__await__ resuming with value: 42.
Coroutine received value: 42 from rock.
Coroutine main() finished and provided value: 23.
```

It’s worth pausing for a moment here and making sure you followed the various ways that control flow and values were passed. A lot of important ideas were covered and it's worth ensuring your understanding is firm.

The only way to yield (or effectively cede control) from a coroutine is to `await` an object that `yield`s in its `__await__` method. That might sound odd to you. You might be thinking:

1. What about a `yield` directly within the coroutine function? The coroutine function becomes an async generator function, a different beast entirely.

2. What about a yield from within the coroutine function to a (plain) generator? That causes the error: `SyntaxError: yield from not allowed in a coroutine`. This was intentionally designed for the sake of simplicity – mandating only one way of using coroutines. Initially `yield` was barred as well, but was re-accepted to allow for async generators. Despite that, `yield from` and `await` effectively do the same thing.

Futures

A future is an object meant to represent a computation's status and result. The term is a nod to the idea of something still to come or not yet happened, and the object is a way to keep an eye on that something.

A future has a few important attributes. One is its state, which can be either "pending", "cancelled", or "done". Another is its result, which is set when the state transitions to done. Unlike a coroutine, a future does not represent the actual computation to be done; instead, it represents the status and result of that computation, kind of like a status light (red, yellow, or green) or indicator.

`asyncio.Task` subclasses `asyncio.Future` in order to gain these various capabilities. The prior section said tasks store a list of callbacks, which wasn’t entirely accurate. It’s actually the `Future` class that implements this logic, which `Task` inherits.

Futures may also be used directly (not via tasks). Tasks mark themselves as done when their coroutine is complete. Futures are much more versatile and will be marked as done when you say so. In this way, they’re the flexible interface for you to make your own conditions for waiting and resuming.

A homemade asyncio.sleep

We’ll go through an example of how you could leverage a future to create your own variant of asynchronous sleep (`async_sleep`) which mimics `asyncio.sleep()`.

This snippet registers a few tasks with the event loop and then awaits the task created by `asyncio.create_task`, which wraps the `async_sleep(3)` coroutine. We want that task to finish only after three seconds have elapsed, but without preventing other tasks from running.

```
async def other_work():
    print("I like work. Work work.")

async def main():
    # Add a few other tasks to the event loop, so there's
something
    # to do while asynchronously sleeping.
    work_tasks = [
        asyncio.create_task(other_work()),
        asyncio.create_task(other_work()),
        asyncio.create_task(other_work())
    ]
    print(
        "Beginning asynchronous sleep at time: "
        f"{datetime.datetime.now().strftime("%H:%M:%S")}."
    )
    await asyncio.create_task(async_sleep(3))
    print(
        "Done asynchronous sleep at time: "
        f"{datetime.datetime.now().strftime("%H:%M:%S")}."
    )
    # asyncio.gather effectively awaits each task in the
collection.
    await asyncio.gather(*work_tasks)
```

Below, we use a future to enable custom control over when that task will be marked as done. If `future.set_result()` (the method responsible for marking that future as done) is never called, then this task will never finish. We've also enlisted the help of another task, which we'll see in a moment, that will monitor how much time has elapsed and, accordingly, call `future.set_result()`.

```
async def async_sleep(seconds: float):
    future = asyncio.Future()
    time_to_wake = time.time() + seconds
    # Add the watcher-task to the event loop.
    watcher_task = asyncio.create_task(_sleep_watcher(future,
time_to_wake))
    # Block until the future is marked as done.
    await future
```

Below, we use a rather bare `YieldToEventLoop()` object to `yield` from its `__await__` method, ceding control to the event loop. This is effectively the same as calling `asyncio.sleep(0)`, but this approach offers more clarity, not to mention it's somewhat cheating to use `asyncio.sleep` when showcasing how to implement it!

As usual, the event loop cycles through its tasks, giving them control and receiving control back when they pause or finish. The `watcher_task`, which runs the coroutine `_sleep_watcher(...)`, will be invoked once per full cycle of the event loop. On each resumption, it'll check the time and if not enough has elapsed, then it'll pause once again and hand control back to the event loop. Once enough time has elapsed, `_sleep_watcher(...)` marks the future as done and completes by exiting its infinite `while` loop. Given this helper task is only invoked once per cycle of the event loop, you'd be correct to note that this asynchronous sleep will sleep *at least* three seconds, rather than exactly three seconds. Note this is also true of `asyncio.sleep`.

```
class YieldToEventLoop:
    def __await__(self):
        yield

async def _sleep_watcher(future, time_to_wake):
    while True:
        if time.time() >= time_to_wake:
            # This marks the future as done.
            future.set_result(None)
            break
        else:
            await YieldToEventLoop()
```

Here is the full program's output:

```
$ python custom-async-sleep.py
Beginning asynchronous sleep at time: 14:52:22.
I like work. Work work.
I like work. Work work.
I like work. Work work.
Done asynchronous sleep at time: 14:52:25.
```

You might feel this implementation of asynchronous sleep was unnecessarily convoluted. And, well, it was. The example was meant to showcase the versatility of futures with a simple example that could be mimicked for more complex needs. For reference, you could implement it without futures, like so:

```
async def simpler_async_sleep(seconds):
    time_to_wake = time.time() + seconds
    while True:
        if time.time() >= time_to_wake:
            return
        else:
            await YieldToEventLoop()
```

But that’s all for now. Hopefully you’re ready to more confidently dive into some async programming or check out advanced topics in the **`rest of the documentation`**.

Porting Extension Modules to Python 3

We recommend the following resources for porting extension modules to Python 3:

- The Migrating C extensions [http://python3porting.com/cextensions.html] chapter from *Supporting Python 3: An in-depth guide*, a book on moving from Python 2 to Python 3 in general, guides the reader through porting an extension module.
- The Porting guide [https://py3c.readthedocs.io/en/latest/guide.html] from the *py3c* project provides opinionated suggestions with supporting code.
- Recommended third party tools offer abstractions over the Python's C API. Extensions generally need to be re-written to use one of them, but the library then handles differences between various Python versions and implementations.

Curses Programming with Python

Author:: A.M. Kuchling, Eric S. Raymond

Release:: 2.04

Abstract

This document describes how to use the `curses` extension module to control text-mode displays.

What is curses?

The curses library supplies a terminal-independent screen-painting and keyboard-handling facility for text-based terminals; such terminals include VT100s, the Linux console, and the simulated terminal provided by various programs. Display terminals support various control codes to perform common operations such as moving the cursor, scrolling the screen, and erasing areas. Different terminals use widely differing codes, and often have their own minor quirks.

In a world of graphical displays, one might ask “why bother”? It’s true that character-cell display terminals are an obsolete technology, but there are niches in which being able to do fancy things with them are still valuable. One niche is on small-footprint or embedded Unixes that don’t run an X server. Another is tools such as OS installers and kernel configurators that may have to run before any graphical support is available.

The curses library provides fairly basic functionality, providing the programmer with an abstraction of a display containing multiple non-overlapping windows of text. The contents of a window can be changed in various ways—adding text, erasing it, changing its appearance—and the curses library will figure out what control codes need to be sent to the terminal to produce the right output. curses doesn't provide many user-interface concepts such as buttons, checkboxes, or dialogs; if you need such features, consider a user interface library such as Urwid [https://pypi.org/project/Urwid/].

The curses library was originally written for BSD Unix; the later System V versions of Unix from AT&T added many enhancements and new functions. BSD curses is no longer maintained, having been replaced by ncurses, which is an open-source implementation of the AT&T interface. If you're using an open-source Unix such as Linux or FreeBSD, your system almost certainly uses ncurses. Since most current commercial Unix versions are based on System V code, all the functions described here will probably be available. The older versions of curses carried by some proprietary Unixes may not support everything, though.

The Windows version of Python doesn't include the **`curses`** module. A ported version called UniCurses [https://pypi.org/project/UniCurses/] is available.

The Python curses module

The Python module is a fairly simple wrapper over the C functions provided by curses; if you're already familiar with curses programming in C, it's really easy to transfer that knowledge to Python. The biggest difference is that the Python interface makes things simpler by merging different C functions such as **`addstr()`**, **`mvaddstr()`**, and **`mvwaddstr()`** into a single **`addstr()`** method. You’ll see this covered in more detail later.

This HOWTO is an introduction to writing text-mode programs with curses and Python. It doesn’t attempt to be a complete guide to the curses API; for that, see the Python library guide’s section on ncurses, and the C manual pages for ncurses. It will, however, give you the basic ideas.

Starting and ending a curses application

Before doing anything, curses must be initialized. This is done by calling the **`initscr()`** function, which will determine the terminal type, send any required setup codes to the terminal, and create various internal data structures. If successful, **`initscr()`** returns a window object representing the entire screen; this is usually called `stdscr` after the name of the corresponding C variable.

```
import curses
stdscr = curses.initscr()
```

Usually curses applications turn off automatic echoing of keys to the screen, in order to be able to read keys and only display them under certain circumstances. This requires calling the **`noecho()`** function.

```
curses.noecho()
```

Applications will also commonly need to react to keys instantly, without requiring the Enter key to be pressed; this is called cbreak mode, as opposed to the usual buffered input mode.

```
curses.cbreak()
```

Terminals usually return special keys, such as the cursor keys or navigation keys such as Page Up and Home, as a multibyte escape sequence. While you could write your application to expect such sequences and process them accordingly, curses can do it for you, returning a special value such as `curses.KEY_LEFT`. To get curses to do the job, you'll have to enable keypad mode.

```
stdscr.keypad(True)
```

Terminating a curses application is much easier than starting one. You'll need to call:

```
curses.nocbreak()
stdscr.keypad(False)
curses.echo()
```

to reverse the curses-friendly terminal settings. Then call the `endwin()` function to restore the terminal to its original operating mode.

```
curses.endwin()
```

A common problem when debugging a curses application is to get your terminal messed up when the application dies without restoring the terminal to its previous state. In Python this commonly happens when your code is buggy and raises an uncaught exception. Keys are no longer echoed to the screen when you type them, for example, which makes using the shell difficult.

In Python you can avoid these complications and make debugging much easier by importing the `curses.wrapper()` function and using it like this:

```
from curses import wrapper

def main(stdscr):
    # Clear screen
    stdscr.clear()

    # This raises ZeroDivisionError when i == 10.
    for i in range(0, 11):
        v = i-10
        stdscr.addstr(i, 0, '10 divided by {} is {}'.format(v,
10/v))

        stdscr.refresh()
        stdscr.getkey()

wrapper(main)
```

The `wrapper()` function takes a callable object and does the initializations described above, also initializing colors if color support is present. **`wrapper()`** then runs your provided callable. Once the callable returns, **`wrapper()`** will restore the original state of the terminal. The callable is called inside a `try`…`except` that catches exceptions, restores the state of the terminal, and then re-raises the exception. Therefore your terminal won’t be left in a funny state on exception and you’ll be able to read the exception’s message and traceback.

Windows and Pads

Windows are the basic abstraction in curses. A window object represents a rectangular area of the screen, and supports methods to display text, erase it, allow the user to input strings, and so forth.

The `stdscr` object returned by the `initscr()` function is a window object that covers the entire screen. Many programs may need only this single window, but you might wish to divide the screen into smaller windows, in order to redraw or clear them separately. The `newwin()` function creates a new window of a given size, returning the new window object.

```
begin_x = 20; begin_y = 7
height = 5; width = 40
win = curses.newwin(height, width, begin_y, begin_x)
```

Note that the coordinate system used in curses is unusual. Coordinates are always passed in the order *y,x*, and the top-left corner of a window is coordinate (0,0). This breaks the normal convention for handling coordinates where the *x* coordinate comes first. This is an unfortunate difference from most other computer applications, but it's been part of curses since it was first written, and it's too late to change things now.

Your application can determine the size of the screen by using the `curses.LINES` and `curses.COLS` variables to obtain the *y* and *x* sizes. Legal coordinates will then extend from `(0,0)` to `(curses.LINES - 1, curses.COLS - 1)`.

When you call a method to display or erase text, the effect doesn't immediately show up on the display. Instead you must call the `refresh()` method of window objects to update the screen.

This is because curses was originally written with slow 300-baud terminal connections in mind; with these terminals, minimizing the time required to redraw the screen was very important. Instead curses accumulates changes to the screen and displays them in the most efficient manner when you call **`refresh()`**. For example, if your program displays some text in a window and then clears the window, there's no need to send the original text because they're never visible.

In practice, explicitly telling curses to redraw a window doesn't really complicate programming with curses much. Most programs go into a flurry of activity, and then pause waiting for a keypress or some other action on the part of the user. All you have to do is to be sure that the screen has been redrawn before pausing to wait for user input, by first calling **`stdscr.refresh()`** or the **`refresh()`** method of some other relevant window.

A pad is a special case of a window; it can be larger than the actual display screen, and only a portion of the pad displayed at a time. Creating a pad requires the pad’s height and width, while refreshing a pad requires giving the coordinates of the on-screen area where a subsection of the pad will be displayed.

```
pad = curses.newpad(100, 100)
# These loops fill the pad with letters; addch() is
# explained in the next section
for y in range(0, 99):
    for x in range(0, 99):
        pad.addch(y,x, ord('a') + (x*x+y*y) % 26)

# Displays a section of the pad in the middle of the screen.
# (0,0) : coordinate of upper-left corner of pad area to
display.
# (5,5) : coordinate of upper-left corner of window area to be
filled
#         with pad content.
# (20, 75) : coordinate of lower-right corner of window area to
be
#          : filled with pad content.
pad.refresh( 0,0, 5,5, 20,75)
```

The **`refresh()`** call displays a section of the pad in the rectangle extending from coordinate (5,5) to coordinate (20,75) on the screen; the upper left corner of the displayed section is coordinate (0,0) on the pad. Beyond that difference, pads are exactly like ordinary windows and support the same methods.

If you have multiple windows and pads on screen there is a more efficient way to update the screen and prevent annoying screen flicker as each part of the screen gets updated. **`refresh()`** actually does two things:

1. Calls the `noutrefresh()` method of each window to update an underlying data structure representing the desired state of the screen.
2. Calls the function `doupdate()` function to change the physical screen to match the desired state recorded in the data structure.

Instead you can call **`noutrefresh()`** on a number of windows to update the data structure, and then call **`doupdate()`** to update the screen.

Displaying Text

From a C programmer's point of view, curses may sometimes look like a twisty maze of functions, all subtly different. For example, **`addstr()`** displays a string at the current cursor location in the `stdscr` window, while **`mvaddstr()`** moves to a given y,x coordinate first before displaying the string. **`waddstr()`** is just like **`addstr()`**, but allows specifying a window to use instead of using `stdscr` by default. **`mvwaddstr()`** allows specifying both a window and a coordinate.

Fortunately the Python interface hides all these details. `stdscr` is a window object like any other, and methods such as `addstr()` accept multiple argument forms. Usually there are four different forms.

Form	Description
str or *ch*	Display the string *str* or character *ch* at the current position

Form	Description
str or *ch*, *attr*	Display the string *str* or character *ch*, using attribute *attr* at the current position
y, *x*, *str* or *ch*	Move to position *y,x* within the window, and display *str* or *ch*
y, *x*, *str* or *ch*, *attr*	Move to position *y,x* within the window, and display *str* or *ch*, using attribute *attr*

Attributes allow displaying text in highlighted forms such as boldface, underline, reverse code, or in color. They’ll be explained in more detail in the next subsection.

The `addstr()` method takes a Python string or bytestring as the value to be displayed. The contents of bytestrings are sent to the terminal as-is. Strings are encoded to bytes using the value of the window’s `encoding` attribute; this defaults to the default system encoding as returned by `locale.getencoding()`.

The `addch()` methods take a character, which can be either a string of length 1, a bytestring of length 1, or an integer.

Constants are provided for extension characters; these constants are integers greater than 255. For example, `ACS_PLMINUS` is a +/- symbol, and `ACS_ULCORNER` is the upper left corner of a box (handy for drawing borders). You can also use the appropriate Unicode character.

Windows remember where the cursor was left after the last operation, so if you leave out the *y,x* coordinates, the string or character will be displayed wherever the last operation left off. You can also move the cursor with the `move(y,x)` method. Because some terminals always display a flashing cursor, you may want to ensure that the cursor is positioned in some location where it won’t be distracting; it can be confusing to have the cursor blinking at some apparently random location.

If your application doesn’t need a blinking cursor at all, you can call `curs_set(False)` to make it invisible. For compatibility with older curses versions, there’s a `leaveok(bool)` function that’s a synonym for **`curs_set()`**. When *bool* is true, the curses library will attempt to suppress the flashing cursor, and you won’t need to worry about leaving it in odd locations.

Attributes and Color

Characters can be displayed in different ways. Status lines in a text-based application are commonly shown in reverse video, or a text viewer may need to highlight certain words. curses supports this by allowing you to specify an attribute for each cell on the screen.

An attribute is an integer, each bit representing a different attribute. You can try to display text with multiple attribute bits set, but curses doesn’t guarantee that all the possible combinations are available, or that they’re all visually distinct. That depends on the ability of the terminal being used, so it’s safest to stick to the most commonly available attributes, listed here.

Attribute	Description
`A_BLINK`	Blinking text
`A_BOLD`	Extra bright or bold text
`A_DIM`	Half bright text
`A_REVERSE`	Reverse-video text
`A_STANDOUT`	The best highlighting mode available
`A_UNDERLINE`	Underlined text

So, to display a reverse-video status line on the top line of the screen, you could code:

```
stdscr.addstr(0, 0, "Current mode: Typing mode",
              curses.A_REVERSE)
stdscr.refresh()
```

The curses library also supports color on those terminals that provide it. The most common such terminal is probably the Linux console, followed by color xterms.

To use color, you must call the `start_color()` function soon after calling `initscr()`, to initialize the default color set (the `curses.wrapper()` function does this automatically). Once that’s done, the `has_colors()` function returns TRUE if the terminal in use can actually display color. (Note: curses uses the American spelling ‘color’, instead of the Canadian/British spelling ‘colour’. If you’re used to the British spelling, you’ll have to resign yourself to misspelling it for the sake of these functions.)

The curses library maintains a finite number of color pairs, containing a foreground (or text) color and a background color. You can get the attribute value corresponding to a color pair with the `color_pair()` function; this can be bitwise-OR’ed with other attributes such as `A_REVERSE`, but again, such combinations are not guaranteed to work on all terminals.

An example, which displays a line of text using color pair 1:

```
stdscr.addstr("Pretty text", curses.color_pair(1))
stdscr.refresh()
```

As I said before, a color pair consists of a foreground and background color. The `init_pair(n, f, b)` function changes the definition of color pair *n*, to foreground color f and background color b. Color pair 0 is hard-wired to white on black, and cannot be changed.

Colors are numbered, and `start_color()` initializes 8 basic colors when it activates color mode. They are: 0:black, 1:red, 2:green, 3:yellow, 4:blue, 5:magenta, 6:cyan, and 7:white. The `curses` module defines named constants for each of these colors: `curses.COLOR_BLACK`, `curses.COLOR_RED`, and so forth.

Let’s put all this together. To change color 1 to red text on a white background, you would call:

```
curses.init_pair(1, curses.COLOR_RED, curses.COLOR_WHITE)
```

When you change a color pair, any text already displayed using that color pair will change to the new colors. You can also display new text in this color with:

```
stdscr.addstr(0,0, "RED ALERT!", curses.color_pair(1))
```

Very fancy terminals can change the definitions of the actual colors to a given RGB value. This lets you change color 1, which is usually red, to purple or blue or any other color you like. Unfortunately, the Linux console doesn't support this, so I'm unable to try it out, and can't provide any examples. You can check if your terminal can do this by calling **`can_change_color()`**, which returns `True` if the capability is there. If you're lucky enough to have such a talented terminal, consult your system's man pages for more information.

User Input

The C curses library offers only very simple input mechanisms. Python's **`curses`** module adds a basic text-input widget. (Other libraries such as Urwid [https://pypi.org/project/Urwid/] have more extensive collections of widgets.)

There are two methods for getting input from a window:

- **`getch()`** refreshes the screen and then waits for the user to hit a key, displaying the key if **`echo()`** has been called earlier. You can optionally specify a coordinate to which the cursor should be moved before pausing.
- **`getkey()`** does the same thing but converts the integer to a string. Individual characters are returned as 1-character strings, and special keys such as function keys return longer strings containing a key name such as `KEY_UP` or `^G`.

It’s possible to not wait for the user using the `nodelay()` window method. After `nodelay(True)`, **`getch()`** and **`getkey()`** for the window become non-blocking. To signal that no input is ready, **`getch()`** returns `curses.ERR` (a value of -1) and **`getkey()`** raises an exception. There’s also a `halfdelay()` function, which can be used to (in effect) set a timer on each **`getch()`**; if no input becomes available within a specified delay (measured in tenths of a second), curses raises an exception.

The **`getch()`** method returns an integer; if it’s between 0 and 255, it represents the ASCII code of the key pressed. Values greater than 255 are special keys such as Page Up, Home, or the cursor keys. You can compare the value returned to constants such as `curses.KEY_PPAGE`, `curses.KEY_HOME`, or `curses.KEY_LEFT`. The main loop of your program may look something like this:

```
while True:
    c = stdscr.getch()
    if c == ord('p'):
        PrintDocument()
    elif c == ord('q'):
        break  # Exit the while loop
    elif c == curses.KEY_HOME:
        x = y = 0
```

The `curses.ascii` module supplies ASCII class membership functions that take either integer or 1-character string arguments; these may be useful in writing more readable tests for such loops. It also supplies conversion functions that take either integer or 1-character-string arguments and return the same type. For example, `curses.ascii.ctrl()` returns the control character corresponding to its argument.

There’s also a method to retrieve an entire string, `getstr()`. It isn’t used very often, because its functionality is quite limited; the only editing keys available are the backspace key and the Enter key, which terminates the string. It can optionally be limited to a fixed number of characters.

```
curses.echo()            # Enable echoing of characters

# Get a 15-character string, with the cursor on the top line
s = stdscr.getstr(0,0, 15)
```

The `curses.textpad` module supplies a text box that supports an Emacs-like set of keybindings. Various methods of the `Textbox` class support editing with input validation and gathering the edit results either with or without trailing spaces. Here’s an example:

```
import curses
from curses.textpad import Textbox, rectangle

def main(stdscr):
    stdscr.addstr(0, 0, "Enter IM message: (hit Ctrl-G to
send)")

    editwin = curses.newwin(5,30, 2,1)
    rectangle(stdscr, 1,0, 1+5+1, 1+30+1)
    stdscr.refresh()

    box = Textbox(editwin)

    # Let the user edit until Ctrl-G is struck.
    box.edit()

    # Get resulting contents
    message = box.gather()
```

See the library documentation on `curses.textpad` for more details.

For More Information

This HOWTO doesn’t cover some advanced topics, such as reading the contents of the screen or capturing mouse events from an xterm instance, but the Python library page for the `curses` module is now reasonably complete. You should browse it next.

If you’re in doubt about the detailed behavior of the curses functions, consult the manual pages for your curses implementation, whether it’s ncurses or a proprietary Unix vendor’s. The manual pages will document any quirks, and provide complete lists of all the functions, attributes, and ACS_* characters available to you.

Because the curses API is so large, some functions aren’t supported in the Python interface. Often this isn’t because they’re difficult to implement, but because no one has needed them yet. Also, Python doesn’t yet support the menu library associated with ncurses. Patches adding support for these would be welcome; see the Python Developer’s Guide [https://devguide.python.org/] to learn more about submitting patches to Python.

    - Class methods
    - Member objects and __slots__

Descriptors let objects customize attribute lookup, storage, and deletion.

This guide has four major sections:

1. The “primer” gives a basic overview, moving gently from simple examples, adding one feature at a time. Start here if you’re new to descriptors.
2. The second section shows a complete, practical descriptor example. If you already know the basics, start there.
3. The third section provides a more technical tutorial that goes into the detailed mechanics of how descriptors work. Most people don’t need this level of detail.
4. The last section has pure Python equivalents for built-in descriptors that are written in C. Read this if you’re curious about how functions turn into bound methods or about the implementation of common tools like `classmethod()`, `staticmethod()`, `property()`, and __slots__.

Primer

In this primer, we start with the most basic possible example and then we’ll add new capabilities one by one.

Simple example: A descriptor that returns a constant

The **`Ten`** class is a descriptor whose `__get__()` method always returns the constant `10`:

```
class Ten:
    def __get__(self, obj, objtype=None):
        return 10
```

To use the descriptor, it must be stored as a class variable in another class:

```
class A:
    x = 5                       # Regular class attribute
    y = Ten()                   # Descriptor instance
```

An interactive session shows the difference between normal attribute lookup and descriptor lookup:

```
>>> a = A()                     # Make an instance of class A
>>> a.x                         # Normal attribute lookup
5
>>> a.y                         # Descriptor lookup
10
```

In the `a.x` attribute lookup, the dot operator finds `'x': 5` in the class dictionary. In the `a.y` lookup, the dot operator finds a descriptor instance, recognized by its `__get__` method. Calling that method returns `10`.

Note that the value `10` is not stored in either the class dictionary or the instance dictionary. Instead, the value `10` is computed on demand.

This example shows how a simple descriptor works, but it isn’t very useful. For retrieving constants, normal attribute lookup would be better.

In the next section, we’ll create something more useful, a dynamic lookup.

Dynamic lookups

Interesting descriptors typically run computations instead of returning constants:

```
import os

class DirectorySize:

    def __get__(self, obj, objtype=None):
        return len(os.listdir(obj.dirname))

class Directory:

    size = DirectorySize()              # Descriptor instance

    def __init__(self, dirname):
        self.dirname = dirname          # Regular instance
attribute
```

An interactive session shows that the lookup is dynamic — it computes different, updated answers each time:

```
>>> s = Directory('songs')
>>> g = Directory('games')
>>> s.size                              # The songs directory
has twenty files
20
>>> g.size                              # The games directory
has three files
3
>>> os.remove('games/chess')            # Delete a game
>>> g.size                              # File count is
automatically updated
2
```

Besides showing how descriptors can run computations, this example also reveals the purpose of the parameters to `__get__()`. The *self* parameter is *size*, an instance of *DirectorySize*. The *obj* parameter is either *g* or *s*, an instance of *Directory*. It is the *obj* parameter that lets the `__get__()` method learn the target directory. The *objtype* parameter is the class *Directory*.

Managed attributes

A popular use for descriptors is managing access to instance data. The descriptor is assigned to a public attribute in the class dictionary while the actual data is stored as a private attribute in the instance dictionary. The descriptor’s `__get__()` and `__set__()` methods are triggered when the public attribute is accessed.

In the following example, *age* is the public attribute and _*age* is the private attribute. When the public attribute is accessed, the descriptor logs the lookup or update:

```
import logging

logging.basicConfig(level=logging.INFO)

class LoggedAgeAccess:

    def __get__(self, obj, objtype=None):
        value = obj._age
        logging.info('Accessing %r giving %r', 'age', value)
        return value

    def __set__(self, obj, value):
        logging.info('Updating %r to %r', 'age', value)
        obj._age = value

class Person:

    age = LoggedAgeAccess()             # Descriptor instance

    def __init__(self, name, age):
        self.name = name                # Regular instance
attribute
        self.age = age                  # Calls __set__()

    def birthday(self):
        self.age += 1                   # Calls both __get__()
and __set__()
```

An interactive session shows that all access to the managed attribute *age* is logged, but that the regular attribute *name* is not logged:

```
>>> mary = Person('Mary M', 30)         # The initial age
update is logged
INFO:root:Updating 'age' to 30
>>> dave = Person('David D', 40)
INFO:root:Updating 'age' to 40

>>> vars(mary)                          # The actual data is in
a private attribute
{'name': 'Mary M', '_age': 30}
>>> vars(dave)
{'name': 'David D', '_age': 40}

>>> mary.age                            # Access the data and
log the lookup
INFO:root:Accessing 'age' giving 30
30
>>> mary.birthday()                     # Updates are logged as
well
INFO:root:Accessing 'age' giving 30
INFO:root:Updating 'age' to 31

>>> dave.name                           # Regular attribute
lookup isn't logged
'David D'
>>> dave.age                            # Only the managed
attribute is logged
INFO:root:Accessing 'age' giving 40
40
```

One major issue with this example is that the private name *_age* is hardwired in the *LoggedAgeAccess* class. That means that each instance can only have one logged attribute and that its name is unchangeable. In the next example, we’ll fix that problem.

Customized names

When a class uses descriptors, it can inform each descriptor about which variable name was used.

In this example, the **`Person`** class has two descriptor instances, *name* and *age*. When the **`Person`** class is defined, it makes a callback to `__set_name__()` in *LoggedAccess* so that the field names can be recorded, giving each descriptor its own *public_name* and *private_name*:

```
import logging

logging.basicConfig(level=logging.INFO)

class LoggedAccess:

    def __set_name__(self, owner, name):
        self.public_name = name
        self.private_name = '_' + name

    def __get__(self, obj, objtype=None):
        value = getattr(obj, self.private_name)
        logging.info('Accessing %r giving %r',
self.public_name, value)
        return value

    def __set__(self, obj, value):
        logging.info('Updating %r to %r', self.public_name,
value)
        setattr(obj, self.private_name, value)

class Person:

    name = LoggedAccess()                # First descriptor
instance
    age = LoggedAccess()                 # Second descriptor
instance

    def __init__(self, name, age):
        self.name = name                 # Calls the first
descriptor
        self.age = age                   # Calls the second
```

```
descriptor

    def birthday(self):
        self.age += 1
```

An interactive session shows that the **`Person`** class has called **`__set_name__()`** so that the field names would be recorded. Here we call **`vars()`** to look up the descriptor without triggering it:

```
>>> vars(vars(Person)['name'])
{'public_name': 'name', 'private_name': '_name'}
>>> vars(vars(Person)['age'])
{'public_name': 'age', 'private_name': '_age'}
```

The new class now logs access to both *name* and *age*:

```
>>> pete = Person('Peter P', 10)
INFO:root:Updating 'name' to 'Peter P'
INFO:root:Updating 'age' to 10
>>> kate = Person('Catherine C', 20)
INFO:root:Updating 'name' to 'Catherine C'
INFO:root:Updating 'age' to 20
```

The two *Person* instances contain only the private names:

```
>>> vars(pete)
{'_name': 'Peter P', '_age': 10}
>>> vars(kate)
{'_name': 'Catherine C', '_age': 20}
```

Closing thoughts

A descriptor is what we call any object that defines **`__get__()`**, **`__set__()`**, or **`__delete__()`**.

Optionally, descriptors can have a **`__set_name__()`** method. This is only used in cases where a descriptor needs to know either the class where it was created or the name of class variable it was assigned to. (This method, if present, is called even if the class is not a descriptor.)

Descriptors get invoked by the dot operator during attribute lookup. If a descriptor is accessed indirectly with `vars(some_class)[descriptor_name]`, the descriptor instance is returned without invoking it.

Descriptors only work when used as class variables. When put in instances, they have no effect.

The main motivation for descriptors is to provide a hook allowing objects stored in class variables to control what happens during attribute lookup.

Traditionally, the calling class controls what happens during lookup. Descriptors invert that relationship and allow the data being looked-up to have a say in the matter.

Descriptors are used throughout the language. It is how functions turn into bound methods. Common tools like `classmethod()`, `staticmethod()`, `property()`, and `functools.cached_property()` are all implemented as descriptors.

Complete Practical Example

In this example, we create a practical and powerful tool for locating notoriously hard to find data corruption bugs.

Validator class

A validator is a descriptor for managed attribute access. Prior to storing any data, it verifies that the new value meets various type and range restrictions. If those restrictions aren’t met, it raises an exception to prevent data corruption at its source.

This **`Validator`** class is both an abstract base class and a managed attribute descriptor:

```
from abc import ABC, abstractmethod

class Validator(ABC):

    def __set_name__(self, owner, name):
        self.private_name = '_' + name

    def __get__(self, obj, objtype=None):
        return getattr(obj, self.private_name)

    def __set__(self, obj, value):
        self.validate(value)
        setattr(obj, self.private_name, value)

    @abstractmethod
    def validate(self, value):
        pass
```

Custom validators need to inherit from **`Validator`** and must supply a **`validate()`** method to test various restrictions as needed.

Custom validators

Here are three practical data validation utilities:

1. **`OneOf`** verifies that a value is one of a restricted set of options.
2. **`Number`** verifies that a value is either an **`int`** or **`float`**. Optionally, it verifies that a value is between a given minimum or maximum.
3. **`String`** verifies that a value is a **`str`**. Optionally, it validates a given minimum or maximum length. It can

validate a user-defined predicate [https://en.wikipedia.org/wiki/Predicate_(mathematical_logic)] as well.

```
class OneOf(Validator):

    def __init__(self, *options):
        self.options = set(options)

    def validate(self, value):
        if value not in self.options:
            raise ValueError(
                f'Expected {value!r} to be one of
{self.options!r}'
            )

class Number(Validator):

    def __init__(self, minvalue=None, maxvalue=None):
        self.minvalue = minvalue
        self.maxvalue = maxvalue

    def validate(self, value):
        if not isinstance(value, (int, float)):
            raise TypeError(f'Expected {value!r} to be an int
or float')
        if self.minvalue is not None and value < self.minvalue:
            raise ValueError(
                f'Expected {value!r} to be at least
{self.minvalue!r}'
            )
        if self.maxvalue is not None and value > self.maxvalue:
            raise ValueError(
                f'Expected {value!r} to be no more than
{self.maxvalue!r}'
            )

class String(Validator):

    def __init__(self, minsize=None, maxsize=None,
predicate=None):
        self.minsize = minsize
        self.maxsize = maxsize
        self.predicate = predicate

    def validate(self, value):
        if not isinstance(value, str):
            raise TypeError(f'Expected {value!r} to be a str')
        if self.minsize is not None and len(value) <
self.minsize:
            raise ValueError(
                f'Expected {value!r} to be no smaller than
{self.minsize!r}'
            )
        if self.maxsize is not None and len(value) >
self.maxsize:
            raise ValueError(
                f'Expected {value!r} to be no bigger than
{self.maxsize!r}'
            )
        if self.predicate is not None and not
self.predicate(value):
            raise ValueError(
                f'Expected {self.predicate} to be true for
{value!r}'
            )
```

Practical application

Here’s how the data validators can be used in a real class:

```
class Component:

    name = String(minsize=3, maxsize=10, predicate=str.isupper)
    kind = OneOf('wood', 'metal', 'plastic')
    quantity = Number(minvalue=0)

    def __init__(self, name, kind, quantity):
        self.name = name
        self.kind = kind
        self.quantity = quantity
```

The descriptors prevent invalid instances from being created:

```
>>> Component('Widget', 'metal', 5)      # Blocked: 'Widget' is
not all uppercase
Traceback (most recent call last):
    ...
ValueError: Expected <method 'isupper' of 'str' objects> to be
true for 'Widget'

>>> Component('WIDGET', 'metle', 5)      # Blocked: 'metle' is
misspelled
Traceback (most recent call last):
    ...
ValueError: Expected 'metle' to be one of {'metal', 'plastic',
'wood'}

>>> Component('WIDGET', 'metal', -5)     # Blocked: -5 is
negative
Traceback (most recent call last):
    ...
ValueError: Expected -5 to be at least 0

>>> Component('WIDGET', 'metal', 'V')    # Blocked: 'V' isn't a
number
Traceback (most recent call last):
    ...
TypeError: Expected 'V' to be an int or float

>>> c = Component('WIDGET', 'metal', 5)  # Allowed:  The inputs
are valid
```

Technical Tutorial

What follows is a more technical tutorial for the mechanics and details of how descriptors work.

Abstract

Defines descriptors, summarizes the protocol, and shows how descriptors are called. Provides an example showing how object relational mappings work.

Learning about descriptors not only provides access to a larger toolset, it creates a deeper understanding of how Python works.

Definition and introduction

In general, a descriptor is an attribute value that has one of the methods in the descriptor protocol. Those methods are `__get__()`, `__set__()`, and `__delete__()`. If any of those methods are defined for an attribute, it is said to be a descriptor.

The default behavior for attribute access is to get, set, or delete the attribute from an object's dictionary. For instance, `a.x` has a lookup chain starting with `a.__dict__['x']`, then `type(a).__dict__['x']`, and continuing through the method resolution order of `type(a)`. If the looked-up value is an object defining one of the descriptor methods, then Python may override the default behavior and invoke the descriptor method instead. Where this occurs in the precedence chain depends on which descriptor methods were defined.

Descriptors are a powerful, general purpose protocol. They are the mechanism behind properties, methods, static methods, class methods, and `super()`. They are used throughout Python itself. Descriptors simplify the underlying C code and offer a flexible set of new tools for everyday Python programs.

Descriptor protocol

```
descr.__get__(self, obj, type=None)
```

```
descr.__set__(self, obj, value)
```

```
descr.__delete__(self, obj)
```

That is all there is to it. Define any of these methods and an object is considered a descriptor and can override default behavior upon being looked up as an attribute.

If an object defines `__set__()` or `__delete__()`, it is considered a data descriptor. Descriptors that only define `__get__()` are called non-data descriptors (they are often used for methods but other uses are possible).

Data and non-data descriptors differ in how overrides are calculated with respect to entries in an instance's dictionary. If an instance's dictionary has an entry with the same name as a data descriptor, the data descriptor takes precedence. If an instance's dictionary has an entry with the same name as a non-data descriptor, the dictionary entry takes precedence.

To make a read-only data descriptor, define both `__get__()` and `__set__()` with the `__set__()` raising an `AttributeError` when called. Defining the `__set__()` method with an exception raising placeholder is enough to make it a data descriptor.

Overview of descriptor invocation

A descriptor can be called directly with `desc.__get__(obj)` or `desc.__get__(None, cls)`.

But it is more common for a descriptor to be invoked automatically from attribute access.

The expression `obj.x` looks up the attribute `x` in the chain of namespaces for `obj`. If the search finds a descriptor outside of the instance `__dict__`, its `__get__()` method is invoked according to the precedence rules listed below.

The details of invocation depend on whether `obj` is an object, class, or instance of super.

Invocation from an instance

Instance lookup scans through a chain of namespaces giving data descriptors the highest priority, followed by instance variables, then non-data descriptors, then class variables, and lastly `__getattr__()` if it is provided.

If a descriptor is found for `a.x`, then it is invoked with: `desc.__get__(a, type(a))`.

The logic for a dotted lookup is in `object.__getattribute__()`. Here is a pure Python equivalent:

```
def find_name_in_mro(cls, name, default):
    "Emulate _PyType_Lookup() in Objects/typeobject.c"
    for base in cls.__mro__:
        if name in vars(base):
            return vars(base)[name]
    return default

def object_getattribute(obj, name):
    "Emulate PyObject_GenericGetAttr() in Objects/object.c"
    null = object()
    objtype = type(obj)
    cls_var = find_name_in_mro(objtype, name, null)
    descr_get = getattr(type(cls_var), '__get__', null)
    if descr_get is not null:
        if (hasattr(type(cls_var), '__set__')
            or hasattr(type(cls_var), '__delete__')):
            return descr_get(cls_var, obj, objtype)     # data
descriptor
    if hasattr(obj, '__dict__') and name in vars(obj):
        return vars(obj)[name]                          #
instance variable
    if descr_get is not null:
        return descr_get(cls_var, obj, objtype)         # non-
data descriptor
```

```
    if cls_var is not null:
        return cls_var                                   # class
variable
    raise AttributeError(name)
```

Note, there is no `__getattr__()` hook in the `__getattribute__()` code. That is why calling `__getattribute__()` directly or with `super().__getattribute__` will bypass `__getattr__()` entirely.

Instead, it is the dot operator and the `getattr()` function that are responsible for invoking `__getattr__()` whenever `__getattribute__()` raises an `AttributeError`. Their logic is encapsulated in a helper function:

```
def getattr_hook(obj, name):
    "Emulate slot_tp_getattr_hook() in Objects/typeobject.c"
    try:
        return obj.__getattribute__(name)
    except AttributeError:
        if not hasattr(type(obj), '__getattr__'):
            raise
    return type(obj).__getattr__(obj, name)             #
__getattr__
```

Invocation from a class

The logic for a dotted lookup such as `A.x` is in **`type.__getattribute__()`**. The steps are similar to those for **`object.__getattribute__()`** but the instance dictionary lookup is replaced by a search through the class’s method resolution order.

If a descriptor is found, it is invoked with `desc.__get__(None, A)`.

The full C implementation can be found in **`type_getattro()`** and **`_PyType_Lookup()`** in Objects/typeobject.c [https://github.com/python/cpython/tree/3.14/Objects/typeobject.c].

Invocation from super

The logic for super’s dotted lookup is in the `__getattribute__()` method for object returned by `super()`.

A dotted lookup such as `super(A, obj).m` searches `obj.__class__.__mro__` for the base class `B` immediately following `A` and then returns `B.__dict__['m'].__get__(obj, A)`. If not a descriptor, `m` is returned unchanged.

The full C implementation can be found in **`super_getattro()`** in Objects/typeobject.c [https://github.com/python/cpython/tree/3.14/Objects/typeobject.c]. A pure Python equivalent can be found in Guido’s Tutorial [https://www.python.org/download/releases/2.2.3/descrintro/#cooperation].

Summary of invocation logic

The mechanism for descriptors is embedded in the `__getattribute__()` methods for `object`, `type`, and `super()`.

The important points to remember are:

- Descriptors are invoked by the `__getattribute__()` method.
- Classes inherit this machinery from `object`, `type`, or `super()`.
- Overriding `__getattribute__()` prevents automatic descriptor calls because all the descriptor logic is in that method.
- **`object.__getattribute__()`** and **`type.__getattribute__()`** make different calls to `__get__()`. The first includes the instance and may include the class. The second puts in `None` for the instance and always includes the class.
- Data descriptors always override instance dictionaries.

- Non-data descriptors may be overridden by instance dictionaries.

Automatic name notification

Sometimes it is desirable for a descriptor to know what class variable name it was assigned to. When a new class is created, the `type` metaclass scans the dictionary of the new class. If any of the entries are descriptors and if they define `__set_name__()`, that method is called with two arguments. The *owner* is the class where the descriptor is used, and the *name* is the class variable the descriptor was assigned to.

The implementation details are in **`type_new()`** and **`set_names()`** in Objects/typeobject.c [https://github.com/python/cpython/tree/3.14/Objects/typeobject.c].

Since the update logic is in **`type.__new__()`**, notifications only take place at the time of class creation. If descriptors are added to the class afterwards, `__set_name__()` will need to be called manually.

ORM example

The following code is a simplified skeleton showing how data descriptors could be used to implement an object relational mapping [https://en.wikipedia.org/wiki/Object%E2%80%93relational_mapping].

The essential idea is that the data is stored in an external database. The Python instances only hold keys to the database’s tables. Descriptors take care of lookups or updates:

```
class Field:

    def __set_name__(self, owner, name):
        self.fetch = f'SELECT {name} FROM {owner.table} WHERE
{owner.key}=?;'
        self.store = f'UPDATE {owner.table} SET {name}=? WHERE
{owner.key}=?;'

    def __get__(self, obj, objtype=None):
        return conn.execute(self.fetch, [obj.key]).fetchone()
[0]

    def __set__(self, obj, value):
        conn.execute(self.store, [value, obj.key])
        conn.commit()
```

We can use the **`Field`** class to define models [https://en.wikipedia.org/wiki/Database_model] that describe the schema for each table in a database:

```
class Movie:
    table = 'Movies'                    # Table name
    key = 'title'                       # Primary key
    director = Field()
    year = Field()

    def __init__(self, key):
        self.key = key

class Song:
    table = 'Music'
    key = 'title'
    artist = Field()
    year = Field()
    genre = Field()

    def __init__(self, key):
        self.key = key
```

To use the models, first connect to the database:

```
>>> import sqlite3
>>> conn = sqlite3.connect('entertainment.db')
```

An interactive session shows how data is retrieved from the database and how it can be updated:

```
>>> Movie('Star Wars').director
'George Lucas'
>>> jaws = Movie('Jaws')
>>> f'Released in {jaws.year} by {jaws.director}'
'Released in 1975 by Steven Spielberg'

>>> Song('Country Roads').artist
'John Denver'

>>> Movie('Star Wars').director = 'J.J. Abrams'
>>> Movie('Star Wars').director
'J.J. Abrams'
```

Pure Python Equivalents

The descriptor protocol is simple and offers exciting possibilities. Several use cases are so common that they have been prepackaged into built-in tools. Properties, bound methods, static methods, class methods, and __slots__ are all based on the descriptor protocol.

Properties

Calling `property()` is a succinct way of building a data descriptor that triggers a function call upon access to an attribute. Its signature is:

```
property(fget=None, fset=None, fdel=None, doc=None) -> property
```

The documentation shows a typical use to define a managed attribute `x`:

```
class C:
    def getx(self): return self.__x
    def setx(self, value): self.__x = value
    def delx(self): del self.__x
    x = property(getx, setx, delx, "I'm the 'x' property.")
```

To see how `property()` is implemented in terms of the descriptor protocol, here is a pure Python equivalent that implements most of the core functionality:

```
class Property:
    "Emulate PyProperty_Type() in Objects/descrobject.c"

    def __init__(self, fget=None, fset=None, fdel=None,
doc=None):
        self.fget = fget
        self.fset = fset
        self.fdel = fdel
        if doc is None and fget is not None:
            doc = fget.__doc__
        self.__doc__ = doc

    def __set_name__(self, owner, name):
        self.__name__ = name

    def __get__(self, obj, objtype=None):
        if obj is None:
            return self
        if self.fget is None:
            raise AttributeError
        return self.fget(obj)

    def __set__(self, obj, value):
        if self.fset is None:
            raise AttributeError
        self.fset(obj, value)

    def __delete__(self, obj):
        if self.fdel is None:
            raise AttributeError
        self.fdel(obj)

    def getter(self, fget):
        return type(self)(fget, self.fset, self.fdel,
self.__doc__)
```

```
    def setter(self, fset):
        return type(self)(self.fget, fset, self.fdel,
self.__doc__)

    def deleter(self, fdel):
        return type(self)(self.fget, self.fset, fdel,
self.__doc__)
```

The `property()` builtin helps whenever a user interface has granted attribute access and then subsequent changes require the intervention of a method.

For instance, a spreadsheet class may grant access to a cell value through `Cell('b10').value`. Subsequent improvements to the program require the cell to be recalculated on every access; however, the programmer does not want to affect existing client code accessing the attribute directly. The solution is to wrap access to the value attribute in a property data descriptor:

```
class Cell:
    ...

    @property
    def value(self):
        "Recalculate the cell before returning value"
        self.recalc()
        return self._value
```

Either the built-in `property()` or our **`Property()`** equivalent would work in this example.

Functions and methods

Python’s object oriented features are built upon a function based environment. Using non-data descriptors, the two are merged seamlessly.

Functions stored in class dictionaries get turned into methods when invoked. Methods only differ from regular functions in that the object instance is prepended to the other arguments. By convention, the instance is called *self* but could be called *this* or any other variable name.

Methods can be created manually with `types.MethodType` which is roughly equivalent to:

```
class MethodType:
    "Emulate PyMethod_Type in Objects/classobject.c"

    def __init__(self, func, obj):
        self.__func__ = func
        self.__self__ = obj

    def __call__(self, *args, **kwargs):
        func = self.__func__
        obj = self.__self__
        return func(obj, *args, **kwargs)

    def __getattribute__(self, name):
        "Emulate method_getset() in Objects/classobject.c"
        if name == '__doc__':
            return self.__func__.__doc__
        return object.__getattribute__(self, name)

    def __getattr__(self, name):
        "Emulate method_getattro() in Objects/classobject.c"
        return getattr(self.__func__, name)

    def __get__(self, obj, objtype=None):
        "Emulate method_descr_get() in Objects/classobject.c"
        return self
```

To support automatic creation of methods, functions include the `__get__()` method for binding methods during attribute access. This means that functions are non-data descriptors that return bound methods during dotted lookup from an instance. Here’s how it works:

```
class Function:
    ...

    def __get__(self, obj, objtype=None):
        "Simulate func_descr_get() in Objects/funcobject.c"
        if obj is None:
            return self
        return MethodType(self, obj)
```

Running the following class in the interpreter shows how the function descriptor works in practice:

```
class D:
    def f(self):
         return self

class D2:
    pass
```

The function has a qualified name attribute to support introspection:

```
>>> D.f.__qualname__
'D.f'
```

Accessing the function through the class dictionary does not invoke **`__get__()`**. Instead, it just returns the underlying function object:

```
>>> D.__dict__['f']
<function D.f at 0x00C45070>
```

Dotted access from a class calls **`__get__()`** which just returns the underlying function unchanged:

```
>>> D.f
<function D.f at 0x00C45070>
```

The interesting behavior occurs during dotted access from an instance. The dotted lookup calls **`__get__()`** which returns a bound method object:

```
>>> d = D()
>>> d.f
<bound method D.f of <__main__.D object at 0x00B18C90>>
```

Internally, the bound method stores the underlying function and the bound instance:

```
>>> d.f.__func__
<function D.f at 0x00C45070>

>>> d.f.__self__
<__main__.D object at 0x00B18C90>
```

If you have ever wondered where *self* comes from in regular methods or where *cls* comes from in class methods, this is it!

Kinds of methods

Non-data descriptors provide a simple mechanism for variations on the usual patterns of binding functions into methods.

To recap, functions have a `__get__()` method so that they can be converted to a method when accessed as attributes. The non-data descriptor transforms an `obj.f(*args)` call into `f(obj, *args)`. Calling `cls.f(*args)` becomes `f(*args)`.

This chart summarizes the binding and its two most useful variants:

Transformation	Called from an object	Called from a class
function	f(obj, *args)	f(*args)
staticmethod	f(*args)	f(*args)
classmethod	f(type(obj), *args)	f(cls, *args)

Static methods

Static methods return the underlying function without changes. Calling either `c.f` or `C.f` is the equivalent of a direct lookup into `object.__getattribute__(c, "f")` or `object.__getattribute__(C, "f")`. As a result, the function becomes identically accessible from either an object or a class.

Good candidates for static methods are methods that do not reference the `self` variable.

For instance, a statistics package may include a container class for experimental data. The class provides normal methods for computing the average, mean, median, and other descriptive statistics that depend on the data. However, there may be useful functions which are conceptually related but do not depend on the data. For instance, `erf(x)` is handy conversion routine that comes up in statistical work but does not directly depend on a particular dataset. It can be called either from an object or the class: `s.erf(1.5) --> 0.9332` or `Sample.erf(1.5) --> 0.9332`.

Since static methods return the underlying function with no changes, the example calls are unexciting:

```
class E:
    @staticmethod
    def f(x):
        return x * 10
```

```
>>> E.f(3)
30
>>> E().f(3)
30
```

Using the non-data descriptor protocol, a pure Python version of `staticmethod()` would look like this:

```
import functools

class StaticMethod:
    "Emulate PyStaticMethod_Type() in Objects/funcobject.c"

    def __init__(self, f):
        self.f = f
        functools.update_wrapper(self, f)

    def __get__(self, obj, objtype=None):
        return self.f

    def __call__(self, *args, **kwds):
        return self.f(*args, **kwds)

    @property
    def __annotations__(self):
        return self.f.__annotations__
```

The `functools.update_wrapper()` call adds a `__wrapped__` attribute that refers to the underlying function. Also it carries forward the attributes necessary to make the wrapper look like the wrapped function, including `__name__`, `__qualname__`, and `__doc__`.

Class methods

Unlike static methods, class methods prepend the class reference to the argument list before calling the function. This format is the same for whether the caller is an object or a class:

```
class F:
    @classmethod
    def f(cls, x):
        return cls.__name__, x
```

```
>>> F.f(3)
('F', 3)
>>> F().f(3)
('F', 3)
```

This behavior is useful whenever the method only needs to have a class reference and does not rely on data stored in a specific instance. One use for class methods is to create alternate class constructors. For example, the classmethod `dict.fromkeys()` creates a new dictionary from a list of keys. The pure Python equivalent is:

```
class Dict(dict):
    @classmethod
    def fromkeys(cls, iterable, value=None):
        "Emulate dict_fromkeys() in Objects/dictobject.c"
        d = cls()
        for key in iterable:
            d[key] = value
        return d
```

Now a new dictionary of unique keys can be constructed like this:

```
>>> d = Dict.fromkeys('abracadabra')
>>> type(d) is Dict
True
```

```
>>> d
{'a': None, 'b': None, 'r': None, 'c': None, 'd': None}
```

Using the non-data descriptor protocol, a pure Python version of `classmethod()` would look like this:

```
import functools

class ClassMethod:
    "Emulate PyClassMethod_Type() in Objects/funcobject.c"

    def __init__(self, f):
        self.f = f
        functools.update_wrapper(self, f)

    def __get__(self, obj, cls=None):
        if cls is None:
            cls = type(obj)
        return MethodType(self.f, cls)
```

The `functools.update_wrapper()` call in `ClassMethod` adds a `__wrapped__` attribute that refers to the underlying function. Also it carries forward the attributes necessary to make the wrapper look like the wrapped function: `__name__`, `__qualname__`, `__doc__`, and `__annotations__`.

Member objects and __slots__

When a class defines `__slots__`, it replaces instance dictionaries with a fixed-length array of slot values. From a user point of view that has several effects:

1. Provides immediate detection of bugs due to misspelled attribute assignments. Only attribute names specified in `__slots__` are allowed:

```
class Vehicle:
    __slots__ = ('id_number', 'make', 'model')
```

```
>>> auto = Vehicle()
>>> auto.id_nubmer = 'VYE483814LQEX'
Traceback (most recent call last):
    ...
AttributeError: 'Vehicle' object has no attribute 'id_nubmer'
```

2. Helps create immutable objects where descriptors manage access to private attributes stored in `__slots__`:

```
class Immutable:

    __slots__ = ('_dept', '_name')          # Replace the
instance dictionary

    def __init__(self, dept, name):
        self._dept = dept                   # Store to private
attribute
        self._name = name                   # Store to private
attribute

    @property                               # Read-only
descriptor
    def dept(self):
        return self._dept

    @property
    def name(self):                         # Read-only
descriptor
        return self._name
```

```
>>> mark = Immutable('Botany', 'Mark Watney')
>>> mark.dept
'Botany'
>>> mark.dept = 'Space Pirate'
Traceback (most recent call last):
    ...
AttributeError: property 'dept' of 'Immutable' object has no
setter
>>> mark.location = 'Mars'
Traceback (most recent call last):
    ...
AttributeError: 'Immutable' object has no attribute 'location'
```

3. Saves memory. On a 64-bit Linux build, an instance with two attributes takes 48 bytes with `__slots__` and 152 bytes without. This flyweight design pattern [https://en.wikipedia.org/wiki/Flyweight_pattern] likely only matters when a large number of instances are going to be created.

4. Improves speed. Reading instance variables is 35% faster with `__slots__` (as measured with Python 3.10 on an Apple M1 processor).

5. Blocks tools like **`functools.cached_property()`** which require an instance dictionary to function correctly:

```
from functools import cached_property

class CP:
    __slots__ = ()                          # Eliminates the
instance dict

    @cached_property                        # Requires an
instance dict
    def pi(self):
        return 4 * sum((-1.0)**n / (2.0*n + 1.0)
                       for n in reversed(range(100_000)))

>>> CP().pi
Traceback (most recent call last):
  ...
TypeError: No '__dict__' attribute on 'CP' instance to cache
'pi' property.
```

It is not possible to create an exact drop-in pure Python version of `__slots__` because it requires direct access to C structures and control over object memory allocation. However, we can build a mostly faithful simulation where the actual C structure for slots is emulated by a private `_slotvalues` list. Reads and writes to that private structure are managed by member descriptors:

```
null = object()

class Member:

    def __init__(self, name, clsname, offset):
        'Emulate PyMemberDef in Include/structmember.h'
        # Also see descr_new() in Objects/descrobject.c
        self.name = name
        self.clsname = clsname
        self.offset = offset

    def __get__(self, obj, objtype=None):
        'Emulate member_get() in Objects/descrobject.c'
        # Also see PyMember_GetOne() in Python/structmember.c
        if obj is None:
            return self
        value = obj._slotvalues[self.offset]
        if value is null:
            raise AttributeError(self.name)
        return value

    def __set__(self, obj, value):
        'Emulate member_set() in Objects/descrobject.c'
        obj._slotvalues[self.offset] = value

    def __delete__(self, obj):
        'Emulate member_delete() in Objects/descrobject.c'
        value = obj._slotvalues[self.offset]
        if value is null:
            raise AttributeError(self.name)
        obj._slotvalues[self.offset] = null

    def __repr__(self):
        'Emulate member_repr() in Objects/descrobject.c'
        return f'<Member {self.name!r} of {self.clsname!r}>'
```

The **`type.__new__()`** method takes care of adding member objects to class variables:

```
class Type(type):
    'Simulate how the type metaclass adds member objects for 
slots'
```

```
    def __new__(mcls, clsname, bases, mapping, **kwargs):
        'Emulate type_new() in Objects/typeobject.c'
        # type_new() calls PyTypeReady() which calls
add_methods()
        slot_names = mapping.get('slot_names', [])
        for offset, name in enumerate(slot_names):
            mapping[name] = Member(name, clsname, offset)
        return type.__new__(mcls, clsname, bases, mapping,
**kwargs)
```

The `object.__new__()` method takes care of creating instances that have slots instead of an instance dictionary. Here is a rough simulation in pure Python:

```
class Object:
    'Simulate how object.__new__() allocates memory for
__slots__'

    def __new__(cls, *args, **kwargs):
        'Emulate object_new() in Objects/typeobject.c'
        inst = super().__new__(cls)
        if hasattr(cls, 'slot_names'):
            empty_slots = [null] * len(cls.slot_names)
            object.__setattr__(inst, '_slotvalues',
empty_slots)
        return inst

    def __setattr__(self, name, value):
        'Emulate _PyObject_GenericSetAttrWithDict()
Objects/object.c'
        cls = type(self)
        if hasattr(cls, 'slot_names') and name not in
cls.slot_names:
            raise AttributeError(
                f'{cls.__name__!r} object has no attribute
{name!r}'
            )
        super().__setattr__(name, value)

    def __delattr__(self, name):
        'Emulate _PyObject_GenericSetAttrWithDict()
```

```
Objects/object.c'
        cls = type(self)
        if hasattr(cls, 'slot_names') and name not in
cls.slot_names:
            raise AttributeError(
                f'{cls.__name__!r} object has no attribute
{name!r}'
            )
        super().__delattr__(name)
```

To use the simulation in a real class, just inherit from **`Object`** and set the metaclass to **`Type`**:

```
class H(Object, metaclass=Type):
    'Instance variables stored in slots'

    slot_names = ['x', 'y']

    def __init__(self, x, y):
        self.x = x
        self.y = y
```

At this point, the metaclass has loaded member objects for *x* and *y*:

```
>>> from pprint import pp
>>> pp(dict(vars(H)))
{'__module__': '__main__',
 '__doc__': 'Instance variables stored in slots',
 'slot_names': ['x', 'y'],
 '__init__': <function H.__init__ at 0x7fb5d302f9d0>,
 'x': <Member 'x' of 'H'>,
 'y': <Member 'y' of 'H'>}
```

When instances are created, they have a `slot_values` list where the attributes are stored:

```
>>> h = H(10, 20)
>>> vars(h)
{'_slotvalues': [10, 20]}
>>> h.x = 55
>>> vars(h)
{'_slotvalues': [55, 20]}
```

Misspelled or unassigned attributes will raise an exception:

```
>>> h.xz
Traceback (most recent call last):
    ...
AttributeError: 'H' object has no attribute 'xz'
```

Debugging C API extensions and CPython Internals with GDB

This document explains how the Python GDB extension, `python-gdb.py`, can be used with the GDB debugger to debug CPython extensions and the CPython interpreter itself.

When debugging low-level problems such as crashes or deadlocks, a low-level debugger, such as GDB, is useful to diagnose and correct the issue. By default, GDB (or any of its front-ends) doesn’t support high-level information specific to the CPython interpreter.

The `python-gdb.py` extension adds CPython interpreter information to GDB. The extension helps introspect the stack of currently executing Python functions. Given a Python object represented by a PyObject* pointer, the extension surfaces the type and value of the object.

Developers who are working on CPython extensions or tinkering with parts of CPython that are written in C can use this document to learn how to use the `python-gdb.py` extension with GDB.

Note

This document assumes that you are familiar with the basics of GDB and the CPython C API. It consolidates guidance from the devguide [https://devguide.python.org] and the Python wiki [https://wiki.python.org/moin/DebuggingWithGdb].

Prerequisites

You need to have:

- GDB 7 or later. (For earlier versions of GDB, see `Misc/gdbinit` in the sources of Python 3.11 or earlier.)
- GDB-compatible debugging information for Python and any extension you are debugging.
- The `python-gdb.py` extension.

The extension is built with Python, but might be distributed separately or not at all. Below, we include tips for a few common systems as examples. Note that even if the instructions match your system, they might be outdated.

Setup with Python built from source

When you build CPython from source, debugging information should be available, and the build should add a `python-gdb.py` file to the root directory of your repository.

To activate support, you must add the directory containing `python-gdb.py` to GDB’s “auto-load-safe-path”. If you haven’t done this, recent versions of GDB will print out a warning with instructions on how to do this.

Note

If you do not see instructions for your version of GDB, put this in your configuration file (`~/.gdbinit` or `~/.config/gdb/gdbinit`):

```
add-auto-load-safe-path /path/to/cpython
```

You can also add multiple paths, separated by `:`.

Setup for Python from a Linux distro

Most Linux systems provide debug information for the system Python in a package called `python-debuginfo`, `python-dbg` or similar. For example:

- Fedora:

  ```
  sudo dnf install gdb
  sudo dnf debuginfo-install python3
  ```

- Ubuntu:

  ```
  sudo apt install gdb python3-dbg
  ```

On several recent Linux systems, GDB can download debugging symbols automatically using *debuginfod*. However, this will not install the `python-gdb.py` extension; you generally do need to install the debug info package separately.

Using the Debug build and Development mode

For easier debugging, you might want to:

- Use a debug build of Python. (When building from source, use `configure --with-pydebug`. On Linux distros, install and run a package like `python-debug` or `python-dbg`, if available.)
- Use the runtime development mode (`-X dev`).

Both enable extra assertions and disable some optimizations. Sometimes this hides the bug you are trying to find, but in most cases they make the process easier.

Using the `python-gdb` extension

When the extension is loaded, it provides two main features: pretty printers for Python values, and additional commands.

Pretty-printers

This is what a GDB backtrace looks like (truncated) when this extension is enabled:

```
#0  0x000000000041a6b1 in PyObject_Malloc (nbytes=Cannot access
memory at address 0x7fffff7fefe8
) at Objects/obmalloc.c:748
#1  0x000000000041b7c0 in _PyObject_DebugMallocApi (id=111 'o',
nbytes=24) at Objects/obmalloc.c:1445
#2  0x000000000041b717 in _PyObject_DebugMalloc (nbytes=24) at
Objects/obmalloc.c:1412
#3  0x000000000044060a in _PyUnicode_New (length=11) at
Objects/unicodeobject.c:346
#4  0x00000000004466aa in PyUnicodeUCS2_DecodeUTF8Stateful
(s=0x5c2b8d "__lltrace__", size=11, errors=0x0, consumed=
    0x0) at Objects/unicodeobject.c:2531
#5  0x0000000000446647 in PyUnicodeUCS2_DecodeUTF8 (s=0x5c2b8d
"__lltrace__", size=11, errors=0x0)
    at Objects/unicodeobject.c:2495
#6  0x0000000000440d1b in PyUnicodeUCS2_FromStringAndSize
(u=0x5c2b8d "__lltrace__", size=11)
    at Objects/unicodeobject.c:551
#7  0x0000000000440d94 in PyUnicodeUCS2_FromString (u=0x5c2b8d
"__lltrace__") at Objects/unicodeobject.c:569
#8  0x0000000000584abd in PyDict_GetItemString (v=
    {'Yuck': <type at remote 0xad4730>, '__builtins__': <module
at remote 0x7ffff7fd5ee8>, '__file__':
'Lib/test/crashers/nasty_eq_vs_dict.py', '__package__': None,
'y': <Yuck(i=0) at remote 0xaacd80>, 'dict': {0: 0, 1: 1, 2: 2,
3: 3}, '__cached__': None, '__name__': '__main__', 'z':
<Yuck(i=0) at remote 0xaace60>, '__doc__': None}, key=
    0x5c2b8d "__lltrace__") at Objects/dictobject.c:2171
```

Notice how the dictionary argument to `PyDict_GetItemString` is displayed as its `repr()`, rather than an opaque `PyObject *` pointer.

The extension works by supplying a custom printing routine for values of type `PyObject *`. If you need to access lower-level details of an object, then cast the value to a pointer of the appropriate type. For example:

```
(gdb) p globals
$1 = {'__builtins__': <module at remote 0x7ffff7fb1868>,
'__name__':
'__main__', 'ctypes': <module at remote 0x7ffff7f14360>,
'__doc__': None,
'__package__': None}

(gdb) p *(PyDictObject*)globals
$2 = {ob_refcnt = 3, ob_type = 0x3dbdf85820, ma_fill = 5,
ma_used = 5,
ma_mask = 7, ma_table = 0x63d0f8, ma_lookup = 0x3dbdc7ea70
<lookdict_string>, ma_smalltable = {{me_hash =
7065186196740147912,
me_key = '__builtins__', me_value = <module at remote
0x7ffff7fb1868>},
{me_hash = -368181376027291943, me_key = '__name__',
me_value ='__main__'}, {me_hash = 0, me_key = 0x0, me_value =
0x0},
{me_hash = 0, me_key = 0x0, me_value = 0x0},
{me_hash = -9177857982131165996, me_key = 'ctypes',
me_value = <module at remote 0x7ffff7f14360>},
{me_hash = -8518757509529533123, me_key = '__doc__', me_value =
None},
{me_hash = 0, me_key = 0x0, me_value = 0x0}, {
  me_hash = 6614918939584953775, me_key = '__package__',
me_value = None}}}
```

Note that the pretty-printers do not actually call `repr()`. For basic types, they try to match its result closely.

An area that can be confusing is that the custom printer for some types look a lot like GDB’s built-in printer for standard types. For example, the pretty-printer for a Python `int` (PyLongObject*) gives a representation that is not distinguishable from one of a regular machine-level integer:

```
(gdb) p some_machine_integer
$3 = 42

(gdb) p some_python_integer
$4 = 42
```

The internal structure can be revealed with a cast to PyLongObject*:

```
(gdb) p *(PyLongObject*)some_python_integer
$5 = {ob_base = {ob_base = {ob_refcnt = 8, ob_type =
0x3dad39f5e0}, ob_size = 1},
ob_digit = {42}}
```

A similar confusion can arise with the `str` type, where the output looks a lot like gdb’s built-in printer for `char *`:

```
(gdb) p ptr_to_python_str
$6 = '__builtins__'
```

The pretty-printer for `str` instances defaults to using single-quotes (as does Python’s `repr` for strings) whereas the standard printer for `char *` values uses double-quotes and contains a hexadecimal address:

```
(gdb) p ptr_to_char_star
$7 = 0x6d72c0 "hello world"
```

Again, the implementation details can be revealed with a cast to PyUnicodeObject*:

```
(gdb) p *(PyUnicodeObject*)$6
$8 = {ob_base = {ob_refcnt = 33, ob_type = 0x3dad3a95a0},
length = 12,
str = 0x7ffff2128500, hash = 7065186196740147912, state = 1,
defenc = 0x0}
```

`py-list`

The extension adds a `py-list` command, which lists the Python source code (if any) for the current frame in the selected thread. The current line is marked with a “>”:

```
(gdb) py-list
 901        if options.profile:
 902            options.profile = False
 903            profile_me()
 904            return
 905
>906        u = UI()
 907        if not u.quit:
 908            try:
 909                gtk.main()
 910            except KeyboardInterrupt:
 911                # properly quit on a keyboard
interrupt...
```

Use `py-list START` to list at a different line number within the Python source, and `py-list START,END` to list a specific range of lines within the Python source.

`py-up` and `py-down`

The `py-up` and `py-down` commands are analogous to GDB’s regular `up` and `down` commands, but try to move at the level of CPython frames, rather than C frames.

GDB is not always able to read the relevant frame information, depending on the optimization level with which CPython was compiled. Internally, the commands look for C frames that are executing the default frame evaluation function (that is, the core bytecode interpreter loop within CPython) and look up the value of the related `PyFrameObject *`.

They emit the frame number (at the C level) within the thread.

For example:

```
(gdb) py-up
#37 Frame 0x9420b04, for file /usr/lib/python2.6/site-
packages/
gnome_sudoku/main.py, line 906, in start_game ()
    u = UI()
(gdb) py-up
#40 Frame 0x948e82c, for file /usr/lib/python2.6/site-
packages/
gnome_sudoku/gnome_sudoku.py, line 22, in start_game(main=
<module at remote 0xb771b7f4>)
    main.start_game()
(gdb) py-up
Unable to find an older python frame
```

so we’re at the top of the Python stack.

The frame numbers correspond to those displayed by GDB’s standard `backtrace` command. The command skips C frames which are not executing Python code.

Going back down:

```
(gdb) py-down
#37 Frame 0x9420b04, for file /usr/lib/python2.6/site-
packages/gnome_sudoku/main.py, line 906, in start_game ()
    u = UI()
(gdb) py-down
#34 (unable to read python frame information)
(gdb) py-down
#23 (unable to read python frame information)
(gdb) py-down
#19 (unable to read python frame information)
(gdb) py-down
#14 Frame 0x99262ac, for file /usr/lib/python2.6/site-
packages/gnome_sudoku/game_selector.py, line 201, in
run_swallowed_dialog (self=
<NewOrSavedGameSelector(new_game_model=<gtk.ListStore at
remote 0x98fab44>, puzzle=None, saved_games=
[{'gsd.auto_fills': 0, 'tracking': {}, 'trackers': {},

0x984b464>}], dialog=<gtk.Dialog at remote 0x98faaa4>,
saved_game_model=<gtk.ListStore at remote 0x98fad24>,
sudoku_maker=<SudokuMaker(terminated=False, played=[],
batch_siz...(truncated)
            swallower.run_dialog(self.dialog)
(gdb) py-down
#11 Frame 0x9aead74, for file /usr/lib/python2.6/site-
packages/gnome_sudoku/dialog_swallower.py, line 48, in
run_dialog (self=<SwappableArea(running=<gtk.Dialog at
remote 0x98faaa4>, main_page=0) at remote 0x98fa6e4>, d=
<gtk.Dialog at remote 0x98faaa4>)
            gtk.main()
(gdb) py-down
#8 (unable to read python frame information)
(gdb) py-down
Unable to find a newer python frame
```

and we’re at the bottom of the Python stack.

Note that in Python 3.12 and newer, the same C stack frame can be used for multiple Python stack frames. This means that `py-up` and `py-down` may move multiple Python frames at once. For example:

```
(gdb) py-up
#6 Frame 0x7ffff7fb62b0, for file /tmp/rec.py, line 5, in
recursive_function (n=0)
   time.sleep(5)
#6 Frame 0x7ffff7fb6240, for file /tmp/rec.py, line 7, in
```

```
recursive_function (n=1)
   recursive_function(n-1)
#6 Frame 0x7ffff7fb61d0, for file /tmp/rec.py, line 7, in
recursive_function (n=2)
   recursive_function(n-1)
#6 Frame 0x7ffff7fb6160, for file /tmp/rec.py, line 7, in
recursive_function (n=3)
   recursive_function(n-1)
#6 Frame 0x7ffff7fb60f0, for file /tmp/rec.py, line 7, in
recursive_function (n=4)
   recursive_function(n-1)
#6 Frame 0x7ffff7fb6080, for file /tmp/rec.py, line 7, in
recursive_function (n=5)
   recursive_function(n-1)
#6 Frame 0x7ffff7fb6020, for file /tmp/rec.py, line 9, in
<module> ()
   recursive_function(5)
(gdb) py-up
Unable to find an older python frame
```

py-bt

The `py-bt` command attempts to display a Python-level backtrace of the current thread.

For example:

```
(gdb) py-bt
#8 (unable to read python frame information)
#11 Frame 0x9aead74, for file /usr/lib/python2.6/site-
packages/gnome_sudoku/dialog_swallower.py, line 48, in
run_dialog (self=<SwappableArea(running=<gtk.Dialog at
remote 0x98faaa4>, main_page=0) at remote 0x98fa6e4>, d=
<gtk.Dialog at remote 0x98faaa4>)
            gtk.main()
#14 Frame 0x99262ac, for file /usr/lib/python2.6/site-
packages/gnome_sudoku/game_selector.py, line 201, in
run_swallowed_dialog (self=
<NewOrSavedGameSelector(new_game_model=<gtk.ListStore at
remote 0x98fab44>, puzzle=None, saved_games=
[{'gsd.auto_fills': 0, 'tracking': {}, 'trackers': {},
'notes': [], 'saved_at': 1270084485, 'game': '7 8 0 0 0 0 0
5 6 0 0 9 0 8 0 1 0 0 0 4 6 0 0 0 0 7 0 6 5 0 0 0 4 7 9 2 0
0 0 9 0 1 0 0 0 3 9 7 6 0 0 0 1 8 0 6 0 0 0 0 2 8 0 0 0 5 0
4 0 6 0 0 2 1 0 0 0 0 0 4 5\n7 8 0 0 0 0 0 5 6 0 0 9 0 8 0
1 0 0 0 4 6 0 0 0 0 7 0 6 5 1 8 3 4 7 9 2 0 0 0 9 0 1 0 0 0
3 9 7 6 0 0 0 1 8 0 6 0 0 0 0 2 8 0 0 0 5 0 4 0 6 0 0 2 1 0
0 0 0 0 4 5', 'gsd.impossible_hints': 0,
'timer.__absolute_start_time__': <float at remote
0x984b474>, 'gsd.hints': 0, 'timer.active_time': <float at
remote 0x984b494>, 'timer.total_time': <float at remote
0x984b464>}], dialog=<gtk.Dialog at remote 0x98faaa4>,
saved_game_model=<gtk.ListStore at remote 0x98fad24>,
sudoku_maker=<SudokuMaker(terminated=False, played=[],
batch_siz...(truncated)
            swallower.run_dialog(self.dialog)
#19 (unable to read python frame information)
#23 (unable to read python frame information)
#34 (unable to read python frame information)
#37 Frame 0x9420b04, for file /usr/lib/python2.6/site-
packages/gnome_sudoku/main.py, line 906, in start_game ()
    u = UI()
#40 Frame 0x948e82c, for file /usr/lib/python2.6/site-
packages/gnome_sudoku/gnome_sudoku.py, line 22, in
start_game (main=<module at remote 0xb771b7f4>)
    main.start_game()
```

The frame numbers correspond to those displayed by GDB’s standard `backtrace` command.

py-print

The `py-print` command looks up a Python name and tries to print it. It looks in locals within the current thread, then globals, then finally builtins:

```
(gdb) py-print self
local 'self' = <SwappableArea(running=<gtk.Dialog at remote
0x98faaa4>,
main_page=0) at remote 0x98fa6e4>
(gdb) py-print __name__
global '__name__' = 'gnome_sudoku.dialog_swallower'
(gdb) py-print len
```

```
builtin 'len' = <built-in function len>
(gdb) py-print scarlet_pimpernel
'scarlet_pimpernel' not found
```

If the current C frame corresponds to multiple Python frames, `py-print` only considers the first one.

`py-locals`

The `py-locals` command looks up all Python locals within the current Python frame in the selected thread, and prints their representations:

```
(gdb) py-locals
self = <SwappableArea(running=<gtk.Dialog at remote
0x98faaa4>,
main_page=0) at remote 0x98fa6e4>
d = <gtk.Dialog at remote 0x98faaa4>
```

If the current C frame corresponds to multiple Python frames, locals from all of them will be shown:

```
(gdb) py-locals
Locals for recursive_function
n = 0
Locals for recursive_function
n = 1
Locals for recursive_function
n = 2
Locals for recursive_function
n = 3
Locals for recursive_function
n = 4
Locals for recursive_function
n = 5
Locals for <module>
```

Use with GDB commands

The extension commands complement GDB's built-in commands. For example, you can use a frame numbers shown by `py-bt` with the `frame` command to go a specific frame within the selected thread, like this:

```
(gdb) py-bt
(output snipped)
#68 Frame 0xaa4560, for file Lib/test/regrtest.py, line 1548,
in <module> ()
        main()
(gdb) frame 68
#68 0x00000000004cd1e6 in PyEval_EvalFrameEx (f=Frame 0xaa4560,
for file Lib/test/regrtest.py, line 1548, in <module> (),
throwflag=0) at Python/ceval.c:2665
2665                            x = call_function(&sp, oparg);
(gdb) py-list
1543        # Run the tests in a context manager that temporary
changes the CWD to a
1544        # temporary and writable directory. If it's not
possible to create or
1545        # change the CWD, the original CWD will be used.
The original CWD is
1546        # available from test_support.SAVEDCWD.
1547        with test_support.temp_cwd(TESTCWD, quiet=True):
>1548            main()
```

The `info threads` command will give you a list of the threads within the process, and you can use the `thread` command to select a different one:

```
(gdb) info threads
  105 Thread 0x7fffefa18710 (LWP 10260)  sem_wait () at
../nptl/sysdeps/unix/sysv/linux/x86_64/sem_wait.S:86
  104 Thread 0x7fffdf5fe710 (LWP 10259)  sem_wait () at
../nptl/sysdeps/unix/sysv/linux/x86_64/sem_wait.S:86
* 1 Thread 0x7ffff7fe2700 (LWP 10145)  0x00000038e46d73e3 in
select () at ../sysdeps/unix/syscall-template.S:82
```

You can use `thread apply all COMMAND` or (`t a a COMMAND` for short) to run a command on all threads. With `py-bt`, this lets you see what every thread is doing at the Python level:

```
(gdb) t a a py-bt

Thread 105 (Thread 0x7fffefa18710 (LWP 10260)):

Enum HOWTO

An `Enum` is a set of symbolic names bound to unique values. They are similar to global variables, but they offer a more useful `repr()`, grouping, type-safety, and a few other features.

They are most useful when you have a variable that can take one of a limited selection of values. For example, the days of the week:

```
>>> from enum import Enum
>>> class Weekday(Enum):
...     MONDAY = 1
...     TUESDAY = 2
...     WEDNESDAY = 3
...     THURSDAY = 4
...     FRIDAY = 5
...     SATURDAY = 6
...     SUNDAY = 7
```

Or perhaps the RGB primary colors:

```
>>> from enum import Enum
>>> class Color(Enum):
...     RED = 1
...     GREEN = 2
...     BLUE = 3
```

As you can see, creating an `Enum` is as simple as writing a class that inherits from `Enum` itself.

Note

Case of Enum Members

Because Enums are used to represent constants, and to help avoid issues with name clashes between mixin-class methods/attributes and enum names, we strongly recommend using UPPER_CASE names for members, and will be using that style in our examples.

Depending on the nature of the enum a member’s value may or may not be important, but either way that value can be used to get the corresponding member:

```
>>> Weekday(3)
<Weekday.WEDNESDAY: 3>
```

As you can see, the `repr()` of a member shows the enum name, the member name, and the value. The `str()` of a member shows only the enum name and member name:

```
>>> print(Weekday.THURSDAY)
Weekday.THURSDAY
```

The *type* of an enumeration member is the enum it belongs to:

```
>>> type(Weekday.MONDAY)
<enum 'Weekday'>
>>> isinstance(Weekday.FRIDAY, Weekday)
True
```

Enum members have an attribute that contains just their **`name`**:

```
>>> print(Weekday.TUESDAY.name)
TUESDAY
```

Likewise, they have an attribute for their **`value`**:

```
>>> Weekday.WEDNESDAY.value
3
```

Unlike many languages that treat enumerations solely as name/value pairs, Python Enums can have behavior added. For example, `datetime.date` has two methods for returning the weekday: `weekday()` and `isoweekday()`. The difference is that one of them counts from 0-6 and the other from 1-7. Rather than keep track of that ourselves we can add a method to the **`Weekday`** enum to extract the day from the `date` instance and return the matching enum member:

```
@classmethod
def from_date(cls, date):
    return cls(date.isoweekday())
```

The complete **`Weekday`** enum now looks like this:

```
>>> class Weekday(Enum):
...     MONDAY = 1
...     TUESDAY = 2
...     WEDNESDAY = 3
...     THURSDAY = 4
...     FRIDAY = 5
...     SATURDAY = 6
...     SUNDAY = 7
...     #
...     @classmethod
...     def from_date(cls, date):
...         return cls(date.isoweekday())
```

Now we can find out what today is! Observe:

```
>>> from datetime import date
>>> Weekday.from_date(date.today())
<Weekday.TUESDAY: 2>
```

Of course, if you’re reading this on some other day, you’ll see that day instead.

This **`Weekday`** enum is great if our variable only needs one day, but what if we need several? Maybe we’re writing a function to plot chores during a week, and don’t want to use a `list` – we could use a different type of `Enum`:

```
>>> from enum import Flag
>>> class Weekday(Flag):
...     MONDAY = 1
...     TUESDAY = 2
...     WEDNESDAY = 4
...     THURSDAY = 8
...     FRIDAY = 16
...     SATURDAY = 32
...     SUNDAY = 64
```

We’ve changed two things: we’re inherited from `Flag`, and the values are all powers of 2.

Just like the original **`Weekday`** enum above, we can have a single selection:

```
>>> first_week_day = Weekday.MONDAY
>>> first_week_day
<Weekday.MONDAY: 1>
```

But `Flag` also allows us to combine several members into a single variable:

```
>>> weekend = Weekday.SATURDAY | Weekday.SUNDAY
>>> weekend
<Weekday.SATURDAY|SUNDAY: 96>
```

You can even iterate over a `Flag` variable:

```
>>> for day in weekend:
...     print(day)
Weekday.SATURDAY
Weekday.SUNDAY
```

Okay, let’s get some chores set up:

```
>>> chores_for_ethan = {
...     'feed the cat': Weekday.MONDAY | Weekday.WEDNESDAY |
Weekday.FRIDAY,
...     'do the dishes': Weekday.TUESDAY | Weekday.THURSDAY,
...     'answer SO questions': Weekday.SATURDAY,
...     }
```

And a function to display the chores for a given day:

```
>>> def show_chores(chores, day):
...     for chore, days in chores.items():
...         if day in days:
...             print(chore)
...
>>> show_chores(chores_for_ethan, Weekday.SATURDAY)
answer SO questions
```

In cases where the actual values of the members do not matter, you can save yourself some work and use `auto()` for the values:

```
>>> from enum import auto
>>> class Weekday(Flag):
...     MONDAY = auto()
...     TUESDAY = auto()
...     WEDNESDAY = auto()
...     THURSDAY = auto()
...     FRIDAY = auto()
...     SATURDAY = auto()
...     SUNDAY = auto()
...     WEEKEND = SATURDAY | SUNDAY
```

Programmatic access to enumeration members and their attributes

Sometimes it’s useful to access members in enumerations programmatically (i.e. situations where `Color.RED` won’t do because the exact color is not known at program-writing time). `Enum` allows such access:

```
>>> Color(1)
<Color.RED: 1>
>>> Color(3)
<Color.BLUE: 3>
```

If you want to access enum members by *name*, use item access:

```
>>> Color['RED']
<Color.RED: 1>
>>> Color['GREEN']
<Color.GREEN: 2>
```

If you have an enum member and need its **`name`** or **`value`**:

```
>>> member = Color.RED
>>> member.name
'RED'
>>> member.value
1
```

Duplicating enum members and values

Having two enum members with the same name is invalid:

```
>>> class Shape(Enum):
...     SQUARE = 2
...     SQUARE = 3
...
Traceback (most recent call last):
...
TypeError: 'SQUARE' already defined as 2
```

However, an enum member can have other names associated with it. Given two entries `A` and `B` with the same value (and `A` defined first), `B` is an alias for the member `A`. By-value lookup of the value of `A` will return the member `A`.

By-name lookup of `A` will return the member `A`. By-name lookup of `B` will also return the member `A`:

```
>>> class Shape(Enum):
...     SQUARE = 2
...     DIAMOND = 1
...     CIRCLE = 3
...     ALIAS_FOR_SQUARE = 2
...
>>> Shape.SQUARE
<Shape.SQUARE: 2>
>>> Shape.ALIAS_FOR_SQUARE
<Shape.SQUARE: 2>
>>> Shape(2)
<Shape.SQUARE: 2>
```

Note

Attempting to create a member with the same name as an already defined attribute (another member, a method, etc.) or attempting to create an attribute with the same name as a member is not allowed.

Ensuring unique enumeration values

By default, enumerations allow multiple names as aliases for the same value. When this behavior isn’t desired, you can use the `unique()` decorator:

```
>>> from enum import Enum, unique
>>> @unique
... class Mistake(Enum):
...     ONE = 1
...     TWO = 2
...     THREE = 3
...     FOUR = 3
...
Traceback (most recent call last):
```

```
...
ValueError: duplicate values found in <enum 'Mistake'>: FOUR ->
THREE
```

Using automatic values

If the exact value is unimportant you can use `auto`:

```
>>> from enum import Enum, auto
>>> class Color(Enum):
...     RED = auto()
...     BLUE = auto()
...     GREEN = auto()
...
>>> [member.value for member in Color]
[1, 2, 3]
```

The values are chosen by `_generate_next_value_()`, which can be overridden:

```
>>> class AutoName(Enum):
...     @staticmethod
...     def _generate_next_value_(name, start, count,
last_values):
...         return name
...
>>> class Ordinal(AutoName):
...     NORTH = auto()
...     SOUTH = auto()
...     EAST = auto()
...     WEST = auto()
...
>>> [member.value for member in Ordinal]
['NORTH', 'SOUTH', 'EAST', 'WEST']
```

Note

The `_generate_next_value_()` method must be defined before any members.

Iteration

Iterating over the members of an enum does not provide the aliases:

```
>>> list(Shape)
[<Shape.SQUARE: 2>, <Shape.DIAMOND: 1>, <Shape.CIRCLE: 3>]
>>> list(Weekday)
[<Weekday.MONDAY: 1>, <Weekday.TUESDAY: 2>, <Weekday.WEDNESDAY:
4>, <Weekday.THURSDAY: 8>, <Weekday.FRIDAY: 16>,
<Weekday.SATURDAY: 32>, <Weekday.SUNDAY: 64>]
```

Note that the aliases `Shape.ALIAS_FOR_SQUARE` and `Weekday.WEEKEND` aren't shown.

The special attribute `__members__` is a read-only ordered mapping of names to members. It includes all names defined in the enumeration, including the aliases:

```
>>> for name, member in Shape.__members__.items():
...     name, member
...
('SQUARE', <Shape.SQUARE: 2>)
('DIAMOND', <Shape.DIAMOND: 1>)
('CIRCLE', <Shape.CIRCLE: 3>)
('ALIAS_FOR_SQUARE', <Shape.SQUARE: 2>)
```

The `__members__` attribute can be used for detailed programmatic access to the enumeration members. For example, finding all the aliases:

```
>>> [name for name, member in Shape.__members__.items() if
member.name != name]
['ALIAS_FOR_SQUARE']
```

Note

Aliases for flags include values with multiple flags set, such as `3`, and no flags set, i.e. `0`.

Comparisons

Enumeration members are compared by identity:

```
>>> Color.RED is Color.RED
True
>>> Color.RED is Color.BLUE
False
>>> Color.RED is not Color.BLUE
True
```

Ordered comparisons between enumeration values are *not* supported. Enum members are not integers (but see IntEnum below):

```
>>> Color.RED < Color.BLUE
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
TypeError: '<' not supported between instances of 'Color' and
'Color'
```

Equality comparisons are defined though:

```
>>> Color.BLUE == Color.RED
False
>>> Color.BLUE != Color.RED
True
>>> Color.BLUE == Color.BLUE
True
```

Comparisons against non-enumeration values will always compare not equal (again, **`IntEnum`** was explicitly designed to behave differently, see below):

```
>>> Color.BLUE == 2
False
```

Warning

It is possible to reload modules – if a reloaded module contains enums, they will be recreated, and the new members may not compare identical/equal to the original members.

Allowed members and attributes of enumerations

Most of the examples above use integers for enumeration values. Using integers is short and handy (and provided by default by the Functional API), but not strictly enforced. In the vast majority of use-cases, one doesn't care what the actual value of an enumeration is. But if the value *is* important, enumerations can have arbitrary values.

Enumerations are Python classes, and can have methods and special methods as usual. If we have this enumeration:

```
>>> class Mood(Enum):
...     FUNKY = 1
...     HAPPY = 3
...
...     def describe(self):
...         # self is the member here
...         return self.name, self.value
...
...     def __str__(self):
...         return 'my custom str! {0}'.format(self.value)
...
...     @classmethod
...     def favorite_mood(cls):
...         # cls here is the enumeration
...         return cls.HAPPY
...
```

Then:

```
>>> Mood.favorite_mood()
<Mood.HAPPY: 3>
>>> Mood.HAPPY.describe()
('HAPPY', 3)
>>> str(Mood.FUNKY)
'my custom str! 1'
```

The rules for what is allowed are as follows: names that start and end with a single underscore are reserved by enum and cannot be used; all other attributes defined within an enumeration will become members of this enumeration, with the exception of special methods (`__str__()`, `__add__()`, etc.), descriptors (methods are also descriptors), and variable names listed in `_ignore_`.

Note: if your enumeration defines `__new__()` and/or `__init__()`, any value(s) given to the enum member will be passed into those methods. See Planet for an example.

Note

The `__new__()` method, if defined, is used during creation of the Enum members; it is then replaced by Enum’s `__new__()` which is used after class creation for lookup of existing members. See When to use __new__() vs. __init__() for more details.

Restricted Enum subclassing

A new `Enum` class must have one base enum class, up to one concrete data type, and as many `object`-based mixin classes as needed. The order of these base classes is:

```
class EnumName([mix-in, ...,] [data-type,] base-enum):
    pass
```

Also, subclassing an enumeration is allowed only if the enumeration does not define any members. So this is forbidden:

```
>>> class MoreColor(Color):
...     PINK = 17
...
Traceback (most recent call last):
...
TypeError: <enum 'MoreColor'> cannot extend <enum 'Color'>
```

But this is allowed:

```
>>> class Foo(Enum):
...     def some_behavior(self):
...         pass
...
>>> class Bar(Foo):
...     HAPPY = 1
...     SAD = 2
...
```

Allowing subclassing of enums that define members would lead to a violation of some important invariants of types and instances. On the other hand, it makes sense to allow sharing some common behavior between a group of enumerations. (See OrderedEnum for an example.)

Dataclass support

When inheriting from a **`dataclass`**, the **`__repr__()`** omits the inherited class' name. For example:

```
>>> from dataclasses import dataclass, field
>>> @dataclass
... class CreatureDataMixin:
...     size: str
...     legs: int
...     tail: bool = field(repr=False, default=True)
...
>>> class Creature(CreatureDataMixin, Enum):
...     BEETLE = 'small', 6
...     DOG = 'medium', 4
...
>>> Creature.DOG
<Creature.DOG: size='medium', legs=4>
```

Use the **`dataclass()`** argument `repr=False` to use the standard **`repr()`**.

Changed in version 3.12: Only the dataclass fields are shown in the value area, not the dataclass' name.

Note

Adding **`dataclass()`** decorator to **`Enum`** and its subclasses is not supported. It will not raise any errors, but it will produce very strange results at runtime, such as members being equal to each other:

```
>>> @dataclass               # don't do this: it does not
make any sense
... class Color(Enum):
...    RED = 1
...    BLUE = 2
...
>>> Color.RED is Color.BLUE
False
>>> Color.RED == Color.BLUE  # problem is here: they should
not be equal
True
```

Pickling

Enumerations can be pickled and unpickled:

```
>>> from test.test_enum import Fruit
>>> from pickle import dumps, loads
>>> Fruit.TOMATO is loads(dumps(Fruit.TOMATO))
True
```

The usual restrictions for pickling apply: picklable enums must be defined in the top level of a module, since unpickling requires them to be importable from that module.

Note

With pickle protocol version 4 it is possible to easily pickle enums nested in other classes.

It is possible to modify how enum members are pickled/unpickled by defining `__reduce_ex__()` in the enumeration class. The default method is by-value, but enums with complicated values may want to use by-name:

```
>>> import enum
>>> class MyEnum(enum.Enum):
...     __reduce_ex__ = enum.pickle_by_enum_name
```

Note

Using by-name for flags is not recommended, as unnamed aliases will not unpickle.

Functional API

The **`Enum`** class is callable, providing the following functional API:

```
>>> Animal = Enum('Animal', 'ANT BEE CAT DOG')
>>> Animal
<enum 'Animal'>
>>> Animal.ANT
<Animal.ANT: 1>
>>> list(Animal)
[<Animal.ANT: 1>, <Animal.BEE: 2>, <Animal.CAT: 3>,
<Animal.DOG: 4>]
```

The semantics of this API resemble **`namedtuple`**. The first argument of the call to **`Enum`** is the name of the enumeration.

The second argument is the *source* of enumeration member names. It can be a whitespace-separated string of names, a sequence of names, a sequence of 2-tuples with key/value pairs, or a mapping (e.g. dictionary) of names to values. The last two options enable assigning arbitrary values to enumerations; the others auto-assign increasing integers starting with 1 (use the `start` parameter to specify a different starting value). A new class derived from **`Enum`** is returned. In other words, the above assignment to **`Animal`** is equivalent to:

```
>>> class Animal(Enum):
...     ANT = 1
...     BEE = 2
...     CAT = 3
...     DOG = 4
...
```

The reason for defaulting to `1` as the starting number and not `0` is that `0` is `False` in a boolean sense, but by default enum members all evaluate to `True`.

Pickling enums created with the functional API can be tricky as frame stack implementation details are used to try and figure out which module the enumeration is being created in (e.g. it will fail if you use a utility function in a separate module, and also may not work on IronPython or Jython). The solution is to specify the module name explicitly as follows:

```
>>> Animal = Enum('Animal', 'ANT BEE CAT DOG', module=__name__)
```

Warning

If `module` is not supplied, and Enum cannot determine what it is, the new Enum members will not be unpicklable; to keep errors closer to the source, pickling will be disabled.

The new pickle protocol 4 also, in some circumstances, relies on `__qualname__` being set to the location where pickle will be able to find the class. For example, if the class was made available in class SomeData in the global scope:

```
>>> Animal = Enum('Animal', 'ANT BEE CAT DOG',
qualname='SomeData.Animal')
```

The complete signature is:

```
Enum(
    value='NewEnumName',
    names=<...>,
    *,
    module='...',
    qualname='...',
    type=<mixed-in class>,
    start=1,
    )
```

- *value*: What the new enum class will record as its name.
- *names*: The enum members. This can be a whitespace- or comma-separated string (values will start at 1 unless

otherwise specified):

`'RED GREEN BLUE' | 'RED,GREEN,BLUE' | 'RED, GREEN, BLUE'`

or an iterator of names:

`['RED', 'GREEN', 'BLUE']`

or an iterator of (name, value) pairs:

`[('CYAN', 4), ('MAGENTA', 5), ('YELLOW', 6)]`

or a mapping:

`{'CHARTREUSE': 7, 'SEA_GREEN': 11, 'ROSEMARY': 42}`

- *module*: name of module where new enum class can be found.
- *qualname*: where in module new enum class can be found.
- *type*: type to mix in to new enum class.
- *start*: number to start counting at if only names are passed in.

Changed in version 3.5: The *start* parameter was added.

Derived Enumerations

IntEnum

The first variation of `Enum` that is provided is also a subclass of `int`. Members of an `IntEnum` can be compared to integers; by extension, integer enumerations of different types can also be compared to each other:

```
>>> from enum import IntEnum
>>> class Shape(IntEnum):
...     CIRCLE = 1
...     SQUARE = 2
...
>>> class Request(IntEnum):
...     POST = 1
...     GET = 2
...
>>> Shape == 1
False
>>> Shape.CIRCLE == 1
True
>>> Shape.CIRCLE == Request.POST
True
```

However, they still can’t be compared to standard `Enum` enumerations:

```
>>> class Shape(IntEnum):
...     CIRCLE = 1
...     SQUARE = 2
...
>>> class Color(Enum):
...     RED = 1
...     GREEN = 2
...
>>> Shape.CIRCLE == Color.RED
False
```

`IntEnum` values behave like integers in other ways you’d expect:

```
>>> int(Shape.CIRCLE)
1
>>> ['a', 'b', 'c'][Shape.CIRCLE]
'b'
>>> [i for i in range(Shape.SQUARE)]
[0, 1]
```

StrEnum

The second variation of `Enum` that is provided is also a subclass of `str`. Members of a `StrEnum` can be compared to strings; by extension, string enumerations of different types can also be compared to each other.

Added in version 3.11.

IntFlag

The next variation of `Enum` provided, `IntFlag`, is also based on `int`. The difference being `IntFlag` members can be combined using the bitwise operators (&, |, ^, ~) and the result is still an `IntFlag` member, if possible. Like `IntEnum`, `IntFlag` members are also integers and can be used wherever an `int` is used.

Note

Any operation on an `IntFlag` member besides the bit-wise operations will lose the `IntFlag` membership.

Bit-wise operations that result in invalid `IntFlag` values will lose the `IntFlag` membership. See `FlagBoundary` for details.

Added in version 3.6.

Changed in version 3.11.

Sample `IntFlag` class:

```
>>> from enum import IntFlag
>>> class Perm(IntFlag):
...     R = 4
...     W = 2
...     X = 1
...
>>> Perm.R | Perm.W
```

```
<Perm.R|W: 6>
>>> Perm.R + Perm.W
6
>>> RW = Perm.R | Perm.W
>>> Perm.R in RW
True
```

It is also possible to name the combinations:

```
>>> class Perm(IntFlag):
...     R = 4
...     W = 2
...     X = 1
...     RWX = 7
...
>>> Perm.RWX
<Perm.RWX: 7>
>>> ~Perm.RWX
<Perm: 0>
>>> Perm(7)
<Perm.RWX: 7>
```

Note

Named combinations are considered aliases. Aliases do not show up during iteration, but can be returned from by-value lookups.

Changed in version 3.11.

Another important difference between `IntFlag` and `Enum` is that if no flags are set (the value is 0), its boolean evaluation is `False`:

```
>>> Perm.R & Perm.X
<Perm: 0>
>>> bool(Perm.R & Perm.X)
False
```

Because `IntFlag` members are also subclasses of `int` they can be combined with them (but may lose `IntFlag` membership:

```
>>> Perm.X | 4
<Perm.R|X: 5>

>>> Perm.X + 8
9
```

Note

The negation operator, ~, always returns an `IntFlag` member with a positive value:

```
>>> (~Perm.X).value == (Perm.R|Perm.W).value == 6
True
```

`IntFlag` members can also be iterated over:

```
>>> list(RW)
[<Perm.R: 4>, <Perm.W: 2>]
```

Added in version 3.11.

Flag

The last variation is `Flag`. Like `IntFlag`, `Flag` members can be combined using the bitwise operators (&, |, ^, ~). Unlike `IntFlag`, they cannot be combined with, nor compared against, any other `Flag` enumeration, nor `int`. While it is possible to specify the values directly it is recommended to use `auto` as the value and let `Flag` select an appropriate value.

Added in version 3.6.

Like `IntFlag`, if a combination of `Flag` members results in no flags being set, the boolean evaluation is `False`:

```
>>> from enum import Flag, auto
>>> class Color(Flag):
...     RED = auto()
...     BLUE = auto()
...     GREEN = auto()
...
>>> Color.RED & Color.GREEN
<Color: 0>
>>> bool(Color.RED & Color.GREEN)
False
```

Individual flags should have values that are powers of two (1, 2, 4, 8, …), while combinations of flags will not:

```
>>> class Color(Flag):
...     RED = auto()
...     BLUE = auto()
...     GREEN = auto()
...     WHITE = RED | BLUE | GREEN
...
>>> Color.WHITE
<Color.WHITE: 7>
```

Giving a name to the “no flags set” condition does not change its boolean value:

```
>>> class Color(Flag):
...     BLACK = 0
...     RED = auto()
...     BLUE = auto()
...     GREEN = auto()
...
>>> Color.BLACK
<Color.BLACK: 0>
>>> bool(Color.BLACK)
False
```

`Flag` members can also be iterated over:

```
>>> purple = Color.RED | Color.BLUE
>>> list(purple)
[<Color.RED: 1>, <Color.BLUE: 2>]
```

Added in version 3.11.

Note

For the majority of new code, `Enum` and `Flag` are strongly recommended, since `IntEnum` and `IntFlag` break some semantic promises of an enumeration (by being comparable to integers, and thus by transitivity to other unrelated enumerations). `IntEnum` and `IntFlag` should be used only in cases where `Enum` and `Flag` will not do; for example, when integer constants are replaced with enumerations, or for interoperability with other systems.

Others

While `IntEnum` is part of the `enum` module, it would be very simple to implement independently:

```
class IntEnum(int, ReprEnum):   # or Enum instead of ReprEnum
    pass
```

This demonstrates how similar derived enumerations can be defined; for example a **`FloatEnum`** that mixes in `float` instead of `int`.

Some rules:

1. When subclassing `Enum`, mix-in types must appear before the `Enum` class itself in the sequence of bases, as in the `IntEnum` example above.
2. Mix-in types must be subclassable. For example, `bool` and `range` are not subclassable and will throw an error

during Enum creation if used as the mix-in type.

3. While `Enum` can have members of any type, once you mix in an additional type, all the members must have values of that type, e.g. `int` above. This restriction does not apply to mix-ins which only add methods and don't specify another type.
4. When another data type is mixed in, the `value` attribute is *not the same* as the enum member itself, although it is equivalent and will compare equal.
5. A `data type` is a mixin that defines `__new__()`, or a `dataclass`
6. %-style formatting: `%s` and `%r` call the `Enum` class's `__str__()` and `__repr__()` respectively; other codes (such as `%i` or `%h` for IntEnum) treat the enum member as its mixed-in type.
7. Formatted string literals, `str.format()`, and `format()` will use the enum's `__str__()` method.

Note

Because `IntEnum`, `IntFlag`, and `StrEnum` are designed to be drop-in replacements for existing constants, their `__str__()` method has been reset to their data types' `__str__()` method.

When to use `__new__()` vs. `__init__()`

`__new__()` must be used whenever you want to customize the actual value of the `Enum` member. Any other modifications may go in either `__new__()` or `__init__()`, with `__init__()` being preferred.

For example, if you want to pass several items to the constructor, but only want one of them to be the value:

```
>>> class Coordinate(bytes, Enum):
...     """
...     Coordinate with binary codes that can be indexed by the
int code.
...     """
...     def __new__(cls, value, label, unit):
...         obj = bytes.__new__(cls, [value])
...         obj._value_ = value
...         obj.label = label
...         obj.unit = unit
...         return obj
...     PX = (0, 'P.X', 'km')
...     PY = (1, 'P.Y', 'km')
...     VX = (2, 'V.X', 'km/s')
...     VY = (3, 'V.Y', 'km/s')
...

>>> print(Coordinate['PY'])
Coordinate.PY

>>> print(Coordinate(3))
Coordinate.VY
```

Warning

Do not call `super().__new__()`, as the lookup-only `__new__` is the one that is found; instead, use the data type directly.

Finer Points

Supported `__dunder__` names

`__members__` is a read-only ordered mapping of `member_name`:`member` items. It is only available on the class.

`__new__()`, if specified, must create and return the enum members; it is also a very good idea to set the member’s `_value_` appropriately. Once all the members are created it is no longer used.

Supported `_sunder_` names

- `_name_` – name of the member
- `_value_` – value of the member; can be set in `__new__`
- `_missing_()` – a lookup function used when a value is not found; may be overridden
- `_ignore_` – a list of names, either as a `list` or a `str`, that will not be transformed into members, and will be removed from the final class
- `_generate_next_value_()` – used to get an appropriate value for an enum member; may be overridden
- `_add_alias_()` – adds a new name as an alias to an existing member.
- `_add_value_alias_()` – adds a new value as an alias to an existing member. See MultiValueEnum for an example.

  Note

  For standard `Enum` classes the next value chosen is the highest value seen incremented by one.

  For `Flag` classes the next value chosen will be the next highest power-of-two.

Changed in version 3.13: Prior versions would use the last seen value instead of the highest value.

Added in version 3.6: `_missing_`, `_order_`, `_generate_next_value_`

Added in version 3.7: `_ignore_`

Added in version 3.13: `_add_alias_`, `_add_value_alias_`

To help keep Python 2 / Python 3 code in sync an **`_order_`** attribute can be provided. It will be checked against the actual order of the enumeration and raise an error if the two do not match:

```
>>> class Color(Enum):
...     _order_ = 'RED GREEN BLUE'
...     RED = 1
...     BLUE = 3
...     GREEN = 2
...
Traceback (most recent call last):
...
TypeError: member order does not match _order_:
  ['RED', 'BLUE', 'GREEN']
  ['RED', 'GREEN', 'BLUE']
```

Note

In Python 2 code the **`_order_`** attribute is necessary as definition order is lost before it can be recorded.

_Private__names

Private names are not converted to enum members, but remain normal attributes.

Changed in version 3.11.

`Enum` member type

Enum members are instances of their enum class, and are normally accessed as `EnumClass.member`. In certain situations, such as writing custom enum behavior, being able to access one member directly from another is useful, and is supported; however, in order to avoid name clashes between member names and attributes/methods from mixed-in classes, upper-case names are strongly recommended.

Changed in version 3.5.

Creating members that are mixed with other data types

When subclassing other data types, such as **`int`** or **`str`**, with an **`Enum`**, all values after the `=` are passed to that data type's constructor. For example:

```
>>> class MyEnum(IntEnum):      # help(int) -> int(x, base=10)
-> integer
...     example = '11', 16      # so x='11' and base=16
...
>>> MyEnum.example.value        # and hex(11) is...
17
```

Boolean value of `Enum` classes and members

Enum classes that are mixed with non-**`Enum`** types (such as **`int`**, **`str`**, etc.) are evaluated according to the mixed-in type's rules; otherwise, all members evaluate as **`True`**. To make your own enum's boolean evaluation depend on the member's value add the following to your class:

```
def __bool__(self):
    return bool(self.value)
```

Plain **`Enum`** classes always evaluate as **`True`**.

`Enum` classes with methods

If you give your enum subclass extra methods, like the Planet class below, those methods will show up in a **`dir()`** of the member, but not of the class:

```
>>> dir(Planet)
['EARTH', 'JUPITER', 'MARS', 'MERCURY', 'NEPTUNE', 'SATURN',
'URANUS', 'VENUS', '__class__', '__doc__', '__members__',
'__module__']
>>> dir(Planet.EARTH)
['__class__', '__doc__', '__module__', 'mass', 'name',
'radius', 'surface_gravity', 'value']
```

Combining members of `Flag`

Iterating over a combination of **`Flag`** members will only return the members that are comprised of a single bit:

```
>>> class Color(Flag):
...     RED = auto()
...     GREEN = auto()
...     BLUE = auto()
...     MAGENTA = RED | BLUE
...     YELLOW = RED | GREEN
...     CYAN = GREEN | BLUE
...
>>> Color(3)  # named combination
<Color.YELLOW: 3>
>>> Color(7)      # not named combination
<Color.RED|GREEN|BLUE: 7>
```

`Flag` and `IntFlag` minutia

Using the following snippet for our examples:

```
>>> class Color(IntFlag):
...     BLACK = 0
...     RED = 1
...     GREEN = 2
...     BLUE = 4
...     PURPLE = RED | BLUE
...     WHITE = RED | GREEN | BLUE
...
```

the following are true:

- single-bit flags are canonical
- multi-bit and zero-bit flags are aliases
- only canonical flags are returned during iteration:

  ```
  >>> list(Color.WHITE)
  [<Color.RED: 1>, <Color.GREEN: 2>, <Color.BLUE: 4>]
  ```

- negating a flag or flag set returns a new flag/flag set with the corresponding positive integer value:

  ```
  >>> Color.BLUE
  <Color.BLUE: 4>

  >>> ~Color.BLUE
  <Color.RED|GREEN: 3>
  ```

- names of pseudo-flags are constructed from their members' names:

  ```
  >>> (Color.RED | Color.GREEN).name
  'RED|GREEN'

  >>> class Perm(IntFlag):
  ...     R = 4
  ...     W = 2
  ...     X = 1
  ...
  >>> (Perm.R & Perm.W).name is None  # effectively Perm(0)
  True
  ```

- multi-bit flags, aka aliases, can be returned from operations:

  ```
  >>> Color.RED | Color.BLUE
  <Color.PURPLE: 5>

  >>> Color(7)  # or Color(-1)
  <Color.WHITE: 7>

  >>> Color(0)
  <Color.BLACK: 0>
  ```

- membership / containment checking: zero-valued flags are always considered to be contained:

  ```
  >>> Color.BLACK in Color.WHITE
  True
  ```

  otherwise, only if all bits of one flag are in the other flag will True be returned:

  ```
  >>> Color.PURPLE in Color.WHITE
  True

  >>> Color.GREEN in Color.PURPLE
  False
  ```

There is a new boundary mechanism that controls how out-of-range / invalid bits are handled: `STRICT`, `CONFORM`, `EJECT`, and `KEEP`:

- STRICT –> raises an exception when presented with invalid values
- CONFORM –> discards any invalid bits
- EJECT –> lose Flag status and become a normal int with the given value
- KEEP –> keep the extra bits
  - keeps Flag status and extra bits
  - extra bits do not show up in iteration

  - extra bits do show up in repr() and str()

The default for Flag is `STRICT`, the default for `IntFlag` is `EJECT`, and the default for `_convert_` is `KEEP` (see `ssl.Options` for an example of when `KEEP` is needed).

How are Enums and Flags different?

Enums have a custom metaclass that affects many aspects of both derived `Enum` classes and their instances (members).

Enum Classes

The `EnumType` metaclass is responsible for providing the `__contains__()`, `__dir__()`, `__iter__()` and other methods that allow one to do things with an `Enum` class that fail on a typical class, such as `list(Color)` or `some_enum_var in Color`. `EnumType` is responsible for ensuring that various other methods on the final `Enum` class are correct (such as `__new__()`, `__getnewargs__()`, `__str__()` and `__repr__()`).

Flag Classes

Flags have an expanded view of aliasing: to be canonical, the value of a flag needs to be a power-of-two value, and not a duplicate name. So, in addition to the `Enum` definition of alias, a flag with no value (a.k.a. `0`) or with more than one power-of-two value (e.g. `3`) is considered an alias.

Enum Members (aka instances)

The most interesting thing about enum members is that they are singletons. `EnumType` creates them all while it is creating the enum class itself, and then puts a custom `__new__()` in place to ensure that no new ones are ever instantiated by returning only the existing member instances.

Flag Members

Flag members can be iterated over just like the `Flag` class, and only the canonical members will be returned. For example:

```
>>> list(Color)
[<Color.RED: 1>, <Color.GREEN: 2>, <Color.BLUE: 4>]
```

(Note that `BLACK`, `PURPLE`, and `WHITE` do not show up.)

Inverting a flag member returns the corresponding positive value, rather than a negative value — for example:

```
>>> ~Color.RED
<Color.GREEN|BLUE: 6>
```

Flag members have a length corresponding to the number of power-of-two values they contain. For example:

```
>>> len(Color.PURPLE)
2
```

Enum Cookbook

While `Enum`, `IntEnum`, `StrEnum`, `Flag`, and `IntFlag` are expected to cover the majority of use-cases, they cannot cover them all. Here are recipes for some different types of enumerations that can be used directly, or as examples for creating one's own.

Omitting values

In many use-cases, one doesn't care what the actual value of an enumeration is. There are several ways to define this type of simple enumeration:

- use instances of `auto` for the value
- use instances of `object` as the value
- use a descriptive string as the value
- use a tuple as the value and a custom `__new__()` to replace the tuple with an `int` value

Using any of these methods signifies to the user that these values are not important, and also enables one to add, remove, or reorder members without having to renumber the remaining members.

Using `auto`

Using `auto` would look like:

```
>>> class Color(Enum):
...     RED = auto()
...     BLUE = auto()
...     GREEN = auto()
...
>>> Color.GREEN
<Color.GREEN: 3>
```

Using `object`

Using `object` would look like:

```
>>> class Color(Enum):
...     RED = object()
...     GREEN = object()
...     BLUE = object()
...
>>> Color.GREEN
<Color.GREEN: <object object at 0x...>>
```

This is also a good example of why you might want to write your own `__repr__()`:

```
>>> class Color(Enum):
...     RED = object()
...     GREEN = object()
...     BLUE = object()
...     def __repr__(self):
...         return "<%s.%s>" % (self.__class__.__name__,
self._name_)
...
>>> Color.GREEN
<Color.GREEN>
```

Using a descriptive string

Using a string as the value would look like:

```
>>> class Color(Enum):
...     RED = 'stop'
...     GREEN = 'go'
...     BLUE = 'too fast!'
...
>>> Color.GREEN
<Color.GREEN: 'go'>
```

Using a custom `__new__()`

Using an auto-numbering `__new__()` would look like:

```
>>> class AutoNumber(Enum):
...     def __new__(cls):
...         value = len(cls.__members__) + 1
...         obj = object.__new__(cls)
...         obj._value_ = value
...         return obj
...
>>> class Color(AutoNumber):
...     RED = ()
...     GREEN = ()
...     BLUE = ()
...
>>> Color.GREEN
<Color.GREEN: 2>
```

To make a more general purpose `AutoNumber`, add `*args` to the signature:

```
>>> class AutoNumber(Enum):
...     def __new__(cls, *args):      # this is the only change
from above
...         value = len(cls.__members__) + 1
...         obj = object.__new__(cls)
...         obj._value_ = value
...         return obj
...
```

Then when you inherit from `AutoNumber` you can write your own `__init__` to handle any extra arguments:

```
>>> class Swatch(AutoNumber):
...     def __init__(self, pantone='unknown'):
...         self.pantone = pantone
...     AUBURN = '3497'
...     SEA_GREEN = '1246'
...     BLEACHED_CORAL = () # New color, no Pantone code yet!
...
>>> Swatch.SEA_GREEN
<Swatch.SEA_GREEN: 2>
>>> Swatch.SEA_GREEN.pantone
'1246'
>>> Swatch.BLEACHED_CORAL.pantone
'unknown'
```

Note

The `__new__()` method, if defined, is used during creation of the Enum members; it is then replaced by Enum’s `__new__()`

which is used after class creation for lookup of existing members.

Warning

Do not call `super().__new__()`, as the lookup-only `__new__` is the one that is found; instead, use the data type directly – e.g.:

```
obj = int.__new__(cls, value)
```

OrderedEnum

An ordered enumeration that is not based on **`IntEnum`** and so maintains the normal **`Enum`** invariants (such as not being comparable to other enumerations):

```
>>> class OrderedEnum(Enum):
...     def __ge__(self, other):
...         if self.__class__ is other.__class__:
...             return self.value >= other.value
...         return NotImplemented
...     def __gt__(self, other):
...         if self.__class__ is other.__class__:
...             return self.value > other.value
...         return NotImplemented
...     def __le__(self, other):
...         if self.__class__ is other.__class__:
...             return self.value <= other.value
...         return NotImplemented
...     def __lt__(self, other):
...         if self.__class__ is other.__class__:
...             return self.value < other.value
...         return NotImplemented
...
>>> class Grade(OrderedEnum):
...     A = 5
...     B = 4
...     C = 3
...     D = 2
...     F = 1
...
>>> Grade.C < Grade.A
True
```

DuplicateFreeEnum

Raises an error if a duplicate member value is found instead of creating an alias:

```
>>> class DuplicateFreeEnum(Enum):
...     def __init__(self, *args):
...         cls = self.__class__
...         if any(self.value == e.value for e in cls):
...             a = self.name
...             e = cls(self.value).name
...             raise ValueError(
...                 "aliases not allowed in DuplicateFreeEnum:
%r --> %r"
...                 % (a, e))
...
>>> class Color(DuplicateFreeEnum):
...     RED = 1
...     GREEN = 2
...     BLUE = 3
...     GRENE = 2
...
Traceback (most recent call last):
  ...
ValueError: aliases not allowed in DuplicateFreeEnum:  'GRENE'
--> 'GREEN'
```

Note

This is a useful example for subclassing Enum to add or change other behaviors as well as disallowing aliases. If the only desired change is disallowing aliases, the `unique()` decorator can be used instead.

MultiValueEnum

Supports having more than one value per member:

```
>>> class MultiValueEnum(Enum):
...     def __new__(cls, value, *values):
...         self = object.__new__(cls)
...         self._value_ = value
...         for v in values:
...             self._add_value_alias_(v)
...         return self
...
>>> class DType(MultiValueEnum):
...     float32 = 'f', 8
...     double64 = 'd', 9
...
>>> DType('f')
<DType.float32: 'f'>
>>> DType(9)
<DType.double64: 'd'>
```

Planet

If `__new__()` or `__init__()` is defined, the value of the enum member will be passed to those methods:

```
>>> class Planet(Enum):
...     MERCURY = (3.303e+23, 2.4397e6)
...     VENUS   = (4.869e+24, 6.0518e6)
...     EARTH   = (5.976e+24, 6.37814e6)
...     MARS    = (6.421e+23, 3.3972e6)
...     JUPITER = (1.9e+27,   7.1492e7)
...     SATURN  = (5.688e+26, 6.0268e7)
...     URANUS  = (8.686e+25, 2.5559e7)
...     NEPTUNE = (1.024e+26, 2.4746e7)
...     def __init__(self, mass, radius):
```

```
...         self.mass = mass       # in kilograms
...         self.radius = radius   # in meters
...     @property
...     def surface_gravity(self):
...         # universal gravitational constant  (m3 kg-1 s-2)
...         G = 6.67300E-11
...         return G * self.mass / (self.radius * self.radius)
...
>>> Planet.EARTH.value
(5.976e+24, 6378140.0)
>>> Planet.EARTH.surface_gravity
9.802652743337129
```

TimePeriod

An example to show the `_ignore_` attribute in use:

```
>>> from datetime import timedelta
>>> class Period(timedelta, Enum):
...     "different lengths of time"
...     _ignore_ = 'Period i'
...     Period = vars()
...     for i in range(367):
...         Period['day_%d' % i] = i
...
>>> list(Period)[:2]
[<Period.day_0: datetime.timedelta(0)>, <Period.day_1:
datetime.timedelta(days=1)>]
>>> list(Period)[-2:]
[<Period.day_365: datetime.timedelta(days=365)>,
<Period.day_366: datetime.timedelta(days=366)>]
```

Subclassing EnumType

While most enum needs can be met by customizing `Enum` subclasses, either with class decorators or custom functions, `EnumType` can be subclassed to provide a different Enum experience.

Functional Programming HOWTO

Author:: A. M. Kuchling
Release:: 0.32

In this document, we’ll take a tour of Python’s features suitable for implementing programs in a functional style. After an introduction to the concepts of functional programming, we’ll look at language features such as iterators and generators and relevant library modules such as **`itertools`** and **`functools`**.

Introduction

This section explains the basic concept of functional programming; if you’re just interested in learning about Python language features, skip to the next section on Iterators.

Programming languages support decomposing problems in several different ways:

- Most programming languages are **procedural**: programs are lists of instructions that tell the computer what to do with the program’s input. C, Pascal, and even Unix shells are procedural languages.
- In **declarative** languages, you write a specification that describes the problem to be solved, and the language implementation figures out how to perform the computation efficiently. SQL is the declarative language you’re most likely to be familiar with; a SQL query

describes the data set you want to retrieve, and the SQL engine decides whether to scan tables or use indexes, which subclauses should be performed first, etc.

- **Object-oriented** programs manipulate collections of objects. Objects have internal state and support methods that query or modify this internal state in some way. Smalltalk and Java are object-oriented languages. C++ and Python are languages that support object-oriented programming, but don’t force the use of object-oriented features.
- **Functional** programming decomposes a problem into a set of functions. Ideally, functions only take inputs and produce outputs, and don’t have any internal state that affects the output produced for a given input. Well-known functional languages include the ML family (Standard ML, OCaml, and other variants) and Haskell.

The designers of some computer languages choose to emphasize one particular approach to programming. This often makes it difficult to write programs that use a different approach. Other languages are multi-paradigm languages that support several different approaches. Lisp, C++, and Python are multi-paradigm; you can write programs or libraries that are largely procedural, object-oriented, or functional in all of these languages. In a large program, different sections might be written using different approaches; the GUI might be object-oriented while the processing logic is procedural or functional, for example.

In a functional program, input flows through a set of functions. Each function operates on its input and produces some output. Functional style discourages functions with side effects that modify internal state or make other changes that aren’t visible in the function’s return value. Functions that have no side effects at all are called **purely functional**. Avoiding side effects means not using data structures that get updated as a program runs; every function’s output must only depend on its input.

Some languages are very strict about purity and don’t even have assignment statements such as `a=3` or `c = a + b`, but it’s difficult to avoid all side effects, such as printing to the screen or writing to a disk file. Another example is a call to the `print()` or `time.sleep()` function, neither of which returns a useful value. Both are called only for their side effects of sending some text to the screen or pausing execution for a second.

Python programs written in functional style usually won’t go to the extreme of avoiding all I/O or all assignments; instead, they’ll provide a functional-appearing interface but will use non-functional features internally. For example, the implementation of a function will still use assignments to local variables, but won’t modify global variables or have other side effects.

Functional programming can be considered the opposite of object-oriented programming. Objects are little capsules containing some internal state along with a collection of method calls that let you modify this state, and programs consist of making the right set of state changes. Functional programming wants to avoid state changes as much as possible and works with data flowing between functions. In Python you might combine the two approaches by writing functions that take and return instances representing objects in your application (e-mail messages, transactions, etc.).

Functional design may seem like an odd constraint to work under. Why should you avoid objects and side effects? There are theoretical and practical advantages to the functional style:

- Formal provability.
- Modularity.
- Composability.
- Ease of debugging and testing.

Formal provability

A theoretical benefit is that it’s easier to construct a mathematical proof that a functional program is correct.

For a long time researchers have been interested in finding ways to mathematically prove programs correct. This is different from testing a program on numerous inputs and concluding that its output is usually correct, or reading a program’s source code and concluding that the code looks right; the goal is instead a rigorous proof that a program produces the right result for all possible inputs.

The technique used to prove programs correct is to write down **invariants**, properties of the input data and of the program’s variables that are always true. For each line of code, you then show that if invariants X and Y are true **before** the line is executed, the slightly different invariants X’ and Y’ are true **after** the line is executed. This continues until you reach the end of the program, at which point the invariants should match the desired conditions on the program’s output.

Functional programming’s avoidance of assignments arose because assignments are difficult to handle with this technique; assignments can break invariants that were true before the assignment without producing any new invariants that can be propagated onward.

Unfortunately, proving programs correct is largely impractical and not relevant to Python software. Even trivial programs require proofs that are several pages long; the proof of correctness for a moderately complicated program would be enormous, and few or none of the programs you use daily (the Python interpreter, your XML parser, your web browser) could be proven correct. Even if you wrote down or generated a proof, there would then be the question of verifying the proof; maybe there’s an error in it, and you wrongly believe you’ve proved the program correct.

Modularity

A more practical benefit of functional programming is that it forces you to break apart your problem into small pieces. Programs are more modular as a result. It’s easier to specify and write a small function that does one thing than a large function that performs a complicated transformation. Small functions are also easier to read and to check for errors.

Ease of debugging and testing

Testing and debugging a functional-style program is easier.

Debugging is simplified because functions are generally small and clearly specified. When a program doesn’t work, each function is an interface point where you can check that the data are correct. You can look at the intermediate inputs and outputs to quickly isolate the function that’s responsible for a bug.

Testing is easier because each function is a potential subject for a unit test. Functions don’t depend on system state that needs to be replicated before running a test; instead you only have to synthesize the right input and then check that the output matches expectations.

Composability

As you work on a functional-style program, you'll write a number of functions with varying inputs and outputs. Some of these functions will be unavoidably specialized to a particular application, but others will be useful in a wide variety of programs. For example, a function that takes a directory path and returns all the XML files in the directory, or a function that takes a filename and returns its contents, can be applied to many different situations.

Over time you'll form a personal library of utilities. Often you'll assemble new programs by arranging existing functions in a new configuration and writing a few functions specialized for the current task.

Iterators

I'll start by looking at a Python language feature that's an important foundation for writing functional-style programs: iterators.

An iterator is an object representing a stream of data; this object returns the data one element at a time. A Python iterator must support a method called `__next__()` that takes no arguments and always returns the next element of the stream. If there are no more elements in the stream, `__next__()` must raise the `StopIteration` exception. Iterators don't have to be finite, though; it's perfectly reasonable to write an iterator that produces an infinite stream of data.

The built-in `iter()` function takes an arbitrary object and tries to return an iterator that will return the object's contents or elements, raising `TypeError` if the object doesn't support iteration. Several of Python's built-in data types support iteration, the most common being lists and dictionaries. An object is called iterable if you can get an iterator for it.

You can experiment with the iteration interface manually:

```
>>> L = [1, 2, 3]
>>> it = iter(L)
>>> it
<...iterator object at ...>
>>> it.__next__()  # same as next(it)
1
>>> next(it)
2
>>> next(it)
3
>>> next(it)
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
StopIteration
>>>
```

Python expects iterable objects in several different contexts, the most important being the **`for`** statement. In the statement `for X in Y`, Y must be an iterator or some object for which **`iter()`** can create an iterator. These two statements are equivalent:

```
for i in iter(obj):
    print(i)

for i in obj:
    print(i)
```

Iterators can be materialized as lists or tuples by using the **`list()`** or **`tuple()`** constructor functions:

```
>>> L = [1, 2, 3]
>>> iterator = iter(L)
>>> t = tuple(iterator)
>>> t
(1, 2, 3)
```

Sequence unpacking also supports iterators: if you know an iterator will return N elements, you can unpack them into an

N-tuple:

```
>>> L = [1, 2, 3]
>>> iterator = iter(L)
>>> a, b, c = iterator
>>> a, b, c
(1, 2, 3)
```

Built-in functions such as `max()` and `min()` can take a single iterator argument and will return the largest or smallest element. The `"in"` and `"not in"` operators also support iterators: `X in iterator` is true if X is found in the stream returned by the iterator. You'll run into obvious problems if the iterator is infinite; `max()`, `min()` will never return, and if the element X never appears in the stream, the `"in"` and `"not in"` operators won't return either.

Note that you can only go forward in an iterator; there's no way to get the previous element, reset the iterator, or make a copy of it. Iterator objects can optionally provide these additional capabilities, but the iterator protocol only specifies the `__next__()` method. Functions may therefore consume all of the iterator's output, and if you need to do something different with the same stream, you'll have to create a new iterator.

Data Types That Support Iterators

We've already seen how lists and tuples support iterators. In fact, any Python sequence type, such as strings, will automatically support creation of an iterator.

Calling `iter()` on a dictionary returns an iterator that will loop over the dictionary's keys:

```
>>> m = {'Jan': 1, 'Feb': 2, 'Mar': 3, 'Apr': 4, 'May': 5,
'Jun': 6,
...      'Jul': 7, 'Aug': 8, 'Sep': 9, 'Oct': 10, 'Nov': 11,
'Dec': 12}
>>> for key in m:
...     print(key, m[key])
Jan 1
Feb 2
Mar 3
Apr 4
May 5
Jun 6
Jul 7
Aug 8
Sep 9
Oct 10
Nov 11
Dec 12
```

Note that starting with Python 3.7, dictionary iteration order is guaranteed to be the same as the insertion order. In earlier versions, the behaviour was unspecified and could vary between implementations.

Applying `iter()` to a dictionary always loops over the keys, but dictionaries have methods that return other iterators. If you want to iterate over values or key/value pairs, you can explicitly call the `values()` or `items()` methods to get an appropriate iterator.

The `dict()` constructor can accept an iterator that returns a finite stream of `(key, value)` tuples:

```
>>> L = [('Italy', 'Rome'), ('France', 'Paris'), ('US',
'Washington DC')]
>>> dict(iter(L))
{'Italy': 'Rome', 'France': 'Paris', 'US': 'Washington DC'}
```

Files also support iteration by calling the `readline()` method until there are no more lines in the file. This means you can read each line of a file like this:

```
for line in file:
    # do something for each line
    ...
```

Sets can take their contents from an iterable and let you iterate over the set’s elements:

```
>>> S = {2, 3, 5, 7, 11, 13}
>>> for i in S:
...     print(i)
2
3
5
7
11
13
```

Generator expressions and list comprehensions

Two common operations on an iterator’s output are 1) performing some operation for every element, 2) selecting a subset of elements that meet some condition. For example, given a list of strings, you might want to strip off trailing whitespace from each line or extract all the strings containing a given substring.

List comprehensions and generator expressions (short form: “listcomps” and “genexps”) are a concise notation for such operations, borrowed from the functional programming language Haskell (https://www.haskell.org/). You can strip all the whitespace from a stream of strings with the following code:

```
>>> line_list = ['  line 1\n', 'line 2  \n', ' \n', '']

>>> # Generator expression -- returns iterator
>>> stripped_iter = (line.strip() for line in line_list)
>>> # List comprehension -- returns list
>>> stripped_list = [line.strip() for line in line_list]
```

You can select only certain elements by adding an `"if"` condition:

```
>>> stripped_list = [line.strip() for line in line_list
...                  if line != ""]
```

With a list comprehension, you get back a Python list; `stripped_list` is a list containing the resulting lines, not an iterator. Generator expressions return an iterator that computes the values as necessary, not needing to materialize all the values at once. This means that list comprehensions aren’t useful if you’re working with iterators that return an infinite stream or a very large amount of data. Generator expressions are preferable in these situations.

Generator expressions are surrounded by parentheses (“()”) and list comprehensions are surrounded by square brackets (“[]”). Generator expressions have the form:

```
( expression for expr in sequence1
             if condition1
             for expr2 in sequence2
             if condition2
             for expr3 in sequence3
             ...
             if condition3
             for exprN in sequenceN
             if conditionN )
```

Again, for a list comprehension only the outside brackets are different (square brackets instead of parentheses).

The elements of the generated output will be the successive values of `expression`. The `if` clauses are all optional; if present, `expression` is only evaluated and added to the result when `condition` is true.

Generator expressions always have to be written inside parentheses, but the parentheses signalling a function call also count. If you want to create an iterator that will be immediately passed to a function you can write:

```
obj_total = sum(obj.count for obj in list_all_objects())
```

The `for...in` clauses contain the sequences to be iterated over. The sequences do not have to be the same length, because they are iterated over from left to right, **not** in parallel. For each element in `sequence1`, `sequence2` is looped over from the beginning. `sequence3` is then looped over for each resulting pair of elements from `sequence1` and `sequence2`.

To put it another way, a list comprehension or generator expression is equivalent to the following Python code:

```
for expr1 in sequence1:
    if not (condition1):
        continue   # Skip this element
    for expr2 in sequence2:
        if not (condition2):
            continue   # Skip this element
        ...
        for exprN in sequenceN:
            if not (conditionN):
                continue   # Skip this element

            # Output the value of
            # the expression.
```

This means that when there are multiple `for...in` clauses but no `if` clauses, the length of the resulting output will be equal to the product of the lengths of all the sequences. If you have two lists of length 3, the output list is 9 elements long:

```
>>> seq1 = 'abc'
>>> seq2 = (1, 2, 3)
>>> [(x, y) for x in seq1 for y in seq2]
[('a', 1), ('a', 2), ('a', 3),
 ('b', 1), ('b', 2), ('b', 3),
 ('c', 1), ('c', 2), ('c', 3)]
```

To avoid introducing an ambiguity into Python’s grammar, if `expression` is creating a tuple, it must be surrounded with parentheses. The first list comprehension below is a syntax error, while the second one is correct:

```
# Syntax error
[x, y for x in seq1 for y in seq2]
# Correct
[(x, y) for x in seq1 for y in seq2]
```

Generators

Generators are a special class of functions that simplify the task of writing iterators. Regular functions compute a value and return it, but generators return an iterator that returns a stream of values.

You’re doubtless familiar with how regular function calls work in Python or C. When you call a function, it gets a private namespace where its local variables are created. When the function reaches a `return` statement, the local variables are destroyed and the value is returned to the caller. A later call to the same function creates a new private namespace and a fresh set of local variables. But, what if the local variables weren’t thrown away on exiting a function? What if you could later resume the function where it left off? This is what generators provide; they can be thought of as resumable functions.

Here’s the simplest example of a generator function:

```
>>> def generate_ints(N):
...    for i in range(N):
...        yield i
```

Any function containing a **`yield`** keyword is a generator function; this is detected by Python's bytecode compiler which compiles the function specially as a result.

When you call a generator function, it doesn't return a single value; instead it returns a generator object that supports the iterator protocol. On executing the `yield` expression, the generator outputs the value of `i`, similar to a `return` statement. The big difference between `yield` and a `return` statement is that on reaching a `yield` the generator's state of execution is suspended and local variables are preserved. On the next call to the generator's **`__next__()`** method, the function will resume executing.

Here's a sample usage of the `generate_ints()` generator:

```
>>> gen = generate_ints(3)
>>> gen
<generator object generate_ints at ...>
>>> next(gen)
0
>>> next(gen)
1
>>> next(gen)
2
>>> next(gen)
Traceback (most recent call last):
  File "stdin", line 1, in <module>
  File "stdin", line 2, in generate_ints
StopIteration
```

You could equally write `for i in generate_ints(5)`, or `a, b, c = generate_ints(3)`.

Inside a generator function, `return value` causes `StopIteration(value)` to be raised from the `__next__()` method. Once this happens, or the bottom of the function is reached, the procession of values ends and the generator cannot yield any further values.

You could achieve the effect of generators manually by writing your own class and storing all the local variables of the generator as instance variables. For example, returning a list of integers could be done by setting `self.count` to 0, and having the `__next__()` method increment `self.count` and return it. However, for a moderately complicated generator, writing a corresponding class can be much messier.

The test suite included with Python's library, Lib/test/test_generators.py [https://github.com/python/cpython/tree/3.14/Lib/test/test_generators.py], contains a number of more interesting examples. Here's one generator that implements an in-order traversal of a tree using generators recursively.

```
# A recursive generator that generates Tree leaves in in-order.
def inorder(t):
    if t:
        for x in inorder(t.left):
            yield x

        yield t.label

        for x in inorder(t.right):
            yield x
```

Two other examples in `test_generators.py` produce solutions for the N-Queens problem (placing N queens on an NxN chess board so that no queen threatens another) and the Knight's Tour (finding a route that takes a knight to every square of an NxN chessboard without visiting any square twice).

Passing values into a generator

In Python 2.4 and earlier, generators only produced output. Once a generator's code was invoked to create an iterator, there was no way to pass any new information into the function when its execution is resumed. You could hack together this ability by making the generator look at a global variable or by passing in some mutable object that callers then modify, but these approaches are messy.

In Python 2.5 there's a simple way to pass values into a generator. `yield` became an expression, returning a value that can be assigned to a variable or otherwise operated on:

```
val = (yield i)
```

I recommend that you **always** put parentheses around a `yield` expression when you're doing something with the returned value, as in the above example. The parentheses aren't always necessary, but it's easier to always add them instead of having to remember when they're needed.

(**PEP 342** [https://peps.python.org/pep-0342/] explains the exact rules, which are that a `yield`-expression must always be parenthesized except when it occurs at the top-level expression on the right-hand side of an assignment. This means you can write `val = yield i` but have to use parentheses when there's an operation, as in `val = (yield i) + 12`.)

Values are sent into a generator by calling its `send(value)` method. This method resumes the generator's code and the `yield` expression returns the specified value. If the regular `__next__()` method is called, the `yield` returns `None`.

Here's a simple counter that increments by 1 and allows changing the value of the internal counter.

```
def counter(maximum):
    i = 0
    while i < maximum:
        val = (yield i)
        # If value provided, change counter
        if val is not None:
            i = val
        else:
            i += 1
```

And here’s an example of changing the counter:

```
>>> it = counter(10)
>>> next(it)
0
>>> next(it)
1
>>> it.send(8)
8
>>> next(it)
9
>>> next(it)
Traceback (most recent call last):
  File "t.py", line 15, in <module>
    it.next()
StopIteration
```

Because `yield` will often be returning `None`, you should always check for this case. Don’t just use its value in expressions unless you’re sure that the `send()` method will be the only method used to resume your generator function.

In addition to `send()`, there are two other methods on generators:

- `throw(value)` is used to raise an exception inside the generator; the exception is raised by the `yield` expression where the generator’s execution is paused.

- `close()` sends a `GeneratorExit` exception to the generator to terminate the iteration. On receiving this exception, the generator's code must either raise `GeneratorExit` or `StopIteration`; catching the exception and doing anything else is illegal and will trigger a `RuntimeError`. `close()` will also be called by Python's garbage collector when the generator is garbage-collected.

  If you need to run cleanup code when a `GeneratorExit` occurs, I suggest using a `try: ... finally:` suite instead of catching `GeneratorExit`.

The cumulative effect of these changes is to turn generators from one-way producers of information into both producers and consumers.

Generators also become **coroutines**, a more generalized form of subroutines. Subroutines are entered at one point and exited at another point (the top of the function, and a `return` statement), but coroutines can be entered, exited, and resumed at many different points (the `yield` statements).

Built-in functions

Let's look in more detail at built-in functions often used with iterators.

Two of Python's built-in functions, `map()` and `filter()` duplicate the features of generator expressions:

`map(f, iterA, iterB, ...)` returns an iterator over the sequence

```
f(iterA[0], iterB[0]), f(iterA[1], iterB[1]), f(iterA[2], iterB[2]), ....
```

```
>>> def upper(s):
...     return s.upper()

>>> list(map(upper, ['sentence', 'fragment']))
['SENTENCE', 'FRAGMENT']
>>> [upper(s) for s in ['sentence', 'fragment']]
['SENTENCE', 'FRAGMENT']
```

You can of course achieve the same effect with a list comprehension.

`filter(predicate, iter)` returns an iterator over all the sequence elements that meet a certain condition, and is similarly duplicated by list comprehensions. A **predicate** is a function that returns the truth value of some condition; for use with `filter()`, the predicate must take a single value.

```
>>> def is_even(x):
...     return (x % 2) == 0

>>> list(filter(is_even, range(10)))
[0, 2, 4, 6, 8]
```

This can also be written as a list comprehension:

```
>>> list(x for x in range(10) if is_even(x))
[0, 2, 4, 6, 8]
```

`enumerate(iter, start=0)` counts off the elements in the iterable returning 2-tuples containing the count (from *start*) and each element.

```
>>> for item in enumerate(['subject', 'verb', 'object']):
...     print(item)
(0, 'subject')
(1, 'verb')
(2, 'object')
```

`enumerate()` is often used when looping through a list and recording the indexes at which certain conditions are met:

```
f = open('data.txt', 'r')
for i, line in enumerate(f):
    if line.strip() == '':
        print('Blank line at line #%i' % i)
```

`sorted(iterable, key=None, reverse=False)` collects all the elements of the iterable into a list, sorts the list, and returns the sorted result. The *key* and *reverse* arguments are passed through to the constructed list's `sort()` method.

```
>>> import random
>>> # Generate 8 random numbers between [0, 10000)
>>> rand_list = random.sample(range(10000), 8)
>>> rand_list
[769, 7953, 9828, 6431, 8442, 9878, 6213, 2207]
>>> sorted(rand_list)
[769, 2207, 6213, 6431, 7953, 8442, 9828, 9878]
>>> sorted(rand_list, reverse=True)
[9878, 9828, 8442, 7953, 6431, 6213, 2207, 769]
```

(For a more detailed discussion of sorting, see the Sorting Techniques.)

The `any(iter)` and `all(iter)` built-ins look at the truth values of an iterable's contents. `any()` returns `True` if any element in the iterable is a true value, and `all()` returns `True` if all of the elements are true values:

```
>>> any([0, 1, 0])
True
>>> any([0, 0, 0])
False
>>> any([1, 1, 1])
True
>>> all([0, 1, 0])
False
>>> all([0, 0, 0])
False
>>> all([1, 1, 1])
True
```

`zip(iterA, iterB, ...)` takes one element from each iterable and returns them in a tuple:

```
zip(['a', 'b', 'c'], (1, 2, 3)) =>
  ('a', 1), ('b', 2), ('c', 3)
```

It doesn’t construct an in-memory list and exhaust all the input iterators before returning; instead tuples are constructed and returned only if they’re requested. (The technical term for this behaviour is lazy evaluation [https://en.wikipedia.org/wiki/Lazy_evaluation].)

This iterator is intended to be used with iterables that are all of the same length. If the iterables are of different lengths, the resulting stream will be the same length as the shortest iterable.

```
zip(['a', 'b'], (1, 2, 3)) =>
  ('a', 1), ('b', 2)
```

You should avoid doing this, though, because an element may be taken from the longer iterators and discarded. This means you can’t go on to use the iterators further because you risk skipping a discarded element.

The itertools module

The `itertools` module contains a number of commonly used iterators as well as functions for combining several iterators. This section will introduce the module’s contents by showing small examples.

The module’s functions fall into a few broad classes:

- Functions that create a new iterator based on an existing iterator.

- Functions for treating an iterator’s elements as function arguments.
- Functions for selecting portions of an iterator’s output.
- A function for grouping an iterator’s output.

Creating new iterators

`itertools.count(start, step)` returns an infinite stream of evenly spaced values. You can optionally supply the starting number, which defaults to 0, and the interval between numbers, which defaults to 1:

```
itertools.count() =>
  0, 1, 2, 3, 4, 5, 6, 7, 8, 9, ...
itertools.count(10) =>
  10, 11, 12, 13, 14, 15, 16, 17, 18, 19, ...
itertools.count(10, 5) =>
  10, 15, 20, 25, 30, 35, 40, 45, 50, 55, ...
```

`itertools.cycle(iter)` saves a copy of the contents of a provided iterable and returns a new iterator that returns its elements from first to last. The new iterator will repeat these elements infinitely.

```
itertools.cycle([1, 2, 3, 4, 5]) =>
  1, 2, 3, 4, 5, 1, 2, 3, 4, 5, ...
```

`itertools.repeat(elem, [n])` returns the provided element *n* times, or returns the element endlessly if *n* is not provided.

```
itertools.repeat('abc') =>
  abc, abc, abc, abc, abc, abc, abc, abc, abc, abc, ...
itertools.repeat('abc', 5) =>
  abc, abc, abc, abc, abc
```

`itertools.chain(iterA, iterB, ...)` takes an arbitrary number of iterables as input, and returns all the elements of the first iterator, then all the elements of the second, and so on, until all of the iterables have been exhausted.

```
itertools.chain(['a', 'b', 'c'], (1, 2, 3)) =>
  a, b, c, 1, 2, 3
```

`itertools.islice(iter, [start], stop, [step])` returns a stream that's a slice of the iterator. With a single *stop* argument, it will return the first *stop* elements. If you supply a starting index, you'll get *stop-start* elements, and if you supply a value for *step*, elements will be skipped accordingly. Unlike Python's string and list slicing, you can't use negative values for *start*, *stop*, or *step*.

```
itertools.islice(range(10), 8) =>
  0, 1, 2, 3, 4, 5, 6, 7
itertools.islice(range(10), 2, 8) =>
  2, 3, 4, 5, 6, 7
itertools.islice(range(10), 2, 8, 2) =>
  2, 4, 6
```

`itertools.tee(iter, [n])` replicates an iterator; it returns *n* independent iterators that will all return the contents of the source iterator. If you don't supply a value for *n*, the default is 2. Replicating iterators requires saving some of the contents of the source iterator, so this can consume significant memory if the iterator is large and one of the new iterators is consumed more than the others.

```
itertools.tee( itertools.count() ) =>
   iterA, iterB

where iterA ->
   0, 1, 2, 3, 4, 5, 6, 7, 8, 9, ...

and   iterB ->
   0, 1, 2, 3, 4, 5, 6, 7, 8, 9, ...
```

Calling functions on elements

The `operator` module contains a set of functions corresponding to Python's operators. Some examples are `operator.add(a, b)` (adds two values), `operator.ne(a, b)` (same as `a != b`), and `operator.attrgetter('id')` (returns a callable that fetches the `.id` attribute).

`itertools.starmap(func, iter)` assumes that the iterable will return a stream of tuples, and calls *func* using these tuples as the arguments:

```
itertools.starmap(os.path.join,
                  [('/bin', 'python'), ('/usr', 'bin', 'java'),
                   ('/usr', 'bin', 'perl'), ('/usr', 'bin',
'ruby')])
=>
  /bin/python, /usr/bin/java, /usr/bin/perl, /usr/bin/ruby
```

Selecting elements

Another group of functions chooses a subset of an iterator's elements based on a predicate.

`itertools.filterfalse(predicate, iter)` is the opposite of `filter()`, returning all elements for which the predicate returns false:

```
itertools.filterfalse(is_even, itertools.count()) =>
  1, 3, 5, 7, 9, 11, 13, 15, ...
```

`itertools.takewhile(predicate, iter)` returns elements for as long as the predicate returns true. Once the predicate returns false, the iterator will signal the end of its results.

```
def less_than_10(x):
    return x < 10

itertools.takewhile(less_than_10, itertools.count()) =>
  0, 1, 2, 3, 4, 5, 6, 7, 8, 9

itertools.takewhile(is_even, itertools.count()) =>
  0
```

`itertools.dropwhile(predicate, iter)` discards elements while the predicate returns true, and then returns the rest of the iterable's results.

```
itertools.dropwhile(less_than_10, itertools.count()) =>
  10, 11, 12, 13, 14, 15, 16, 17, 18, 19, ...

itertools.dropwhile(is_even, itertools.count()) =>
  1, 2, 3, 4, 5, 6, 7, 8, 9, 10, ...
```

`itertools.compress(data, selectors)` takes two iterators and returns only those elements of *data* for which the corresponding element of *selectors* is true, stopping whenever either one is exhausted:

```
itertools.compress([1, 2, 3, 4, 5], [True, True, False, False,
True]) =>
   1, 2, 5
```

Combinatoric functions

The `itertools.combinations(iterable, r)` returns an iterator giving all possible *r*-tuple combinations of the elements contained in *iterable*.

```
itertools.combinations([1, 2, 3, 4, 5], 2) =>
  (1, 2), (1, 3), (1, 4), (1, 5),
  (2, 3), (2, 4), (2, 5),
  (3, 4), (3, 5),
  (4, 5)

itertools.combinations([1, 2, 3, 4, 5], 3) =>
  (1, 2, 3), (1, 2, 4), (1, 2, 5), (1, 3, 4), (1, 3, 5), (1, 4,
5),
  (2, 3, 4), (2, 3, 5), (2, 4, 5),
  (3, 4, 5)
```

The elements within each tuple remain in the same order as *iterable* returned them. For example, the number 1 is always before 2, 3, 4, or 5 in the examples above. A similar function, [`itertools.permutations(iterable, r=None)`](), removes this constraint on the order, returning all possible arrangements of length *r*:

```
itertools.permutations([1, 2, 3, 4, 5], 2) =>
  (1, 2), (1, 3), (1, 4), (1, 5),
  (2, 1), (2, 3), (2, 4), (2, 5),
  (3, 1), (3, 2), (3, 4), (3, 5),
  (4, 1), (4, 2), (4, 3), (4, 5),
  (5, 1), (5, 2), (5, 3), (5, 4)

itertools.permutations([1, 2, 3, 4, 5]) =>
  (1, 2, 3, 4, 5), (1, 2, 3, 5, 4), (1, 2, 4, 3, 5),
  ...
  (5, 4, 3, 2, 1)
```

If you don’t supply a value for *r* the length of the iterable is used, meaning that all the elements are permuted.

Note that these functions produce all of the possible combinations by position and don’t require that the contents of *iterable* are unique:

```
itertools.permutations('aba', 3) =>
  ('a', 'b', 'a'), ('a', 'a', 'b'), ('b', 'a', 'a'),
  ('b', 'a', 'a'), ('a', 'a', 'b'), ('a', 'b', 'a')
```

The identical tuple `('a', 'a', 'b')` occurs twice, but the two ‘a’ strings came from different positions.

The [`itertools.combinations_with_replacement(iterable, r)`]() function relaxes a different constraint: elements can be repeated within a single tuple. Conceptually an element is selected for the first position of each tuple and then is replaced before the second element is selected.

```
itertools.combinations_with_replacement([1, 2, 3, 4, 5], 2) =>
  (1, 1), (1, 2), (1, 3), (1, 4), (1, 5),
  (2, 2), (2, 3), (2, 4), (2, 5),
  (3, 3), (3, 4), (3, 5),
  (4, 4), (4, 5),
  (5, 5)
```

Grouping elements

The last function I’ll discuss, `itertools.groupby(iter, key_func=None)`, is the most complicated. `key_func(elem)` is a function that can compute a key value for each element returned by the iterable. If you don’t supply a key function, the key is simply each element itself.

`groupby()` collects all the consecutive elements from the underlying iterable that have the same key value, and returns a stream of 2-tuples containing a key value and an iterator for the elements with that key.

```
city_list = [('Decatur', 'AL'), ('Huntsville', 'AL'), ('Selma',
'AL'),
             ('Anchorage', 'AK'), ('Nome', 'AK'),
             ('Flagstaff', 'AZ'), ('Phoenix', 'AZ'), ('Tucson',
'AZ'),
             ...
            ]

def get_state(city_state):
    return city_state[1]

itertools.groupby(city_list, get_state) =>
  ('AL', iterator-1),
  ('AK', iterator-2),
  ('AZ', iterator-3), ...

where
iterator-1 =>
  ('Decatur', 'AL'), ('Huntsville', 'AL'), ('Selma', 'AL')
iterator-2 =>
  ('Anchorage', 'AK'), ('Nome', 'AK')
iterator-3 =>
  ('Flagstaff', 'AZ'), ('Phoenix', 'AZ'), ('Tucson', 'AZ')
```

`groupby()` assumes that the underlying iterable's contents will already be sorted based on the key. Note that the returned iterators also use the underlying iterable, so you have to consume the results of iterator-1 before requesting iterator-2 and its corresponding key.

The functools module

The `functools` module contains some higher-order functions. A **higher-order function** takes one or more functions as input and returns a new function. The most useful tool in this module is the `functools.partial()` function.

For programs written in a functional style, you'll sometimes want to construct variants of existing functions that have some of the parameters filled in. Consider a Python function `f(a, b, c)`; you may wish to create a new function `g(b, c)` that's equivalent to `f(1, b, c)`; you're filling in a value for one of `f()`'s parameters. This is called "partial function application".

The constructor for `partial()` takes the arguments `(function, arg1, arg2, ..., kwarg1=value1, kwarg2=value2)`. The resulting object is callable, so you can just call it to invoke `function` with the filled-in arguments.

Here's a small but realistic example:

```
import functools

def log(message, subsystem):
    """Write the contents of 'message' to the specified
subsystem."""
    print('%s: %s' % (subsystem, message))
    ...
```

```
server_log = functools.partial(log, subsystem='server')
server_log('Unable to open socket')
```

`functools.reduce(func, iter, [initial_value])` cumulatively performs an operation on all the iterable's elements and, therefore, can't be applied to infinite iterables. *func* must be a function that takes two elements and returns a single value. **`functools.reduce()`** takes the first two elements A and B returned by the iterator and calculates `func(A, B)`. It then requests the third element, C, calculates `func(func(A, B), C)`, combines this result with the fourth element returned, and continues until the iterable is exhausted. If the iterable returns no values at all, a **`TypeError`** exception is raised. If the initial value is supplied, it's used as a starting point and `func(initial_value, A)` is the first calculation.

```
>>> import operator, functools
>>> functools.reduce(operator.concat, ['A', 'BB', 'C'])
'ABBC'
>>> functools.reduce(operator.concat, [])
Traceback (most recent call last):
  ...
TypeError: reduce() of empty sequence with no initial value
>>> functools.reduce(operator.mul, [1, 2, 3], 1)
6
>>> functools.reduce(operator.mul, [], 1)
1
```

If you use **`operator.add()`** with **`functools.reduce()`**, you'll add up all the elements of the iterable. This case is so common that there's a special built-in called **`sum()`** to compute it:

```
>>> import functools, operator
>>> functools.reduce(operator.add, [1, 2, 3, 4], 0)
10
>>> sum([1, 2, 3, 4])
10
>>> sum([])
0
```

For many uses of `functools.reduce()`, though, it can be clearer to just write the obvious `for` loop:

```
import functools
# Instead of:
product = functools.reduce(operator.mul, [1, 2, 3], 1)

# You can write:
product = 1
for i in [1, 2, 3]:
    product *= i
```

A related function is `itertools.accumulate(iterable, func=operator.add)`. It performs the same calculation, but instead of returning only the final result, `accumulate()` returns an iterator that also yields each partial result:

```
itertools.accumulate([1, 2, 3, 4, 5]) =>
  1, 3, 6, 10, 15

itertools.accumulate([1, 2, 3, 4, 5], operator.mul) =>
  1, 2, 6, 24, 120
```

The operator module

The `operator` module was mentioned earlier. It contains a set of functions corresponding to Python’s operators. These functions are often useful in functional-style code because they save you from writing trivial functions that perform a single operation.

Some of the functions in this module are:

- Math operations: `add()`, `sub()`, `mul()`, `floordiv()`, `abs()`, …
- Logical operations: `not_()`, `truth()`.
- Bitwise operations: `and_()`, `or_()`, `invert()`.
- Comparisons: `eq()`, `ne()`, `lt()`, `le()`, `gt()`, and `ge()`.
- Object identity: `is_()`, `is_not()`.

Consult the operator module’s documentation for a complete list.

Small functions and the lambda expression

When writing functional-style programs, you’ll often need little functions that act as predicates or that combine elements in some way.

If there’s a Python built-in or a module function that’s suitable, you don’t need to define a new function at all:

```
stripped_lines = [line.strip() for line in lines]
existing_files = filter(os.path.exists, file_list)
```

If the function you need doesn’t exist, you need to write it. One way to write small functions is to use the **`lambda`** expression. `lambda` takes a number of parameters and an expression combining these parameters, and creates an anonymous function that returns the value of the expression:

```
adder = lambda x, y: x+y

print_assign = lambda name, value: name + '=' + str(value)
```

An alternative is to just use the `def` statement and define a function in the usual way:

```
def adder(x, y):
    return x + y

def print_assign(name, value):
    return name + '=' + str(value)
```

Which alternative is preferable? That’s a style question; my usual course is to avoid using `lambda`.

One reason for my preference is that `lambda` is quite limited in the functions it can define. The result has to be computable as a single expression, which means you can't have multiway `if... elif... else` comparisons or `try... except` statements. If you try to do too much in a `lambda` statement, you'll end up with an overly complicated expression that's hard to read. Quick, what's the following code doing?

```
import functools
total = functools.reduce(lambda a, b: (0, a[1] + b[1]), items)
[1]
```

You can figure it out, but it takes time to disentangle the expression to figure out what's going on. Using a short nested `def` statements makes things a little bit better:

```
import functools
def combine(a, b):
    return 0, a[1] + b[1]

total = functools.reduce(combine, items)[1]
```

But it would be best of all if I had simply used a `for` loop:

```
total = 0
for a, b in items:
    total += b
```

Or the `sum()` built-in and a generator expression:

```
total = sum(b for a, b in items)
```

Many uses of `functools.reduce()` are clearer when written as `for` loops.

Fredrik Lundh once suggested the following set of rules for refactoring uses of `lambda`:

1. Write a lambda function.
2. Write a comment explaining what the heck that lambda does.
3. Study the comment for a while, and think of a name that captures the essence of the comment.
4. Convert the lambda to a def statement, using that name.
5. Remove the comment.

I really like these rules, but you’re free to disagree about whether this lambda-free style is better.

Revision History and Acknowledgements

The author would like to thank the following people for offering suggestions, corrections and assistance with various drafts of this article: Ian Bicking, Nick Coghlan, Nick Efford, Raymond Hettinger, Jim Jewett, Mike Krell, Leandro Lameiro, Jussi Salmela, Collin Winter, Blake Winton.

Version 0.1: posted June 30 2006.

Version 0.11: posted July 1 2006. Typo fixes.

Version 0.2: posted July 10 2006. Merged genexp and listcomp sections into one. Typo fixes.

Version 0.21: Added more references suggested on the tutor mailing list.

Version 0.30: Adds a section on the `functional` module written by Collin Winter; adds short section on the operator module; a few other edits.

Logging HOWTO

Author:: Vinay Sajip <vinay_sajip at red-dove dot com>

This page contains tutorial information. For links to reference information and a logging cookbook, please see Other resources.

Basic Logging Tutorial

Logging is a means of tracking events that happen when some software runs. The software's developer adds logging calls to their code to indicate that certain events have occurred. An event is described by a descriptive message which can optionally contain variable data (i.e. data that is potentially different for each occurrence of the event). Events also have an importance which the developer ascribes to the event; the importance can also be called the *level* or *severity*.

When to use logging

You can access logging functionality by creating a logger via `logger = getLogger(__name__)`, and then calling the logger's `debug()`, `info()`, `warning()`, `error()` and `critical()` methods. To determine when to use logging, and to see which logger methods to use when, see the table below. It states, for each of a set of common tasks, the best tool to use for that task.

Task you want to perform	The best tool for the task
Display console output for ordinary usage of a command line script or program	`print()`
Report events that occur during normal operation of a program (e.g. for status monitoring or fault investigation)	A logger's `info()` (or `debug()` method for very detailed output for diagnostic purposes)
Issue a warning regarding a particular runtime event	`warnings.warn()` in library code if the issue is avoidable and the client application should be modified to eliminate the warning A logger's `warning()` method if there is nothing the client application can do

Task you want to perform	The best tool for the task
	about the situation, but the event should still be noted
Report an error regarding a particular runtime event	Raise an exception
Report suppression of an error without raising an exception (e.g. error handler in a long-running server process)	A logger’s `error()`, `exception()` or `critical()` method as appropriate for the specific error and application domain

The logger methods are named after the level or severity of the events they are used to track. The standard levels and their applicability are described below (in increasing order of severity):

Level	When it’s used
`DEBUG`	Detailed information, typically of interest only when diagnosing problems.
`INFO`	Confirmation that things are working as expected.
`WARNING`	An indication that something unexpected happened, or indicative of some problem in the near future (e.g. ‘disk space low’). The software is still working as expected.
`ERROR`	Due to a more serious problem, the software has not been able to perform some function.
`CRITICAL`	A serious error, indicating that the program itself may be unable to continue running.

The default level is `WARNING`, which means that only events of this severity and higher will be tracked, unless the logging package is configured to do otherwise.

Events that are tracked can be handled in different ways. The simplest way of handling tracked events is to print them to the console. Another common way is to write them to a disk file.

A simple example

A very simple example is:

```
import logging
logging.warning('Watch out!')  # will print a message to the console
logging.info('I told you so')  # will not print anything
```

If you type these lines into a script and run it, you'll see:

```
WARNING:root:Watch out!
```

printed out on the console. The `INFO` message doesn't appear because the default level is `WARNING`. The printed message includes the indication of the level and the description of the event provided in the logging call, i.e. 'Watch out!'. The actual output can be formatted quite flexibly if you need that; formatting options will also be explained later.

Notice that in this example, we use functions directly on the `logging` module, like `logging.debug`, rather than creating a logger and calling functions on it. These functions operate on the root logger, but can be useful as they will call **`basicConfig()`** for you if it has not been called yet, like in this example. In larger programs you'll usually want to control the logging configuration explicitly however - so for that reason as well as others, it's better to create loggers and call their methods.

Logging to a file

A very common situation is that of recording logging events in a file, so let's look at that next. Be sure to try the following in a newly started Python interpreter, and don't just continue from the session described above:

```
import logging
logger = logging.getLogger(__name__)
logging.basicConfig(filename='example.log', encoding='utf-8', level=logging.DEBUG)
logger.debug('This message should go to the log file')
logger.info('So should this')
logger.warning('And this, too')
logger.error('And non-ASCII stuff, too, like Øresund and Malmö')
```

Changed in version 3.9: The *encoding* argument was added. In earlier Python versions, or if not specified, the encoding used is the default value used by **`open()`**. While not shown in the above example, an *errors* argument can also now be passed, which determines how encoding errors are handled. For available values and the default, see the documentation for **`open()`**.

And now if we open the file and look at what we have, we should find the log messages:

```
DEBUG:__main__:This message should go to the log file
INFO:__main__:So should this
WARNING:__main__:And this, too
ERROR:__main__:And non-ASCII stuff, too, like Øresund and Malmö
```

This example also shows how you can set the logging level which acts as the threshold for tracking. In this case, because we set the threshold to `DEBUG`, all of the messages were printed.

If you want to set the logging level from a command-line option such as:

```
--log=INFO
```

and you have the value of the parameter passed for `--log` in some variable *loglevel*, you can use:

```
getattr(logging, loglevel.upper())
```

to get the value which you'll pass to `basicConfig()` via the *level* argument. You may want to error check any user input value, perhaps as in the following example:

```
# assuming loglevel is bound to the string value obtained from the
# command line argument. Convert to upper case to allow the user to
# specify --log=DEBUG or --log=debug
numeric_level = getattr(logging, loglevel.upper(), None)
if not isinstance(numeric_level, int):
    raise ValueError('Invalid log level: %s' % loglevel)
logging.basicConfig(level=numeric_level, ...)
```

The call to `basicConfig()` should come *before* any calls to a logger's methods such as `debug()`, `info()`, etc. Otherwise, that logging event may not be handled in the desired manner.

If you run the above script several times, the messages from successive runs are appended to the file *example.log*. If you want each run to start afresh, not remembering the messages from earlier runs, you can specify the *filemode* argument, by changing the call in the above example to:

```
logging.basicConfig(filename='example.log', filemode='w', level=logging.DEBUG)
```

The output will be the same as before, but the log file is no longer appended to, so the messages from earlier runs are lost.

Logging variable data

To log variable data, use a format string for the event description message and append the variable data as arguments. For example:

```
import logging
logging.warning('%s before you %s', 'Look', 'leap!')
```

will display:

```
WARNING:root:Look before you leap!
```

As you can see, merging of variable data into the event description message uses the old, %-style of string formatting. This is for backwards compatibility: the logging package pre-dates newer formatting options such as **`str.format()`** and **`string.Template`**. These newer formatting options *are* supported, but exploring them is outside the scope of this tutorial: see Using particular formatting styles throughout your application for more information.

Changing the format of displayed messages

To change the format which is used to display messages, you need to specify the format you want to use:

```
import logging
logging.basicConfig(format='%(levelname)s:%(message)s', level=logging.DEBUG)
logging.debug('This message should appear on the console')
logging.info('So should this')
logging.warning('And this, too')
```

which would print:

```
DEBUG:This message should appear on the console
INFO:So should this
WARNING:And this, too
```

Notice that the 'root' which appeared in earlier examples has disappeared. For a full set of things that can appear in format strings, you can refer to the documentation for LogRecord attributes, but for simple usage, you just need the *levelname* (severity), *message* (event description, including variable data) and perhaps to display when the event occurred. This is described in the next section.

Displaying the date/time in messages

To display the date and time of an event, you would place '%(asctime)s' in your format string:

```
import logging
logging.basicConfig(format='%(asctime)s %(message)s')
logging.warning('is when this event was logged.')
```

which should print something like this:

```
2010-12-12 11:41:42,612 is when this event was logged.
```

The default format for date/time display (shown above) is like ISO8601 or **RFC 3339** [https://datatracker.ietf.org/doc/html/rfc3339.html]. If you need more control over the formatting of the date/time, provide a *datefmt* argument to `basicConfig`, as in this example:

```
import logging
logging.basicConfig(format='%(asctime)s %(message)s', datefmt='%m/%d/%Y %I:%M:%S %p')
logging.warning('is when this event was logged.')
```

which would display something like this:

```
12/12/2010 11:46:36 AM is when this event was logged.
```

The format of the *datefmt* argument is the same as supported by `time.strftime()`.

Next Steps

That concludes the basic tutorial. It should be enough to get you up and running with logging. There’s a lot more that the logging package offers, but to get the best out of it, you’ll need to invest a little more of your time in reading the following sections. If you’re ready for that, grab some of your favourite beverage and carry on.

If your logging needs are simple, then use the above examples to incorporate logging into your own scripts, and if you run into problems or don’t understand something, please post a question in the Help category of the Python discussion forum [https://discuss.python.org/c/help/7] and you should receive help before too long.

Still here? You can carry on reading the next few sections, which provide a slightly more advanced/in-depth tutorial than the basic one above. After that, you can take a look at the Logging Cookbook.

Advanced Logging Tutorial

The logging library takes a modular approach and offers several categories of components: loggers, handlers, filters, and formatters.

- Loggers expose the interface that application code directly uses.
- Handlers send the log records (created by loggers) to the appropriate destination.
- Filters provide a finer grained facility for determining which log records to output.
- Formatters specify the layout of log records in the final output.

Log event information is passed between loggers, handlers, filters and formatters in a `LogRecord` instance.

Logging is performed by calling methods on instances of the `Logger` class (hereafter called *loggers*). Each instance has a name, and they are conceptually arranged in a namespace hierarchy using dots (periods) as separators. For example, a logger named ‘scan’ is the parent of loggers ‘scan.text’, ‘scan.html’ and ‘scan.pdf’. Logger names can be anything you want, and indicate the area of an application in which a logged message originates.

A good convention to use when naming loggers is to use a module-level logger, in each module which uses logging, named as follows:

```
logger = logging.getLogger(__name__)
```

This means that logger names track the package/module hierarchy, and it’s intuitively obvious where events are logged just from the logger name.

The root of the hierarchy of loggers is called the root logger. That’s the logger used by the functions **`debug()`**, **`info()`**, **`warning()`**, **`error()`** and **`critical()`**, which just call the same-named method of the root logger. The functions and the methods have the same signatures. The root logger’s name is printed as ‘root’ in the logged output.

It is, of course, possible to log messages to different destinations. Support is included in the package for writing log messages to files, HTTP GET/POST locations, email via SMTP, generic sockets, queues, or OS-specific logging mechanisms such as syslog or the Windows NT event log. Destinations are served by *handler* classes. You can create your own log destination class if you have special requirements not met by any of the built-in handler classes.

By default, no destination is set for any logging messages. You can specify a destination (such as console or file) by using **`basicConfig()`** as in the tutorial examples. If you call the functions **`debug()`**, **`info()`**, **`warning()`**, **`error()`** and **`critical()`**, they will check to see if no destination is set; and if one is not set, they will set a destination of the console (`sys.stderr`) and a default format for the displayed message before delegating to the root logger to do the actual message output.

The default format set by **`basicConfig()`** for messages is:

```
severity:logger name:message
```

You can change this by passing a format string to **`basicConfig()`** with the *format* keyword argument. For all options regarding how a format string is constructed, see Formatter Objects.

Logging Flow

The flow of log event information in loggers and handlers is illustrated in the following diagram.

Loggers

`Logger` objects have a threefold job. First, they expose several methods to application code so that applications can log messages at runtime. Second, logger objects determine which log messages to act upon based upon severity (the default filtering facility) or filter objects. Third, logger objects pass along relevant log messages to all interested log handlers.

The most widely used methods on logger objects fall into two categories: configuration and message sending.

These are the most common configuration methods:

- `Logger.setLevel()` specifies the lowest-severity log message a logger will handle, where debug is the lowest built-in severity level and critical is the highest built-in severity. For example, if the severity level is INFO, the logger will handle only INFO, WARNING, ERROR, and CRITICAL messages and will ignore DEBUG messages.
- `Logger.addHandler()` and `Logger.removeHandler()` add and remove handler objects from the logger object. Handlers are covered in more detail in Handlers.
- `Logger.addFilter()` and `Logger.removeFilter()` add and remove filter objects from the logger object. Filters are covered in more detail in Filter Objects.

You don’t need to always call these methods on every logger you create. See the last two paragraphs in this section.

With the logger object configured, the following methods create log messages:

- `Logger.debug()`, `Logger.info()`, `Logger.warning()`, `Logger.error()`, and `Logger.critical()` all create log records with a message and a level that corresponds to their respective method names. The message is actually a format string, which may contain the standard string substitution syntax of `%s`, `%d`, `%f`, and so on. The rest of their arguments is a list of objects that correspond with the substitution fields in the message. With regard to `**kwargs`, the logging methods care only about a keyword of `exc_info` and use it to determine whether to log exception information.
- `Logger.exception()` creates a log message similar to `Logger.error()`. The difference is that `Logger.exception()` dumps a stack trace along with it. Call this method only from an exception handler.
- `Logger.log()` takes a log level as an explicit argument. This is a little more verbose for logging messages than using the log level convenience methods listed above, but this is how to log at custom log levels.

`getLogger()` returns a reference to a logger instance with the specified name if it is provided, or `root` if not. The names are period-separated hierarchical structures. Multiple calls to `getLogger()` with the same name will return a reference to the same logger object. Loggers that are further down in the hierarchical list are children of loggers higher up in the list. For example, given a logger with a name of `foo`, loggers with names of `foo.bar`, `foo.bar.baz`, and `foo.bam` are all descendants of `foo`.

Loggers have a concept of *effective level*. If a level is not explicitly set on a logger, the level of its parent is used instead as its effective level. If the parent has no explicit level set, *its* parent is examined, and so on - all ancestors are searched until an explicitly set level is found. The root logger always has an explicit level set (`WARNING` by default). When deciding whether to process an event, the effective level of the logger is used to determine whether the event is passed to the logger’s handlers.

Child loggers propagate messages up to the handlers associated with their ancestor loggers. Because of this, it is unnecessary to define and configure handlers for all the loggers an application uses. It is sufficient to configure handlers for a top-level logger and create child loggers as needed. (You can, however, turn off propagation by setting the *propagate* attribute of a logger to `False`.)

Handlers

`Handler` objects are responsible for dispatching the appropriate log messages (based on the log messages' severity) to the handler's specified destination. **`Logger`** objects can add zero or more handler objects to themselves with an **`addHandler()`** method. As an example scenario, an application may want to send all log messages to a log file, all log messages of error or higher to stdout, and all messages of critical to an email address. This scenario requires three individual handlers where each handler is responsible for sending messages of a specific severity to a specific location.

The standard library includes quite a few handler types (see Useful Handlers); the tutorials use mainly **`StreamHandler`** and **`FileHandler`** in its examples.

There are very few methods in a handler for application developers to concern themselves with. The only handler methods that seem relevant for application developers who are using the built-in handler objects (that is, not creating custom handlers) are the following configuration methods:

- The **`setLevel()`** method, just as in logger objects, specifies the lowest severity that will be dispatched to the appropriate destination. Why are there two **`setLevel()`** methods? The level set in the logger determines which severity of messages it will pass to its handlers. The level set in each handler determines which messages that handler will send on.
- **`setFormatter()`** selects a Formatter object for this handler to use.
- **`addFilter()`** and **`removeFilter()`** respectively configure and deconfigure filter objects on handlers.

Application code should not directly instantiate and use instances of **`Handler`**. Instead, the **`Handler`** class is a base class that defines the interface that all handlers should have and establishes some default behavior that child classes can use (or override).

Formatters

Formatter objects configure the final order, structure, and contents of the log message. Unlike the base **`logging.Handler`** class, application code may instantiate formatter classes, although you could likely subclass the formatter if your application needs special behavior. The constructor takes three optional arguments – a message format string, a date format string and a style indicator.

logging.Formatter.__init__(*fmt=None*, *datefmt=None*, *style='%'*)

If there is no message format string, the default is to use the raw message. If there is no date format string, the default date format is:

```
%Y-%m-%d %H:%M:%S
```

with the milliseconds tacked on at the end. The `style` is one of `'%'`, `'{'`, or `'$'`. If one of these is not specified, then `'%'` will be used.

If the `style` is `'%'`, the message format string uses `%(<dictionary key>)s` styled string substitution; the possible keys are documented in LogRecord attributes. If the style is `'{'`, the message format string is assumed to be compatible with **`str.format()`** (using keyword arguments), while if the style is `'$'` then the message format string should conform to what is expected by **`string.Template.substitute()`**.

Changed in version 3.2: Added the `style` parameter.

The following message format string will log the time in a human-readable format, the severity of the message, and the contents of the message, in that order:

```
'%(asctime)s - %(levelname)s - %(message)s'
```

Formatters use a user-configurable function to convert the creation time of a record to a tuple. By default, **`time.localtime()`** is used; to change this for a particular formatter instance, set the `converter` attribute of the instance to a function with the same signature as **`time.localtime()`** or **`time.gmtime()`**. To change it for all formatters, for example if you want all logging times to be shown in GMT, set the `converter` attribute in the Formatter class (to `time.gmtime` for GMT display).

Configuring Logging

Programmers can configure logging in three ways:

1. Creating loggers, handlers, and formatters explicitly using Python code that calls the configuration methods listed above.
2. Creating a logging config file and reading it using the **`fileConfig()`** function.
3. Creating a dictionary of configuration information and passing it to the **`dictConfig()`** function.

For the reference documentation on the last two options, see Configuration functions. The following example configures a very simple logger, a console handler, and a simple formatter using Python code:

```
import logging

# create logger
logger = logging.getLogger('simple_example')
logger.setLevel(logging.DEBUG)

# create console handler and set level to debug
```

```
ch = logging.StreamHandler()
ch.setLevel(logging.DEBUG)

# create formatter
formatter = logging.Formatter('%(asctime)s - %(name)s - %(levelname)s - %(message)s')

# add formatter to ch
ch.setFormatter(formatter)

# add ch to logger
logger.addHandler(ch)

# 'application' code
logger.debug('debug message')
logger.info('info message')
logger.warning('warn message')
logger.error('error message')
logger.critical('critical message')
```

Running this module from the command line produces the following output:

```
$ python simple_logging_module.py
2005-03-19 15:10:26,618 - simple_example - DEBUG - debug message
2005-03-19 15:10:26,620 - simple_example - INFO - info message
2005-03-19 15:10:26,695 - simple_example - WARNING - warn message
2005-03-19 15:10:26,697 - simple_example - ERROR - error message
2005-03-19 15:10:26,773 - simple_example - CRITICAL - critical message
```

The following Python module creates a logger, handler, and formatter nearly identical to those in the example listed above, with the only difference being the names of the objects:

```
import logging
import logging.config

logging.config.fileConfig('logging.conf')

# create logger
logger = logging.getLogger('simpleExample')

# 'application' code
logger.debug('debug message')
logger.info('info message')
logger.warning('warn message')
logger.error('error message')
logger.critical('critical message')
```

Here is the logging.conf file:

```
[loggers]
keys=root,simpleExample

[handlers]
keys=consoleHandler

[formatters]
keys=simpleFormatter
```

```
[logger_root]
level=DEBUG
handlers=consoleHandler

[logger_simpleExample]
level=DEBUG
handlers=consoleHandler
qualname=simpleExample
propagate=0

[handler_consoleHandler]
class=StreamHandler
level=DEBUG
formatter=simpleFormatter
args=(sys.stdout,)

[formatter_simpleFormatter]
format=%(asctime)s - %(name)s - %(levelname)s - %(message)s
```

The output is nearly identical to that of the non-config-file-based example:

```
$ python simple_logging_config.py
2005-03-19 15:38:55,977 - simpleExample - DEBUG - debug message
2005-03-19 15:38:55,979 - simpleExample - INFO - info message
2005-03-19 15:38:56,054 - simpleExample - WARNING - warn message
2005-03-19 15:38:56,055 - simpleExample - ERROR - error message
2005-03-19 15:38:56,130 - simpleExample - CRITICAL - critical message
```

You can see that the config file approach has a few advantages over the Python code approach, mainly separation of configuration and code and the ability of noncoders to easily modify the logging properties.

Warning

The **`fileConfig()`** function takes a default parameter, `disable_existing_loggers`, which defaults to `True` for reasons of backward compatibility. This may or may not be what you want, since it will cause any non-root loggers existing before the **`fileConfig()`** call to be disabled unless they (or an ancestor) are explicitly named in the configuration. Please refer to the reference documentation for more information, and specify `False` for this parameter if you wish.

The dictionary passed to **`dictConfig()`** can also specify a Boolean value with key `disable_existing_loggers`, which if not specified explicitly in the dictionary also defaults to being interpreted as `True`. This leads to the logger-disabling behaviour described above, which may not be what you want - in which case, provide the key explicitly with a value of `False`.

Note that the class names referenced in config files need to be either relative to the logging module, or absolute values which can be resolved using normal import mechanisms. Thus, you could use either **`WatchedFileHandler`** (relative to the logging module) or `mypackage.mymodule.MyHandler` (for a class defined in package `mypackage` and module `mymodule`, where `mypackage` is available on the Python import path).

In Python 3.2, a new means of configuring logging has been introduced, using dictionaries to hold configuration information. This provides a superset of the functionality of the config-file-based approach outlined above, and is the recommended configuration method for new applications and deployments. Because a Python dictionary is used to hold configuration information, and since you can populate that dictionary using different means, you have more options for configuration. For example, you can use a configuration file in JSON format, or, if you have access to YAML processing functionality, a file in YAML format, to populate the configuration dictionary. Or, of course, you can construct the dictionary in Python code, receive it in pickled form over a socket, or use whatever approach makes sense for your application.

Here’s an example of the same configuration as above, in YAML format for the new dictionary-based approach:

```
version: 1
formatters:
  simple:
    format: '%(asctime)s - %(name)s - %(levelname)s - %(message)s'
handlers:
  console:
    class: logging.StreamHandler
    level: DEBUG
    formatter: simple
    stream: ext://sys.stdout
loggers:
  simpleExample:
    level: DEBUG
    handlers: [console]
    propagate: no
root:
  level: DEBUG
  handlers: [console]
```

For more information about logging using a dictionary, see Configuration functions.

What happens if no configuration is provided

If no logging configuration is provided, it is possible to have a situation where a logging event needs to be output, but no handlers can be found to output the event.

The event is output using a ‘handler of last resort’, stored in **`lastResort`**. This internal handler is not associated with any logger, and acts like a **`StreamHandler`** which writes the event description message to the current value of `sys.stderr` (therefore respecting any redirections which may be in effect). No formatting is done on the message - just the bare event description message is printed. The handler’s level is set to `WARNING`, so all events at this and greater severities will be output.

Changed in version 3.2: For versions of Python prior to 3.2, the behaviour is as follows:

- If **`raiseExceptions`** is `False` (production mode), the event is silently dropped.
- If **`raiseExceptions`** is `True` (development mode), a message ‘No handlers could be found for logger X.Y.Z’ is printed once.

To obtain the pre-3.2 behaviour, **`lastResort`** can be set to `None`.

Configuring Logging for a Library

When developing a library which uses logging, you should take care to document how the library uses logging - for example, the names of loggers used. Some consideration also needs to be given to its logging configuration. If the using application does not use logging, and library code makes logging calls, then (as described in the previous section) events of severity `WARNING` and greater will be printed to `sys.stderr`. This is regarded as the best default behaviour.

If for some reason you *don’t* want these messages printed in the absence of any logging configuration, you can attach a do-nothing handler to the top-level logger for your library. This avoids the message being printed, since a handler will always be found for the library’s events: it just doesn’t produce any output. If the library user configures logging for application use, presumably that configuration will add some handlers, and if levels are suitably configured then logging calls made in library code will send output to those handlers, as normal.

A do-nothing handler is included in the logging package: **`NullHandler`** (since Python 3.1). An instance of this handler could be added to the top-level logger of the logging namespace used by the library (*if* you want to prevent your library’s logged events being output to `sys.stderr` in the absence of logging configuration). If all logging by a library *foo* is done using loggers with names matching ‘foo.x’, ‘foo.x.y’, etc. then the code:

```
import logging
logging.getLogger('foo').addHandler(logging.NullHandler())
```

should have the desired effect. If an organisation produces a number of libraries, then the logger name specified can be ‘orgname.foo’ rather than just ‘foo’.

Note

It is strongly advised that you *do not log to the root logger* in your library. Instead, use a logger with a unique and easily identifiable name, such as the `__name__` for your library’s top-level package or module. Logging to the root logger will make it difficult or impossible for the application developer to configure the logging verbosity or handlers of your library as they wish.

Note

It is strongly advised that you *do not add any handlers other than* `NullHandler` *to your library's loggers*. This is because the configuration of handlers is the prerogative of the application developer who uses your library. The application developer knows their target audience and what handlers are most appropriate for their application: if you add handlers 'under the hood', you might well interfere with their ability to carry out unit tests and deliver logs which suit their requirements.

Logging Levels

The numeric values of logging levels are given in the following table. These are primarily of interest if you want to define your own levels, and need them to have specific values relative to the predefined levels. If you define a level with the same numeric value, it overwrites the predefined value; the predefined name is lost.

Level	Numeric value
`CRITICAL`	50
`ERROR`	40
`WARNING`	30
`INFO`	20
`DEBUG`	10
`NOTSET`	0

Levels can also be associated with loggers, being set either by the developer or through loading a saved logging configuration. When a logging method is called on a logger, the logger compares its own level with the level associated with the method call. If the logger's level is higher than the method call's, no logging message is actually generated. This is the basic mechanism controlling the verbosity of logging output.

Logging messages are encoded as instances of the `LogRecord` class. When a logger decides to actually log an event, a `LogRecord` instance is created from the logging message.

Logging messages are subjected to a dispatch mechanism through the use of *handlers*, which are instances of subclasses of the `Handler` class. Handlers are responsible for ensuring that a logged message (in the form of a `LogRecord`) ends up in a particular location (or set of locations) which is useful for the target audience for that message (such as end users, support desk staff, system administrators, developers). Handlers are passed `LogRecord` instances intended for particular destinations. Each logger can have zero, one or more handlers associated with it (via the `addHandler()` method of `Logger`). In addition to any handlers directly associated with a logger, *all handlers associated with all ancestors of the logger* are called to dispatch the message (unless the *propagate* flag for a logger is set to a false value, at which point the passing to ancestor handlers stops).

Just as for loggers, handlers can have levels associated with them. A handler's level acts as a filter in the same way as a logger's level does. If a handler decides to actually dispatch an event, the `emit()` method is used to send the message to its destination. Most user-defined subclasses of `Handler` will need to override this `emit()`.

Custom Levels

Defining your own levels is possible, but should not be necessary, as the existing levels have been chosen on the basis of practical experience. However, if you are convinced that you need custom levels, great care should be exercised when doing this, and it is possibly *a very bad idea to define custom levels if you are developing a library*. That's because if multiple library authors all define their own custom levels, there is a chance that the logging output from such multiple libraries used together will be difficult for the using developer to control and/or interpret, because a given numeric value might mean different things for different libraries.

Useful Handlers

In addition to the base `Handler` class, many useful subclasses are provided:

1. `StreamHandler` instances send messages to streams (file-like objects).
2. `FileHandler` instances send messages to disk files.
3. `BaseRotatingHandler` is the base class for handlers that rotate log files at a certain point. It is not meant to be instantiated directly. Instead, use `RotatingFileHandler` or `TimedRotatingFileHandler`.

4. `RotatingFileHandler` instances send messages to disk files, with support for maximum log file sizes and log file rotation.
5. `TimedRotatingFileHandler` instances send messages to disk files, rotating the log file at certain timed intervals.
6. `SocketHandler` instances send messages to TCP/IP sockets. Since 3.4, Unix domain sockets are also supported.
7. `DatagramHandler` instances send messages to UDP sockets. Since 3.4, Unix domain sockets are also supported.
8. `SMTPHandler` instances send messages to a designated email address.
9. `SysLogHandler` instances send messages to a Unix syslog daemon, possibly on a remote machine.
10. `NTEventLogHandler` instances send messages to a Windows NT/2000/XP event log.
11. `MemoryHandler` instances send messages to a buffer in memory, which is flushed whenever specific criteria are met.
12. `HTTPHandler` instances send messages to an HTTP server using either `GET` or `POST` semantics.
13. `WatchedFileHandler` instances watch the file they are logging to. If the file changes, it is closed and reopened using the file name. This handler is only useful on Unix-like systems; Windows does not support the underlying mechanism used.
14. `QueueHandler` instances send messages to a queue, such as those implemented in the `queue` or `multiprocessing` modules.
15. `NullHandler` instances do nothing with error messages. They are used by library developers who want to use logging, but want to avoid the ‘No handlers could be found for logger *XXX*’ message which can be displayed if the library user has not configured logging. See Configuring Logging for a Library for more information.

Added in version 3.1: The `NullHandler` class.

Added in version 3.2: The `QueueHandler` class.

The `NullHandler`, `StreamHandler` and `FileHandler` classes are defined in the core logging package. The other handlers are defined in a sub-module, `logging.handlers`. (There is also another sub-module, `logging.config`, for configuration functionality.)

Logged messages are formatted for presentation through instances of the `Formatter` class. They are initialized with a format string suitable for use with the % operator and a dictionary.

For formatting multiple messages in a batch, instances of `BufferingFormatter` can be used. In addition to the format string (which is applied to each message in the batch), there is provision for header and trailer format strings.

When filtering based on logger level and/or handler level is not enough, instances of `Filter` can be added to both `Logger` and `Handler` instances (through their `addFilter()` method). Before deciding to process a message further, both loggers and handlers consult all their filters for permission. If any filter returns a false value, the message is not processed further.

The basic `Filter` functionality allows filtering by specific logger name. If this feature is used, messages sent to the named logger and its children are allowed through the filter, and all others dropped.

Exceptions raised during logging

The logging package is designed to swallow exceptions which occur while logging in production. This is so that errors which occur while handling logging events - such as logging misconfiguration, network or other similar errors - do not cause the application using logging to terminate prematurely.

`SystemExit` and `KeyboardInterrupt` exceptions are never swallowed. Other exceptions which occur during the `emit()` method of a `Handler` subclass are passed to its `handleError()` method.

The default implementation of `handleError()` in `Handler` checks to see if a module-level variable, `raiseExceptions`, is set. If set, a traceback is printed to `sys.stderr`. If not set, the exception is swallowed.

Note

The default value of `raiseExceptions` is `True`. This is because during development, you typically want to be notified of any exceptions that occur. It’s advised that you set `raiseExceptions` to `False` for production usage.

Using arbitrary objects as messages

In the preceding sections and examples, it has been assumed that the message passed when logging the event is a string. However, this is not the only possibility. You can pass an arbitrary object as a message, and its `__str__()` method will be called when the logging system needs to convert it to a string representation. In fact, if you want to, you can avoid computing a string representation altogether - for example, the `SocketHandler` emits an event by pickling it and sending it over the wire.

Optimization

Formatting of message arguments is deferred until it cannot be avoided. However, computing the arguments passed to the logging method can also be expensive, and you may want to avoid doing it if the logger will just throw away your event. To decide what to do, you can call the `isEnabledFor()` method which takes a level argument and returns true if the event would be created by the Logger for that level of call. You can write code like this:

```
if logger.isEnabledFor(logging.DEBUG):
    logger.debug('Message with %s, %s', expensive_func1(),
                                        expensive_func2())
```

so that if the logger's threshold is set above `DEBUG`, the calls to `expensive_func1` and `expensive_func2` are never made.

Note

In some cases, `isEnabledFor()` can itself be more expensive than you'd like (e.g. for deeply nested loggers where an explicit level is only set high up in the logger hierarchy). In such cases (or if you want to avoid calling a method in tight loops), you can cache the result of a call to `isEnabledFor()` in a local or instance variable, and use that instead of calling the method each time. Such a cached value would only need to be recomputed when the logging configuration changes dynamically while the application is running (which is not all that common).

There are other optimizations which can be made for specific applications which need more precise control over what logging information is collected. Here's a list of things you can do to avoid processing during logging which you don't need:

What you don't want to collect	How to avoid collecting it
Information about where calls were made from.	Set `logging._srcfile` to `None`. This avoids calling `sys._getframe()`, which may help to speed up your code in environments like PyPy (which can't speed up code that uses `sys._getframe()`).
Threading information.	Set `logging.logThreads` to `False`.
Current process ID (`os.getpid()`)	Set `logging.logProcesses` to `False`.
Current process name when using `multiprocessing` to manage multiple processes.	Set `logging.logMultiprocessing` to `False`.
Current `asyncio.Task` name when using `asyncio`.	Set `logging.logAsyncioTasks` to `False`.

Also note that the core logging module only includes the basic handlers. If you don’t import `logging.handlers` and `logging.config`, they won’t take up any memory.

A logging cookbook

Logging Cookbook

Author:: Vinay Sajip <vinay_sajip at red-dove dot com>

This page contains a number of recipes related to logging, which have been found useful in the past. For links to tutorial and reference information, please see Other resources.

Using logging in multiple modules

Multiple calls to `logging.getLogger('someLogger')` return a reference to the same logger object. This is true not only within the same module, but also across modules as long as it is in the same Python interpreter process. It is true for references to the same object; additionally, application code can define and configure a parent logger in one module and create (but not configure) a child logger in a separate module, and all logger calls to the child will pass up to the parent. Here is a main module:

```
import logging
import auxiliary_module

# create logger with 'spam_application'
logger = logging.getLogger('spam_application')
logger.setLevel(logging.DEBUG)
# create file handler which logs even debug messages
fh = logging.FileHandler('spam.log')
fh.setLevel(logging.DEBUG)
# create console handler with a higher log level
ch = logging.StreamHandler()
ch.setLevel(logging.ERROR)
# create formatter and add it to the handlers
formatter = logging.Formatter('%(asctime)s - %(name)s - %
(levelname)s - %(message)s')
fh.setFormatter(formatter)
ch.setFormatter(formatter)
# add the handlers to the logger
logger.addHandler(fh)
logger.addHandler(ch)

logger.info('creating an instance of
auxiliary_module.Auxiliary')
a = auxiliary_module.Auxiliary()
logger.info('created an instance of
auxiliary_module.Auxiliary')
logger.info('calling auxiliary_module.Auxiliary.do_something')
a.do_something()
logger.info('finished auxiliary_module.Auxiliary.do_something')
logger.info('calling auxiliary_module.some_function()')
auxiliary_module.some_function()
logger.info('done with auxiliary_module.some_function()')
```

Here is the auxiliary module:

```
import logging

# create logger
module_logger = logging.getLogger('spam_application.auxiliary')

class Auxiliary:
    def __init__(self):
        self.logger =
logging.getLogger('spam_application.auxiliary.Auxiliary')
        self.logger.info('creating an instance of Auxiliary')

    def do_something(self):
        self.logger.info('doing something')
        a = 1 + 1
        self.logger.info('done doing something')

def some_function():
    module_logger.info('received a call to "some_function"')
```

The output looks like this:

```
2005-03-23 23:47:11,663 - spam_application - INFO -
   creating an instance of auxiliary_module.Auxiliary
2005-03-23 23:47:11,665 - spam_application.auxiliary.Auxiliary
- INFO -
   creating an instance of Auxiliary
2005-03-23 23:47:11,665 - spam_application - INFO -
   created an instance of auxiliary_module.Auxiliary
2005-03-23 23:47:11,668 - spam_application - INFO -
   calling auxiliary_module.Auxiliary.do_something
2005-03-23 23:47:11,668 - spam_application.auxiliary.Auxiliary
- INFO -
   doing something
2005-03-23 23:47:11,669 - spam_application.auxiliary.Auxiliary
- INFO -
   done doing something
2005-03-23 23:47:11,670 - spam_application - INFO -
   finished auxiliary_module.Auxiliary.do_something
2005-03-23 23:47:11,671 - spam_application - INFO -
   calling auxiliary_module.some_function()
2005-03-23 23:47:11,672 - spam_application.auxiliary - INFO -
   received a call to 'some_function'
2005-03-23 23:47:11,673 - spam_application - INFO -
   done with auxiliary_module.some_function()
```

Logging from multiple threads

Logging from multiple threads requires no special effort. The following example shows logging from the main (initial) thread and another thread:

```
import logging
import threading
import time

def worker(arg):
    while not arg['stop']:
        logging.debug('Hi from myfunc')
        time.sleep(0.5)

def main():
    logging.basicConfig(level=logging.DEBUG, format='%
(relativeCreated)6d %(threadName)s %(message)s')
    info = {'stop': False}
    thread = threading.Thread(target=worker, args=(info,))
    thread.start()
    while True:
        try:
            logging.debug('Hello from main')
            time.sleep(0.75)
        except KeyboardInterrupt:
            info['stop'] = True
            break
    thread.join()

if __name__ == '__main__':
    main()
```

When run, the script should print something like the following:

```
   0 Thread-1 Hi from myfunc
   3 MainThread Hello from main
 505 Thread-1 Hi from myfunc
 755 MainThread Hello from main
1007 Thread-1 Hi from myfunc
1507 MainThread Hello from main
1508 Thread-1 Hi from myfunc
2010 Thread-1 Hi from myfunc
2258 MainThread Hello from main
2512 Thread-1 Hi from myfunc
3009 MainThread Hello from main
3013 Thread-1 Hi from myfunc
3515 Thread-1 Hi from myfunc
3761 MainThread Hello from main
4017 Thread-1 Hi from myfunc
4513 MainThread Hello from main
4518 Thread-1 Hi from myfunc
```

This shows the logging output interspersed as one might expect. This approach works for more threads than shown here, of course.

Multiple handlers and formatters

Loggers are plain Python objects. The `addHandler()` method has no minimum or maximum quota for the number of handlers you may add. Sometimes it will be beneficial for an application to log all messages of all severities to a text file while simultaneously logging errors or above to the console. To set this up, simply configure the appropriate handlers. The logging calls in the application code will remain unchanged. Here is a slight modification to the previous simple module-based configuration example:

```
import logging

logger = logging.getLogger('simple_example')
logger.setLevel(logging.DEBUG)
# create file handler which logs even debug messages
fh = logging.FileHandler('spam.log')
fh.setLevel(logging.DEBUG)
# create console handler with a higher log level
ch = logging.StreamHandler()
ch.setLevel(logging.ERROR)
# create formatter and add it to the handlers
formatter = logging.Formatter('%(asctime)s - %(name)s - %
(levelname)s - %(message)s')
ch.setFormatter(formatter)
fh.setFormatter(formatter)
# add the handlers to logger
logger.addHandler(ch)
logger.addHandler(fh)

# 'application' code
logger.debug('debug message')
logger.info('info message')
logger.warning('warn message')
logger.error('error message')
logger.critical('critical message')
```

Notice that the ‘application’ code does not care about multiple handlers. All that changed was the addition and configuration of a new handler named *fh*.

The ability to create new handlers with higher- or lower-severity filters can be very helpful when writing and testing an application. Instead of using many `print` statements for debugging, use `logger.debug`: Unlike the print statements, which you will have to delete or comment out later, the logger.debug statements can remain intact in the source code and remain dormant until you need them again. At that time, the only change that needs to happen is to modify the severity level of the logger and/or handler to debug.

Logging to multiple destinations

Let’s say you want to log to console and file with different message formats and in differing circumstances. Say you want to log messages with levels of DEBUG and higher to file, and those messages at level INFO and higher to the console. Let’s also assume that the file should contain timestamps, but the console messages should not. Here’s how you can achieve this:

```
import logging

# set up logging to file - see previous section for more
details
logging.basicConfig(level=logging.DEBUG,
                    format='%(asctime)s %(name)-12s %
(levelname)-8s %(message)s',
                    datefmt='%m-%d %H:%M',
                    filename='/tmp/myapp.log',
                    filemode='w')
# define a Handler which writes INFO messages or higher to the
sys.stderr
console = logging.StreamHandler()
console.setLevel(logging.INFO)
# set a format which is simpler for console use
```

```
formatter = logging.Formatter('%(name)-12s: %(levelname)-8s %
(message)s')
# tell the handler to use this format
console.setFormatter(formatter)
# add the handler to the root logger
logging.getLogger('').addHandler(console)

# Now, we can log to the root logger, or any other logger.
First the root...
logging.info('Jackdaws love my big sphinx of quartz.')

# Now, define a couple of other loggers which might represent
areas in your
# application:

logger1 = logging.getLogger('myapp.area1')
logger2 = logging.getLogger('myapp.area2')

logger1.debug('Quick zephyrs blow, vexing daft Jim.')
logger1.info('How quickly daft jumping zebras vex.')
logger2.warning('Jail zesty vixen who grabbed pay from quack.')
logger2.error('The five boxing wizards jump quickly.')
```

When you run this, on the console you will see

```
root        : INFO     Jackdaws love my big sphinx of quartz.
myapp.area1 : INFO     How quickly daft jumping zebras vex.
myapp.area2 : WARNING  Jail zesty vixen who grabbed pay from
quack.
myapp.area2 : ERROR    The five boxing wizards jump quickly.
```

and in the file you will see something like

```
10-22 22:19 root         INFO     Jackdaws love my big sphinx
of quartz.
10-22 22:19 myapp.area1  DEBUG    Quick zephyrs blow, vexing
daft Jim.
10-22 22:19 myapp.area1  INFO     How quickly daft jumping
zebras vex.
10-22 22:19 myapp.area2  WARNING  Jail zesty vixen who grabbed
pay from quack.
```

```
10-22 22:19 myapp.area2  ERROR    The five boxing wizards jump
quickly.
```

As you can see, the DEBUG message only shows up in the file. The other messages are sent to both destinations.

This example uses console and file handlers, but you can use any number and combination of handlers you choose.

Note that the above choice of log filename `/tmp/myapp.log` implies use of a standard location for temporary files on POSIX systems. On Windows, you may need to choose a different directory name for the log - just ensure that the directory exists and that you have the permissions to create and update files in it.

Custom handling of levels

Sometimes, you might want to do something slightly different from the standard handling of levels in handlers, where all levels above a threshold get processed by a handler. To do this, you need to use filters. Let’s look at a scenario where you want to arrange things as follows:

- Send messages of severity `INFO` and `WARNING` to `sys.stdout`
- Send messages of severity `ERROR` and above to `sys.stderr`
- Send messages of severity `DEBUG` and above to file `app.log`

Suppose you configure logging with the following JSON:

```
{
    "version": 1,
    "disable_existing_loggers": false,
    "formatters": {
        "simple": {
            "format": "%(levelname)-8s - %(message)s"
        }
    },
    "handlers": {
        "stdout": {
            "class": "logging.StreamHandler",
            "level": "INFO",
            "formatter": "simple",
            "stream": "ext://sys.stdout"
        },
        "stderr": {
            "class": "logging.StreamHandler",
            "level": "ERROR",
            "formatter": "simple",
            "stream": "ext://sys.stderr"
        },
        "file": {
            "class": "logging.FileHandler",
            "formatter": "simple",
            "filename": "app.log",
            "mode": "w"
        }
    },
    "root": {
        "level": "DEBUG",
        "handlers": [
            "stderr",
            "stdout",
            "file"
        ]
    }
}
```

This configuration does *almost* what we want, except that `sys.stdout` would show messages of severity `ERROR` and only events of this severity and higher will be tracked as well as `INFO` and `WARNING` messages. To prevent this, we can set up a filter which excludes those messages and add it to the relevant handler. This can be configured by adding a `filters` section parallel to `formatters` and `handlers`:

```
{
    "filters": {
        "warnings_and_below": {
            "()" : "__main__.filter_maker",
            "level": "WARNING"
        }
    }
}
```

and changing the section on the `stdout` handler to add it:

```
{
    "stdout": {
        "class": "logging.StreamHandler",
        "level": "INFO",
        "formatter": "simple",
        "stream": "ext://sys.stdout",
        "filters": ["warnings_and_below"]
    }
}
```

A filter is just a function, so we can define the `filter_maker` (a factory function) as follows:

```
def filter_maker(level):
    level = getattr(logging, level)

    def filter(record):
        return record.levelno <= level

    return filter
```

This converts the string argument passed in to a numeric level, and returns a function which only returns `True` if the level of the passed in record is at or below the specified level. Note that in this example I have defined the `filter_maker` in a test script `main.py` that I run from the command line, so its module will be `__main__` - hence the `__main__.filter_maker` in the filter configuration. You will need to change that if you define it in a different module.

With the filter added, we can run `main.py`, which in full is:

```
import json
import logging
import logging.config

CONFIG = '''
{
    "version": 1,
    "disable_existing_loggers": false,
    "formatters": {
        "simple": {
            "format": "%(levelname)-8s - %(message)s"
        }
    },
    "filters": {
        "warnings_and_below": {
            "()" : "__main__.filter_maker",
            "level": "WARNING"
        }
    },
    "handlers": {
        "stdout": {
            "class": "logging.StreamHandler",
            "level": "INFO",
            "formatter": "simple",
            "stream": "ext://sys.stdout",
            "filters": ["warnings_and_below"]
        },
        "stderr": {
            "class": "logging.StreamHandler",
            "level": "ERROR",
            "formatter": "simple",
            "stream": "ext://sys.stderr"
        },
        "file": {
            "class": "logging.FileHandler",
            "formatter": "simple",
            "filename": "app.log",
            "mode": "w"
        }
    },
    "root": {
        "level": "DEBUG",
        "handlers": [
            "stderr",
            "stdout",
            "file"
        ]
    }
}
'''

def filter_maker(level):
    level = getattr(logging, level)

    def filter(record):
        return record.levelno <= level

    return filter

logging.config.dictConfig(json.loads(CONFIG))
logging.debug('A DEBUG message')
logging.info('An INFO message')
logging.warning('A WARNING message')
logging.error('An ERROR message')
logging.critical('A CRITICAL message')
```

And after running it like this:

```
python main.py 2>stderr.log >stdout.log
```

We can see the results are as expected:

```
$ more *.log
::::::::::::::
app.log
::::::::::::::
DEBUG    - A DEBUG message
INFO     - An INFO message
WARNING  - A WARNING message
ERROR    - An ERROR message
CRITICAL - A CRITICAL message
::::::::::::::
stderr.log
::::::::::::::
ERROR    - An ERROR message
```

```
CRITICAL - A CRITICAL message
::::::::::::::
stdout.log
::::::::::::::
INFO     - An INFO message
WARNING  - A WARNING message
```

Configuration server example

Here is an example of a module using the logging configuration server:

```
import logging
import logging.config
import time
import os

# read initial config file
logging.config.fileConfig('logging.conf')

# create and start listener on port 9999
t = logging.config.listen(9999)
t.start()

logger = logging.getLogger('simpleExample')

try:
    # loop through logging calls to see the difference
    # new configurations make, until Ctrl+C is pressed
    while True:
        logger.debug('debug message')
        logger.info('info message')
        logger.warning('warn message')
        logger.error('error message')
        logger.critical('critical message')
        time.sleep(5)
except KeyboardInterrupt:
    # cleanup
    logging.config.stopListening()
    t.join()
```

And here is a script that takes a filename and sends that file to the server, properly preceded with the binary-encoded length, as the new logging configuration:

```
#!/usr/bin/env python
import socket, sys, struct

with open(sys.argv[1], 'rb') as f:
    data_to_send = f.read()

HOST = 'localhost'
PORT = 9999
s = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
print('connecting...')
s.connect((HOST, PORT))
print('sending config...')
s.send(struct.pack('>L', len(data_to_send)))
s.send(data_to_send)
s.close()
print('complete')
```

Dealing with handlers that block

Sometimes you have to get your logging handlers to do their work without blocking the thread you’re logging from. This is common in web applications, though of course it also occurs in other scenarios.

A common culprit which demonstrates sluggish behaviour is the `SMTPHandler`: sending emails can take a long time, for a number of reasons outside the developer’s control (for example, a poorly performing mail or network infrastructure). But almost any network-based handler can block: Even a `SocketHandler` operation may do a DNS query under the hood which is too slow (and this query can be deep in the socket library code, below the Python layer, and outside your control).

One solution is to use a two-part approach. For the first part, attach only a [`QueueHandler`] to those loggers which are accessed from performance-critical threads. They simply write to their queue, which can be sized to a large enough capacity or initialized with no upper bound to their size. The write to the queue will typically be accepted quickly, though you will probably need to catch the [`queue.Full`] exception as a precaution in your code. If you are a library developer who has performance-critical threads in their code, be sure to document this (together with a suggestion to attach only `QueueHandlers` to your loggers) for the benefit of other developers who will use your code.

The second part of the solution is [`QueueListener`], which has been designed as the counterpart to [`QueueHandler`]. A [`QueueListener`] is very simple: it’s passed a queue and some handlers, and it fires up an internal thread which listens to its queue for LogRecords sent from `QueueHandlers` (or any other source of `LogRecords`, for that matter). The `LogRecords` are removed from the queue and passed to the handlers for processing.

The advantage of having a separate [`QueueListener`] class is that you can use the same instance to service multiple `QueueHandlers`. This is more resource-friendly than, say, having threaded versions of the existing handler classes, which would eat up one thread per handler for no particular benefit.

An example of using these two classes follows (imports omitted):

```
que = queue.Queue(-1)  # no limit on size
queue_handler = QueueHandler(que)
handler = logging.StreamHandler()
listener = QueueListener(que, handler)
root = logging.getLogger()
```

```
root.addHandler(queue_handler)
formatter = logging.Formatter('%(threadName)s: %(message)s')
handler.setFormatter(formatter)
listener.start()
# The log output will display the thread which generated
# the event (the main thread) rather than the internal
# thread which monitors the internal queue. This is what
# you want to happen.
root.warning('Look out!')
listener.stop()
```

which, when run, will produce:

```
MainThread: Look out!
```

Note

Although the earlier discussion wasn't specifically talking about async code, but rather about slow logging handlers, it should be noted that when logging from async code, network and even file handlers could lead to problems (blocking the event loop) because some logging is done from **`asyncio`** internals. It might be best, if any async code is used in an application, to use the above approach for logging, so that any blocking code runs only in the `QueueListener` thread.

Changed in version 3.5: Prior to Python 3.5, the **`QueueListener`** always passed every message received from the queue to every handler it was initialized with. (This was because it was assumed that level filtering was all done on the other side, where the queue is filled.) From 3.5 onwards, this behaviour can be changed by passing a keyword argument `respect_handler_level=True` to the listener's constructor. When this is done, the listener compares the level of each message with the handler's level, and only passes a message to a handler if it's appropriate to do so.

Changed in version 3.14: The **`QueueListener`** can be started (and stopped) via the **`with`** statement. For example:

```
with QueueListener(que, handler) as listener:
    # The queue listener automatically starts
    # when the 'with' block is entered.
    pass
# The queue listener automatically stops once
# the 'with' block is exited.
```

Sending and receiving logging events across a network

Let’s say you want to send logging events across a network, and handle them at the receiving end. A simple way of doing this is attaching a **`SocketHandler`** instance to the root logger at the sending end:

```
import logging, logging.handlers

rootLogger = logging.getLogger('')
rootLogger.setLevel(logging.DEBUG)
socketHandler = logging.handlers.SocketHandler('localhost',
                    logging.handlers.DEFAULT_TCP_LOGGING_PORT)
# don't bother with a formatter, since a socket handler sends
the event as
# an unformatted pickle
rootLogger.addHandler(socketHandler)

# Now, we can log to the root logger, or any other logger.
First the root...
logging.info('Jackdaws love my big sphinx of quartz.')

# Now, define a couple of other loggers which might represent
areas in your
# application:

logger1 = logging.getLogger('myapp.area1')
logger2 = logging.getLogger('myapp.area2')
```

```
logger1.debug('Quick zephyrs blow, vexing daft Jim.')
logger1.info('How quickly daft jumping zebras vex.')
logger2.warning('Jail zesty vixen who grabbed pay from quack.')
logger2.error('The five boxing wizards jump quickly.')
```

At the receiving end, you can set up a receiver using the `socketserver` module. Here is a basic working example:

```
import pickle
import logging
import logging.handlers
import socketserver
import struct

class
LogRecordStreamHandler(socketserver.StreamRequestHandler):
    """Handler for a streaming logging request.

    This basically logs the record using whatever logging
policy is
    configured locally.
    """

    def handle(self):
        """
        Handle multiple requests - each expected to be a 4-byte
length,
        followed by the LogRecord in pickle format. Logs the
record
        according to whatever policy is configured locally.
        """
        while True:
            chunk = self.connection.recv(4)
            if len(chunk) < 4:
                break
            slen = struct.unpack('>L', chunk)[0]
            chunk = self.connection.recv(slen)
            while len(chunk) < slen:
                chunk = chunk + self.connection.recv(slen -
len(chunk))
            obj = self.unPickle(chunk)
            record = logging.makeLogRecord(obj)
            self.handleLogRecord(record)

    def unPickle(self, data):
        return pickle.loads(data)

    def handleLogRecord(self, record):
        # if a name is specified, we use the named logger
rather than the one
        # implied by the record.
        if self.server.logname is not None:
            name = self.server.logname
        else:
            name = record.name
        logger = logging.getLogger(name)
        # N.B. EVERY record gets logged. This is because
Logger.handle
        # is normally called AFTER logger-level filtering. If
you want
        # to do filtering, do it at the client end to save
wasting
        # cycles and network bandwidth!
        logger.handle(record)

class LogRecordSocketReceiver(socketserver.ThreadingTCPServer):
    """
    Simple TCP socket-based logging receiver suitable for
testing.
    """

    allow_reuse_address = True

    def __init__(self, host='localhost',

port=logging.handlers.DEFAULT_TCP_LOGGING_PORT,
                 handler=LogRecordStreamHandler):
        socketserver.ThreadingTCPServer.__init__(self, (host,
port), handler)
        self.abort = 0
        self.timeout = 1
        self.logname = None

    def serve_until_stopped(self):
        import select
        abort = 0
        while not abort:
            rd, wr, ex = select.select([self.socket.fileno()],
                                       [], [],
                                       self.timeout)
            if rd:
                self.handle_request()
            abort = self.abort

def main():
    logging.basicConfig(
        format='%(relativeCreated)5d %(name)-15s %
(levelname)-8s %(message)s')
    tcpserver = LogRecordSocketReceiver()
    print('About to start TCP server...')
    tcpserver.serve_until_stopped()

if __name__ == '__main__':
    main()
```

First run the server, and then the client. On the client side, nothing is printed on the console; on the server side, you should see something like:

```
About to start TCP server...
   59 root            INFO     Jackdaws love my big sphinx of
quartz.
   59 myapp.area1     DEBUG    Quick zephyrs blow, vexing daft
Jim.
   69 myapp.area1     INFO     How quickly daft jumping zebras
vex.
   69 myapp.area2     WARNING  Jail zesty vixen who grabbed pay
from quack.
   69 myapp.area2     ERROR    The five boxing wizards jump
quickly.
```

Note that there are some security issues with pickle in some scenarios. If these affect you, you can use an alternative serialization scheme by overriding the `makePickle()` method and implementing your alternative there, as well as adapting the above script to use your alternative serialization.

Running a logging socket listener in production

To run a logging listener in production, you may need to use a process-management tool such as Supervisor [http://supervisord.org/]. Here is a Gist [https://gist.github.com/vsajip/4b227eeec43817465ca835ca66f75e2b] which provides the bare-bones files to run the above functionality using Supervisor. It consists of the following files:

File	**Purpose**
`prepare.sh`	A Bash script to prepare the environment for testing
`supervisor.conf`	The Supervisor configuration file, which has entries for the listener and a multi-process web application
`ensure_app.sh`	A Bash script to ensure that Supervisor is running with the above configuration
`log_listener.py`	The socket listener program which receives log events and records them to a file
`main.py`	A simple web application which performs logging via a socket connected to the listener

File	**Purpose**
`webapp.json`	A JSON configuration file for the web application
`client.py`	A Python script to exercise the web application

The web application uses Gunicorn [https://gunicorn.org/], which is a popular web application server that starts multiple worker processes to handle requests. This example setup shows how the workers can write to the same log file without conflicting with one another — they all go through the socket listener.

To test these files, do the following in a POSIX environment:

1. Download the Gist [https://gist.github.com/vsajip/4b227eeec43817465ca835ca66f75e2b] as a ZIP archive using the *Download ZIP* button.
2. Unzip the above files from the archive into a scratch directory.
3. In the scratch directory, run `bash prepare.sh` to get things ready. This creates a `run` subdirectory to contain Supervisor-related and log files, and a `venv` subdirectory to contain a virtual environment into which `bottle`, `gunicorn` and `supervisor` are installed.
4. Run `bash ensure_app.sh` to ensure that Supervisor is running with the above configuration.
5. Run `venv/bin/python client.py` to exercise the web application, which will lead to records being written to the log.

6. Inspect the log files in the `run` subdirectory. You should see the most recent log lines in files matching the pattern `app.log*`. They won't be in any particular order, since they have been handled concurrently by different worker processes in a non-deterministic way.
7. You can shut down the listener and the web application by running `venv/bin/supervisorctl -c supervisor.conf shutdown`.

You may need to tweak the configuration files in the unlikely event that the configured ports clash with something else in your test environment.

The default configuration uses a TCP socket on port 9020. You can use a Unix Domain socket instead of a TCP socket by doing the following:

1. In `listener.json`, add a `socket` key with the path to the domain socket you want to use. If this key is present, the listener listens on the corresponding domain socket and not on a TCP socket (the `port` key is ignored).
2. In `webapp.json`, change the socket handler configuration dictionary so that the `host` value is the path to the domain socket, and set the `port` value to `null`.

Adding contextual information to your logging output

Sometimes you want logging output to contain contextual information in addition to the parameters passed to the logging call. For example, in a networked application, it may be desirable to log client-specific information in the log (e.g. remote client's username, or IP address). Although you could use the *extra* parameter to achieve this, it's not always convenient to pass the information in this way. While it might be tempting to create `Logger` instances on a per-connection basis, this is not a good idea because these instances are not garbage collected. While this is not a problem in practice, when the number of `Logger` instances is dependent on the level of granularity you want to use in logging an application, it could be hard to manage if the number of `Logger` instances becomes effectively unbounded.

Using LoggerAdapters to impart contextual information

An easy way in which you can pass contextual information to be output along with logging event information is to use the `LoggerAdapter` class. This class is designed to look like a `Logger`, so that you can call `debug()`, `info()`, `warning()`, `error()`, `exception()`, `critical()` and `log()`. These methods have the same signatures as their counterparts in `Logger`, so you can use the two types of instances interchangeably.

When you create an instance of `LoggerAdapter`, you pass it a `Logger` instance and a dict-like object which contains your contextual information. When you call one of the logging methods on an instance of `LoggerAdapter`, it delegates the call to the underlying instance of `Logger` passed to its constructor, and arranges to pass the contextual information in the delegated call. Here’s a snippet from the code of `LoggerAdapter`:

```
def debug(self, msg, /, *args, **kwargs):
    """
    Delegate a debug call to the underlying logger, after
adding
    contextual information from this adapter instance.
    """
    msg, kwargs = self.process(msg, kwargs)
    self.logger.debug(msg, *args, **kwargs)
```

The `process()` method of `LoggerAdapter` is where the contextual information is added to the logging output. It's passed the message and keyword arguments of the logging call, and it passes back (potentially) modified versions of these to use in the call to the underlying logger. The default implementation of this method leaves the message alone, but inserts an 'extra' key in the keyword argument whose value is the dict-like object passed to the constructor. Of course, if you had passed an 'extra' keyword argument in the call to the adapter, it will be silently overwritten.

The advantage of using 'extra' is that the values in the dict-like object are merged into the `LogRecord` instance's __dict__, allowing you to use customized strings with your `Formatter` instances which know about the keys of the dict-like object. If you need a different method, e.g. if you want to prepend or append the contextual information to the message string, you just need to subclass `LoggerAdapter` and override `process()` to do what you need. Here is a simple example:

```
class CustomAdapter(logging.LoggerAdapter):
    """
    This example adapter expects the passed in dict-like object
to have a
    'connid' key, whose value in brackets is prepended to the
log message.
    """
    def process(self, msg, kwargs):
        return '[%s] %s' % (self.extra['connid'], msg), kwargs
```

which you can use like this:

```
logger = logging.getLogger(__name__)
adapter = CustomAdapter(logger, {'connid': some_conn_id})
```

Then any events that you log to the adapter will have the value of `some_conn_id` prepended to the log messages.

Using objects other than dicts to pass contextual information

You don’t need to pass an actual dict to a **`LoggerAdapter`** - you could pass an instance of a class which implements `__getitem__` and `__iter__` so that it looks like a dict to logging. This would be useful if you want to generate values dynamically (whereas the values in a dict would be constant).

Using Filters to impart contextual information

You can also add contextual information to log output using a user-defined **`Filter`**. `Filter` instances are allowed to modify the `LogRecords` passed to them, including adding additional attributes which can then be output using a suitable format string, or if needed a custom **`Formatter`**.

For example in a web application, the request being processed (or at least, the interesting parts of it) can be stored in a threadlocal (**`threading.local`**) variable, and then accessed from a `Filter` to add, say, information from the request - say, the remote IP address and remote user’s username - to the `LogRecord`, using the attribute names ‘ip’ and ‘user’ as in the `LoggerAdapter` example above. In that case, the same format string can be used to get similar output to that shown above. Here’s an example script:

```
import logging
from random import choice

class ContextFilter(logging.Filter):
    """
    This is a filter which injects contextual information into
the log.

    Rather than use actual contextual information, we just use
```

```
random
    data in this demo.
    """

    USERS = ['jim', 'fred', 'sheila']
    IPS = ['123.231.231.123', '127.0.0.1', '192.168.0.1']

    def filter(self, record):

        record.ip = choice(ContextFilter.IPS)
        record.user = choice(ContextFilter.USERS)
        return True

if __name__ == '__main__':
    levels = (logging.DEBUG, logging.INFO, logging.WARNING,
logging.ERROR, logging.CRITICAL)
    logging.basicConfig(level=logging.DEBUG,
                        format='%(asctime)-15s %(name)-5s %
(levelname)-8s IP: %(ip)-15s User: %(user)-8s %(message)s')
    a1 = logging.getLogger('a.b.c')
    a2 = logging.getLogger('d.e.f')

    f = ContextFilter()
    a1.addFilter(f)
    a2.addFilter(f)
    a1.debug('A debug message')
    a1.info('An info message with %s', 'some parameters')
    for x in range(10):
        lvl = choice(levels)
        lvlname = logging.getLevelName(lvl)
        a2.log(lvl, 'A message at %s level with %d %s',
lvlname, 2, 'parameters')
```

which, when run, produces something like:

```
2010-09-06 22:38:15,292 a.b.c DEBUG    IP: 123.231.231.123
User: fred     A debug message
2010-09-06 22:38:15,300 a.b.c INFO     IP: 192.168.0.1
User: sheila   An info message with some parameters
2010-09-06 22:38:15,300 d.e.f CRITICAL IP: 127.0.0.1
User: sheila   A message at CRITICAL level with 2 parameters
2010-09-06 22:38:15,300 d.e.f ERROR    IP: 127.0.0.1
User: jim      A message at ERROR level with 2 parameters
```

```
2010-09-06 22:38:15,300 d.e.f DEBUG    IP: 127.0.0.1
User: sheila   A message at DEBUG level with 2 parameters
2010-09-06 22:38:15,300 d.e.f ERROR    IP: 123.231.231.123
User: fred     A message at ERROR level with 2 parameters

Use of `contextvars`

Since Python 3.7, the `contextvars` module has provided context-local storage which works for both `threading` and `asyncio` processing needs. This type of storage may thus be generally preferable to thread-locals. The following example shows how, in a multi-threaded environment, logs can populated with contextual information such as, for example, request attributes handled by web applications.

For the purposes of illustration, say that you have different web applications, each independent of the other but running in the same Python process and using a library common to them. How can each of these applications have their own log, where all logging messages from the library (and other request processing code) are directed to the appropriate application’s log file, while including in the log additional contextual information such as client IP, HTTP request method and client username?

Let’s assume that the library can be simulated by the following code:

```
# webapplib.py
import logging
import time

logger = logging.getLogger(__name__)

def useful():
    # Just a representative event logged from the library
    logger.debug('Hello from webapplib!')
    # Just sleep for a bit so other threads get to run
    time.sleep(0.01)
```

We can simulate the multiple web applications by means of two simple classes, `Request` and `WebApp`. These simulate how real threaded web applications work - each request is handled by a thread:

```
# main.py
import argparse
from contextvars import ContextVar
import logging
import os
from random import choice
import threading
import webapplib

logger = logging.getLogger(__name__)
root = logging.getLogger()
root.setLevel(logging.DEBUG)

class Request:
    """
    A simple dummy request class which just holds dummy HTTP
request method,
    client IP address and client username
    """
    def __init__(self, method, ip, user):
        self.method = method
        self.ip = ip
        self.user = user

# A dummy set of requests which will be used in the simulation
- we'll just pick
# from this list randomly. Note that all GET requests are from
192.168.2.XXX
# addresses, whereas POST requests are from 192.16.3.XXX
addresses. Three users
# are represented in the sample requests.

REQUESTS = [
    Request('GET', '192.168.2.20', 'jim'),
    Request('POST', '192.168.3.20', 'fred'),
    Request('GET', '192.168.2.21', 'sheila'),
    Request('POST', '192.168.3.21', 'jim'),
    Request('GET', '192.168.2.22', 'fred'),
    Request('POST', '192.168.3.22', 'sheila'),
]

# Note that the format string includes references to request
context information
# such as HTTP method, client IP and username

formatter = logging.Formatter('%(threadName)-11s %(appName)s %
(name)-9s %(user)-6s %(ip)s %(method)-4s %(message)s')

# Create our context variables. These will be filled at the
start of request
# processing, and used in the logging that happens during that
processing

ctx_request = ContextVar('request')
ctx_appname = ContextVar('appname')

class InjectingFilter(logging.Filter):
    """
    A filter which injects context-specific information into
logs and ensures
    that only information for a specific webapp is included in
its log
    """
    def __init__(self, app):
        self.app = app
    def filter(self, record):
        request = ctx_request.get()
        record.method = request.method
        record.ip = request.ip
        record.user = request.user
        record.appName = appName = ctx_appname.get()
        return appName == self.app.name

class WebApp:
    """
    A dummy web application class which has its own handler and
filter for a
    webapp-specific log.
    """
    def __init__(self, name):
        self.name = name
        handler = logging.FileHandler(name + '.log', 'w')
        f = InjectingFilter(self)
        handler.setFormatter(formatter)
        handler.addFilter(f)
        root.addHandler(handler)
        self.num_requests = 0

    def process_request(self, request):
        """
        This is the dummy method for processing a request. It's
called on a
        different thread for every request. We store the
context information into
        the context vars before doing anything else.
        """
        ctx_request.set(request)
        ctx_appname.set(self.name)
        self.num_requests += 1
        logger.debug('Request processing started')
        webapplib.useful()
        logger.debug('Request processing finished')

def main():
    fn = os.path.splitext(os.path.basename(__file__))[0]
    adhf = argparse.ArgumentDefaultsHelpFormatter
    ap = argparse.ArgumentParser(formatter_class=adhf, prog=fn,
                                    description='Simulate a couple
of web '
                                                'applications
handling some '
                                                'requests, showing
how request '
                                                'context can be
used to '
                                                'populate logs')
    aa = ap.add_argument
    aa('--count', '-c', type=int, default=100, help='How many
requests to simulate')
    options = ap.parse_args()

    # Create the dummy webapps and put them in a list which we
can use to select
    # from randomly
    app1 = WebApp('app1')
    app2 = WebApp('app2')
    apps = [app1, app2]
    threads = []
    # Add a common handler which will capture all events
    handler = logging.FileHandler('app.log', 'w')
    handler.setFormatter(formatter)
    root.addHandler(handler)

    # Generate calls to process requests
    for i in range(options.count):
        try:
            # Pick an app at random and a request for it to
process
            app = choice(apps)
            request = choice(REQUESTS)
            # Process the request in its own thread
            t = threading.Thread(target=app.process_request,
args=(request,))
            threads.append(t)
            t.start()
        except KeyboardInterrupt:
            break

    # Wait for the threads to terminate
    for t in threads:
        t.join()

    for app in apps:
        print('%s processed %s requests' % (app.name,
app.num_requests))

if __name__ == '__main__':
    main()
```

If you run the above, you should find that roughly half the requests go into `app1.log` and the rest into `app2.log`, and the all the requests are logged to `app.log`. Each webapp-specific log will contain only log entries for only that webapp, and the request information will be displayed consistently in the log (i.e. the information in each dummy request will always appear together in a log line). This is illustrated by the following shell output:

```
~/logging-contextual-webapp$ python main.py
app1 processed 51 requests
app2 processed 49 requests
~/logging-contextual-webapp$ wc -l *.log
  153 app1.log

Imparting contextual information in handlers

Each `Handler` has its own chain of filters. If you want to add contextual information to a `LogRecord` without leaking it to other handlers, you can use a filter that returns a new `LogRecord` instead of modifying it in-place, as shown in the following script:

```
import copy
import logging
```

```
def filter(record: logging.LogRecord):
    record = copy.copy(record)
    record.user = 'jim'
    return record

if __name__ == '__main__':
    logger = logging.getLogger()
    logger.setLevel(logging.INFO)
    handler = logging.StreamHandler()
    formatter = logging.Formatter('%(message)s from %
(user)-8s')
    handler.setFormatter(formatter)
    handler.addFilter(filter)
    logger.addHandler(handler)

    logger.info('A log message')
```

Logging to a single file from multiple processes

Although logging is thread-safe, and logging to a single file from multiple threads in a single process *is* supported, logging to a single file from *multiple processes* is *not* supported, because there is no standard way to serialize access to a single file across multiple processes in Python. If you need to log to a single file from multiple processes, one way of doing this is to have all the processes log to a `SocketHandler`, and have a separate process which implements a socket server which reads from the socket and logs to file. (If you prefer, you can dedicate one thread in one of the existing processes to perform this function.) This section documents this approach in more detail and includes a working socket receiver which can be used as a starting point for you to adapt in your own applications.

You could also write your own handler which uses the `Lock` class from the `multiprocessing` module to serialize access to the file from your processes. The stdlib **`FileHandler`** and subclasses do not make use of **`multiprocessing`**.

Alternatively, you can use a `Queue` and a **`QueueHandler`** to send all logging events to one of the processes in your multi-process application. The following example script demonstrates how you can do this; in the example a separate listener process listens for events sent by other processes and logs them according to its own logging configuration. Although the example only demonstrates one way of doing it (for example, you may want to use a listener thread rather than a separate listener process – the implementation would be analogous) it does allow for completely different logging configurations for the listener and the other processes in your application, and can be used as the basis for code meeting your own specific requirements:

```
# You'll need these imports in your own code
import logging
import logging.handlers
import multiprocessing

# Next two import lines for this demo only
from random import choice, random
import time

#
# Because you'll want to define the logging configurations for
listener and workers, the
# listener and worker process functions take a configurer
parameter which is a callable
# for configuring logging for that process. These functions are
also passed the queue,
# which they use for communication.
#
# In practice, you can configure the listener however you want,
but note that in this
# simple example, the listener does not apply level or filter
logic to received records.
```

```
# In practice, you would probably want to do this logic in the
worker processes, to avoid
# sending events which would be filtered out between processes.
#
# The size of the rotated files is made small so you can see
the results easily.
def listener_configurer():
    root = logging.getLogger()
    h = logging.handlers.RotatingFileHandler('mptest.log', 'a',
300, 10)
    f = logging.Formatter('%(asctime)s %(processName)-10s %
(name)s %(levelname)-8s %(message)s')
    h.setFormatter(f)
    root.addHandler(h)

# This is the listener process top-level loop: wait for logging
events
# (LogRecords)on the queue and handle them, quit when you get a
None for a
# LogRecord.
def listener_process(queue, configurer):
    configurer()
    while True:
        try:
            record = queue.get()
            if record is None:  # We send this as a sentinel to
tell the listener to quit.
                break
            logger = logging.getLogger(record.name)
            logger.handle(record)  # No level or filter logic
applied - just do it!
        except Exception:
            import sys, traceback
            print('Whoops! Problem:', file=sys.stderr)
            traceback.print_exc(file=sys.stderr)

# Arrays used for random selections in this demo

LEVELS = [logging.DEBUG, logging.INFO, logging.WARNING,
          logging.ERROR, logging.CRITICAL]

LOGGERS = ['a.b.c', 'd.e.f']
```

```
MESSAGES = [
    'Random message #1',
    'Random message #2',
    'Random message #3',
]

# The worker configuration is done at the start of the worker
process run.
# Note that on Windows you can't rely on fork semantics, so
each process
# will run the logging configuration code when it starts.
def worker_configurer(queue):
    h = logging.handlers.QueueHandler(queue)  # Just the one
handler needed
    root = logging.getLogger()
    root.addHandler(h)
    # send all messages, for demo; no other level or filter
logic applied.
    root.setLevel(logging.DEBUG)

# This is the worker process top-level loop, which just logs
ten events with
# random intervening delays before terminating.
# The print messages are just so you know it's doing something!
def worker_process(queue, configurer):
    configurer(queue)
    name = multiprocessing.current_process().name
    print('Worker started: %s' % name)
    for i in range(10):
        time.sleep(random())
        logger = logging.getLogger(choice(LOGGERS))
        level = choice(LEVELS)
        message = choice(MESSAGES)
        logger.log(level, message)
    print('Worker finished: %s' % name)

# Here's where the demo gets orchestrated. Create the queue,
create and start
# the listener, create ten workers and start them, wait for
them to finish,
# then send a None to the queue to tell the listener to finish.
def main():
    queue = multiprocessing.Queue(-1)
    listener = multiprocessing.Process(target=listener_process,
                                       args=(queue,
listener_configurer))
    listener.start()
    workers = []
    for i in range(10):
        worker = multiprocessing.Process(target=worker_process,
                                         args=(queue,
worker_configurer))
        workers.append(worker)
        worker.start()
    for w in workers:
        w.join()
    queue.put_nowait(None)
    listener.join()

if __name__ == '__main__':
    main()
```

A variant of the above script keeps the logging in the main process, in a separate thread:

```
import logging
import logging.config
import logging.handlers
from multiprocessing import Process, Queue
import random
import threading
import time

def logger_thread(q):
    while True:
        record = q.get()
        if record is None:
            break
        logger = logging.getLogger(record.name)
        logger.handle(record)

def worker_process(q):
    qh = logging.handlers.QueueHandler(q)
    root = logging.getLogger()
    root.setLevel(logging.DEBUG)
    root.addHandler(qh)
    levels = [logging.DEBUG, logging.INFO, logging.WARNING,
logging.ERROR,
              logging.CRITICAL]
    loggers = ['foo', 'foo.bar', 'foo.bar.baz',
               'spam', 'spam.ham', 'spam.ham.eggs']
    for i in range(100):
        lvl = random.choice(levels)
        logger = logging.getLogger(random.choice(loggers))
        logger.log(lvl, 'Message no. %d', i)

if __name__ == '__main__':
    q = Queue()
    d = {
        'version': 1,
        'formatters': {
            'detailed': {
                'class': 'logging.Formatter',

                'class': 'logging.FileHandler',
                'filename': 'mplog-foo.log',
                'mode': 'w',
                'formatter': 'detailed',
            },
            'errors': {
                'class': 'logging.FileHandler',
                'filename': 'mplog-errors.log',
                'mode': 'w',
                'level': 'ERROR',
                'formatter': 'detailed',
            },
        },
        'loggers': {
            'foo': {
                'handlers': ['foofile']
            }
        },
        'root': {
            'level': 'DEBUG',
            'handlers': ['console', 'file', 'errors']
        },
    }
    workers = []
    for i in range(5):
        wp = Process(target=worker_process, name='worker %d' %
(i + 1), args=(q,))
        workers.append(wp)
        wp.start()
    logging.config.dictConfig(d)
    lp = threading.Thread(target=logger_thread, args=(q,))
    lp.start()
    # At this point, the main process could do some useful work
of its own
    # Once it's done that, it can wait for the workers to
terminate...
    for wp in workers:
        wp.join()
    # And now tell the logging thread to finish up, too
    q.put(None)
    lp.join()
```

This variant shows how you can e.g. apply configuration for particular loggers - e.g. the `foo` logger has a special handler which stores all events in the `foo` subsystem in a file `mplog-foo.log`. This will be used by the logging machinery in the main process (even though the logging events are generated in the worker processes) to direct the messages to the appropriate destinations.

Using concurrent.futures.ProcessPoolExecutor

If you want to use `concurrent.futures.ProcessPoolExecutor` to start your worker processes, you need to create the queue slightly differently. Instead of

```
queue = multiprocessing.Queue(-1)
```

you should use

```
queue = multiprocessing.Manager().Queue(-1)  # also works with
the examples above
```

and you can then replace the worker creation from this:

```
workers = []
for i in range(10):
    worker = multiprocessing.Process(target=worker_process,
                                     args=(queue,
worker_configurer))
    workers.append(worker)
    worker.start()
for w in workers:
    w.join()
```

to this (remembering to first import `concurrent.futures`):

```
with concurrent.futures.ProcessPoolExecutor(max_workers=10) as
executor:
    for i in range(10):
        executor.submit(worker_process, queue,
worker_configurer)
```

Deploying Web applications using Gunicorn and uWSGI

When deploying Web applications using Gunicorn [https://gunicorn.org/] or uWSGI [https://uwsgi-docs.readthedocs.io/en/latest/] (or similar), multiple worker processes are created to handle client requests. In such environments, avoid creating file-based handlers directly in your web application. Instead, use a **`SocketHandler`** to log from the web application to a listener in a separate process. This can be set up using a process management tool such as Supervisor - see Running a logging socket listener in production for more details.

Using file rotation

Sometimes you want to let a log file grow to a certain size, then open a new file and log to that. You may want to keep a certain number of these files, and when that many files have been created, rotate the files so that the number of files and the size of the files both remain bounded. For this usage pattern, the logging package provides a **`RotatingFileHandler`**:

```
import glob
import logging
import logging.handlers

LOG_FILENAME = 'logging_rotatingfile_example.out'

# Set up a specific logger with our desired output level
my_logger = logging.getLogger('MyLogger')
my_logger.setLevel(logging.DEBUG)

# Add the log message handler to the logger
handler = logging.handlers.RotatingFileHandler(
              LOG_FILENAME, maxBytes=20, backupCount=5)

my_logger.addHandler(handler)

# Log some messages
for i in range(20):
    my_logger.debug('i = %d' % i)

# See what files are created
```

```
logfiles = glob.glob('%s*' % LOG_FILENAME)

for filename in logfiles:
    print(filename)
```

The result should be 6 separate files, each with part of the log history for the application:

```
logging_rotatingfile_example.out
logging_rotatingfile_example.out.1
logging_rotatingfile_example.out.2
logging_rotatingfile_example.out.3
logging_rotatingfile_example.out.4
logging_rotatingfile_example.out.5
```

The most current file is always `logging_rotatingfile_example.out`, and each time it reaches the size limit it is renamed with the suffix `.1`. Each of the existing backup files is renamed to increment the suffix (`.1` becomes `.2`, etc.) and the `.6` file is erased.

Obviously this example sets the log length much too small as an extreme example. You would want to set *maxBytes* to an appropriate value.

Use of alternative formatting styles

When logging was added to the Python standard library, the only way of formatting messages with variable content was to use the %-formatting method. Since then, Python has gained two new formatting approaches: **`string.Template`** (added in Python 2.4) and **`str.format()`** (added in Python 2.6).

Logging (as of 3.2) provides improved support for these two additional formatting styles. The **`Formatter`** class been enhanced to take an additional, optional keyword parameter named `style`. This defaults to `'%'`, but other possible values are `'{'` and `'$'`, which correspond to the other two formatting styles. Backwards compatibility is maintained by default (as you would expect), but by explicitly specifying a style parameter, you get the ability to specify format strings which work with **`str.format()`** or **`string.Template`**. Here’s an example console session to show the possibilities:

```
>>> import logging
>>> root = logging.getLogger()
>>> root.setLevel(logging.DEBUG)
>>> handler = logging.StreamHandler()
>>> bf = logging.Formatter('{asctime} {name} {levelname:8s}
{message}',
...                        style='{')
>>> handler.setFormatter(bf)
>>> root.addHandler(handler)
>>> logger = logging.getLogger('foo.bar')
>>> logger.debug('This is a DEBUG message')
2010-10-28 15:11:55,341 foo.bar DEBUG    This is a DEBUG
message
>>> logger.critical('This is a CRITICAL message')
2010-10-28 15:12:11,526 foo.bar CRITICAL This is a CRITICAL
message
>>> df = logging.Formatter('$asctime $name ${levelname}
$message',
...                        style='$')
>>> handler.setFormatter(df)
>>> logger.debug('This is a DEBUG message')
2010-10-28 15:13:06,924 foo.bar DEBUG This is a DEBUG message
>>> logger.critical('This is a CRITICAL message')
2010-10-28 15:13:11,494 foo.bar CRITICAL This is a CRITICAL
message
>>>
```

Note that the formatting of logging messages for final output to logs is completely independent of how an individual logging message is constructed. That can still use %-formatting, as shown here:

```
>>> logger.error('This is an%s %s %s', 'other,', 'ERROR,',
'message')
```

```
2010-10-28 15:19:29,833 foo.bar ERROR This is another, ERROR,
message
>>>
```

Logging calls (`logger.debug()`, `logger.info()` etc.) only take positional parameters for the actual logging message itself, with keyword parameters used only for determining options for how to handle the actual logging call (e.g. the `exc_info` keyword parameter to indicate that traceback information should be logged, or the `extra` keyword parameter to indicate additional contextual information to be added to the log). So you cannot directly make logging calls using **`str.format()`** or **`string.Template`** syntax, because internally the logging package uses %-formatting to merge the format string and the variable arguments. There would be no changing this while preserving backward compatibility, since all logging calls which are out there in existing code will be using %-format strings.

There is, however, a way that you can use {}- and $-formatting to construct your individual log messages. Recall that for a message you can use an arbitrary object as a message format string, and that the logging package will call `str()` on that object to get the actual format string. Consider the following two classes:

```
class BraceMessage:
    def __init__(self, fmt, /, *args, **kwargs):
        self.fmt = fmt
        self.args = args
        self.kwargs = kwargs

    def __str__(self):
        return self.fmt.format(*self.args, **self.kwargs)

class DollarMessage:
    def __init__(self, fmt, /, **kwargs):
        self.fmt = fmt
        self.kwargs = kwargs
    def __str__(self):
        from string import Template
        return Template(self.fmt).substitute(**self.kwargs)
```

Either of these can be used in place of a format string, to allow {}- or $-formatting to be used to build the actual “message” part which appears in the formatted log output in place of “%(message)s” or “{message}” or “$message”. It’s a little unwieldy to use the class names whenever you want to log something, but it’s quite palatable if you use an alias such as __ (double underscore — not to be confused with _, the single underscore used as a synonym/alias for `gettext.gettext()` or its brethren).

The above classes are not included in Python, though they’re easy enough to copy and paste into your own code. They can be used as follows (assuming that they’re declared in a module called `wherever`):

```
>>> from wherever import BraceMessage as __
>>> print(__('Message with {0} {name}', 2,
name='placeholders'))
Message with 2 placeholders
>>> class Point: pass
...
>>> p = Point()
>>> p.x = 0.5
>>> p.y = 0.5
>>> print(__('Message with coordinates: ({point.x:.2f},
{point.y:.2f})',
...          point=p))
Message with coordinates: (0.50, 0.50)
>>> from wherever import DollarMessage as __
>>> print(__('Message with $num $what', num=2,
what='placeholders'))
Message with 2 placeholders
>>>
```

While the above examples use `print()` to show how the formatting works, you would of course use `logger.debug()` or similar to actually log using this approach.

One thing to note is that you pay no significant performance penalty with this approach: the actual formatting happens not when you make the logging call, but when (and if) the logged message is actually about to be output to a log by a handler. So the only slightly unusual thing which might trip you up is that the parentheses go around the format string and the arguments, not just the format string. That’s because the __ notation is just syntax sugar for a constructor call to one of the *XXX*`Message` classes.

If you prefer, you can use a [`LoggerAdapter`] to achieve a similar effect to the above, as in the following example:

```
import logging

class Message:
    def __init__(self, fmt, args):
        self.fmt = fmt
        self.args = args

    def __str__(self):
        return self.fmt.format(*self.args)

class StyleAdapter(logging.LoggerAdapter):
    def log(self, level, msg, /, *args, stacklevel=1,
**kwargs):
        if self.isEnabledFor(level):
            msg, kwargs = self.process(msg, kwargs)
            self.logger.log(level, Message(msg, args),
**kwargs,
                            stacklevel=stacklevel+1)

logger = StyleAdapter(logging.getLogger(__name__))

def main():
    logger.debug('Hello, {}', 'world!')
```

```
if __name__ == '__main__':
    logging.basicConfig(level=logging.DEBUG)
    main()
```

The above script should log the message `Hello, world!` when run with Python 3.8 or later.

Customizing `LogRecord`

Every logging event is represented by a `LogRecord` instance. When an event is logged and not filtered out by a logger's level, a `LogRecord` is created, populated with information about the event and then passed to the handlers for that logger (and its ancestors, up to and including the logger where further propagation up the hierarchy is disabled). Before Python 3.2, there were only two places where this creation was done:

- `Logger.makeRecord()`, which is called in the normal process of logging an event. This invoked `LogRecord` directly to create an instance.
- `makeLogRecord()`, which is called with a dictionary containing attributes to be added to the LogRecord. This is typically invoked when a suitable dictionary has been received over the network (e.g. in pickle form via a `SocketHandler`, or in JSON form via an `HTTPHandler`).

This has usually meant that if you need to do anything special with a `LogRecord`, you've had to do one of the following.

- Create your own `Logger` subclass, which overrides `Logger.makeRecord()`, and set it using `setLoggerClass()` before any loggers that you care about are instantiated.

- Add a `Filter` to a logger or handler, which does the necessary special manipulation you need when its `filter()` method is called.

The first approach would be a little unwieldy in the scenario where (say) several different libraries wanted to do different things. Each would attempt to set its own `Logger` subclass, and the one which did this last would win.

The second approach works reasonably well for many cases, but does not allow you to e.g. use a specialized subclass of `LogRecord`. Library developers can set a suitable filter on their loggers, but they would have to remember to do this every time they introduced a new logger (which they would do simply by adding new packages or modules and doing

```
logger = logging.getLogger(__name__)
```

at module level). It’s probably one too many things to think about. Developers could also add the filter to a `NullHandler` attached to their top-level logger, but this would not be invoked if an application developer attached a handler to a lower-level library logger — so output from that handler would not reflect the intentions of the library developer.

In Python 3.2 and later, `LogRecord` creation is done through a factory, which you can specify. The factory is just a callable you can set with `setLogRecordFactory()`, and interrogate with `getLogRecordFactory()`. The factory is invoked with the same signature as the `LogRecord` constructor, as `LogRecord` is the default setting for the factory.

This approach allows a custom factory to control all aspects of LogRecord creation. For example, you could return a subclass, or just add some additional attributes to the record once created, using a pattern similar to this:

```
old_factory = logging.getLogRecordFactory()

def record_factory(*args, **kwargs):
    record = old_factory(*args, **kwargs)
    record.custom_attribute = 0xdecafbad
    return record

logging.setLogRecordFactory(record_factory)
```

This pattern allows different libraries to chain factories together, and as long as they don’t overwrite each other’s attributes or unintentionally overwrite the attributes provided as standard, there should be no surprises. However, it should be borne in mind that each link in the chain adds run-time overhead to all logging operations, and the technique should only be used when the use of a `Filter` does not provide the desired result.

Subclassing QueueHandler and QueueListener- a ZeroMQ example

Subclass `QueueHandler`

You can use a `QueueHandler` subclass to send messages to other kinds of queues, for example a ZeroMQ ‘publish’ socket. In the example below,the socket is created separately and passed to the handler (as its ‘queue’):

```
import zmq   # using pyzmq, the Python binding for ZeroMQ
import json  # for serializing records portably

ctx = zmq.Context()
sock = zmq.Socket(ctx, zmq.PUB)  # or zmq.PUSH, or other
suitable value
sock.bind('tcp://*:5556')        # or wherever

class ZeroMQSocketHandler(QueueHandler):
    def enqueue(self, record):
        self.queue.send_json(record.__dict__)

handler = ZeroMQSocketHandler(sock)
```

Of course there are other ways of organizing this, for example passing in the data needed by the handler to create the socket:

```
class ZeroMQSocketHandler(QueueHandler):
    def __init__(self, uri, socktype=zmq.PUB, ctx=None):
        self.ctx = ctx or zmq.Context()
        socket = zmq.Socket(self.ctx, socktype)
        socket.bind(uri)
        super().__init__(socket)

    def enqueue(self, record):
        self.queue.send_json(record.__dict__)

    def close(self):
        self.queue.close()
```

Subclass `QueueListener`

You can also subclass `QueueListener` to get messages from other kinds of queues, for example a ZeroMQ ‘subscribe’ socket. Here’s an example:

```
class ZeroMQSocketListener(QueueListener):
    def __init__(self, uri, /, *handlers, **kwargs):
        self.ctx = kwargs.get('ctx') or zmq.Context()
        socket = zmq.Socket(self.ctx, zmq.SUB)
        socket.setsockopt_string(zmq.SUBSCRIBE, '')  #
subscribe to everything
        socket.connect(uri)
        super().__init__(socket, *handlers, **kwargs)

    def dequeue(self):
        msg = self.queue.recv_json()
        return logging.makeLogRecord(msg)
```

Subclassing QueueHandler and QueueListener- a `pynng` example

In a similar way to the above section, we can implement a listener and handler using pynng [https://pypi.org/project/pynng/], which is a Python binding to NNG [https://nng.nanomsg.org/], billed as a spiritual successor to ZeroMQ. The following snippets illustrate – you can test them in an environment which has `pynng` installed. Just for variety, we present the listener first.

Subclass `QueueListener`

```
# listener.py
import json
import logging
import logging.handlers

import pynng

DEFAULT_ADDR = "tcp://localhost:13232"

interrupted = False

class NNGSocketListener(logging.handlers.QueueListener):

    def __init__(self, uri, /, *handlers, **kwargs):
        # Have a timeout for interruptability, and open a
        # subscriber socket
        socket = pynng.Sub0(listen=uri, recv_timeout=500)
        # The b'' subscription matches all topics
        topics = kwargs.pop('topics', None) or b''
        socket.subscribe(topics)
        # We treat the socket as a queue
        super().__init__(socket, *handlers, **kwargs)

    def dequeue(self, block):
        data = None
        # Keep looping while not interrupted and no data
received over the
```

```
        # socket
        while not interrupted:
            try:
                data = self.queue.recv(block=block)
                break
            except pynng.Timeout:
                pass
            except pynng.Closed:  # sometimes happens when you
hit Ctrl-C
                break
        if data is None:
            return None
        # Get the logging event sent from a publisher
        event = json.loads(data.decode('utf-8'))
        return logging.makeLogRecord(event)

    def enqueue_sentinel(self):
        # Not used in this implementation, as the socket isn't
really a
        # queue
        pass

logging.getLogger('pynng').propagate = False
listener = NNGSocketListener(DEFAULT_ADDR,
logging.StreamHandler(), topics=b'')
listener.start()
print('Press Ctrl-C to stop.')
try:
    while True:
        pass
except KeyboardInterrupt:
    interrupted = True
finally:
    listener.stop()
```

Subclass `QueueHandler`

```
# sender.py
import json
import logging
import logging.handlers
import time
import random

import pynng

DEFAULT_ADDR = "tcp://localhost:13232"

class NNGSocketHandler(logging.handlers.QueueHandler):

    def __init__(self, uri):
        socket = pynng.Pub0(dial=uri, send_timeout=500)
        super().__init__(socket)

    def enqueue(self, record):
        # Send the record as UTF-8 encoded JSON
        d = dict(record.__dict__)
        data = json.dumps(d)
        self.queue.send(data.encode('utf-8'))

    def close(self):
        self.queue.close()

logging.getLogger('pynng').propagate = False
handler = NNGSocketHandler(DEFAULT_ADDR)
# Make sure the process ID is in the output
logging.basicConfig(level=logging.DEBUG,
                    handlers=[logging.StreamHandler(),
handler],
                    format='%(levelname)-8s %(name)10s %
(process)6s %(message)s')
levels = (logging.DEBUG, logging.INFO, logging.WARNING,
logging.ERROR,
          logging.CRITICAL)
logger_names = ('myapp', 'myapp.lib1', 'myapp.lib2')
msgno = 1
while True:
    # Just randomly select some loggers and levels and log away
    level = random.choice(levels)
    logger = logging.getLogger(random.choice(logger_names))
    logger.log(level, 'Message no. %5d' % msgno)
    msgno += 1
    delay = random.random() * 2 + 0.5
    time.sleep(delay)
```

You can run the above two snippets in separate command shells. If we run the listener in one shell and run the sender in two separate shells, we should see something like the following. In the first sender shell:

```
$ python sender.py
DEBUG         myapp    613 Message no.     1
WARNING  myapp.lib2    613 Message no.     2
CRITICAL myapp.lib2    613 Message no.     3
WARNING  myapp.lib2    613 Message no.     4
CRITICAL myapp.lib1    613 Message no.     5
DEBUG         myapp    613 Message no.     6
CRITICAL myapp.lib1    613 Message no.     7
INFO     myapp.lib1    613 Message no.     8
(and so on)
```

In the second sender shell:

```
$ python sender.py
INFO     myapp.lib2    657 Message no.     1
CRITICAL myapp.lib2    657 Message no.     2
CRITICAL      myapp    657 Message no.     3
CRITICAL myapp.lib1    657 Message no.     4
INFO     myapp.lib1    657 Message no.     5
WARNING  myapp.lib2    657 Message no.     6
CRITICAL      myapp    657 Message no.     7
DEBUG    myapp.lib1    657 Message no.     8
(and so on)
```

In the listener shell:

```
$ python listener.py
Press Ctrl-C to stop.
DEBUG         myapp    613 Message no.     1
WARNING  myapp.lib2    613 Message no.     2
INFO     myapp.lib2    657 Message no.     1
CRITICAL myapp.lib2    613 Message no.     3
CRITICAL myapp.lib2    657 Message no.     2
CRITICAL      myapp    657 Message no.     3
WARNING  myapp.lib2    613 Message no.     4
CRITICAL myapp.lib1    613 Message no.     5
CRITICAL myapp.lib1    657 Message no.     4
```

```
INFO     myapp.lib1    657 Message no.     5
DEBUG         myapp    613 Message no.     6
WARNING  myapp.lib2    657 Message no.     6
CRITICAL      myapp    657 Message no.     7
CRITICAL myapp.lib1    613 Message no.     7
INFO     myapp.lib1    613 Message no.     8
DEBUG    myapp.lib1    657 Message no.     8
(and so on)
```

As you can see, the logging from the two sender processes is interleaved in the listener's output.

An example dictionary-based configuration

Below is an example of a logging configuration dictionary - it's taken from the documentation on the Django project [https://docs.djangoproject.com/en/stable/topics/logging/#configuring-logging]. This dictionary is passed to **`dictConfig()`** to put the configuration into effect:

```
LOGGING = {
    'version': 1,
    'disable_existing_loggers': False,
    'formatters': {
        'verbose': {
            'format': '{levelname} {asctime} {module}
{process:d} {thread:d} {message}',
            'style': '{',
        },
        'simple': {
            'format': '{levelname} {message}',
            'style': '{',
        },
    },
    'filters': {
        'special': {
            '()': 'project.logging.SpecialFilter',
            'foo': 'bar',
        },
    },
    'handlers': {
        'console': {
            'level': 'INFO',
            'class': 'logging.StreamHandler',
            'formatter': 'simple',
        },
        'mail_admins': {
            'level': 'ERROR',
            'class': 'django.utils.log.AdminEmailHandler',
            'filters': ['special']
        }
    },
    'loggers': {
        'django': {
            'handlers': ['console'],
            'propagate': True,
        },
        'django.request': {
            'handlers': ['mail_admins'],
            'level': 'ERROR',
            'propagate': False,
        },
        'myproject.custom': {
            'handlers': ['console', 'mail_admins'],
            'level': 'INFO',
            'filters': ['special']
        }
    }
}
```

For more information about this configuration, you can see the relevant section [https://docs.djangoproject.com/en/stable/topics/logging/#configuring-logging] of the Django documentation.

Using a rotator and namer to customize log rotation processing

An example of how you can define a namer and rotator is given in the following runnable script, which shows gzip compression of the log file:

```
import gzip
import logging
import logging.handlers
import os
import shutil

def namer(name):
    return name + ".gz"

def rotator(source, dest):
    with open(source, 'rb') as f_in:
        with gzip.open(dest, 'wb') as f_out:
            shutil.copyfileobj(f_in, f_out)
    os.remove(source)

rh = logging.handlers.RotatingFileHandler('rotated.log',
maxBytes=128, backupCount=5)
rh.rotator = rotator
rh.namer = namer

root = logging.getLogger()
root.setLevel(logging.INFO)
root.addHandler(rh)
f = logging.Formatter('%(asctime)s %(message)s')
rh.setFormatter(f)
for i in range(1000):
    root.info(f'Message no. {i + 1}')
```

After running this, you will see six new files, five of which are compressed:

```
$ ls rotated.log*
rotated.log       rotated.log.2.gz  rotated.log.4.gz
rotated.log.1.gz  rotated.log.3.gz  rotated.log.5.gz
$ zcat rotated.log.1.gz
2023-01-20 02:28:17,767 Message no. 996
```

```
2023-01-20 02:28:17,767 Message no. 997
2023-01-20 02:28:17,767 Message no. 998
```

A more elaborate multiprocessing example

The following working example shows how logging can be used with multiprocessing using configuration files. The configurations are fairly simple, but serve to illustrate how more complex ones could be implemented in a real multiprocessing scenario.

In the example, the main process spawns a listener process and some worker processes. Each of the main process, the listener and the workers have three separate configurations (the workers all share the same configuration). We can see logging in the main process, how the workers log to a QueueHandler and how the listener implements a QueueListener and a more complex logging configuration, and arranges to dispatch events received via the queue to the handlers specified in the configuration. Note that these configurations are purely illustrative, but you should be able to adapt this example to your own scenario.

Here’s the script - the docstrings and the comments hopefully explain how it works:

```
import logging
import logging.config
import logging.handlers
from multiprocessing import Process, Queue, Event,
current_process
import os
import random
import time

class MyHandler:
    """
    A simple handler for logging events. It runs in the
listener process and
    dispatches events to loggers based on the name in the
received record,
    which then get dispatched, by the logging system, to the
handlers
    configured for those loggers.
    """

    def handle(self, record):
        if record.name == "root":
            logger = logging.getLogger()
        else:
            logger = logging.getLogger(record.name)

        if logger.isEnabledFor(record.levelno):
            # The process name is transformed just to show that
it's the listener
            # doing the logging to files and console
            record.processName = '%s (for %s)' %
(current_process().name, record.processName)
            logger.handle(record)

def listener_process(q, stop_event, config):
    """
    This could be done in the main process, but is just done in
a separate
    process for illustrative purposes.

    This initialises logging according to the specified
configuration,
    starts the listener and waits for the main process to
signal completion
    via the event. The listener is then stopped, and the
process exits.
    """
    logging.config.dictConfig(config)
    listener = logging.handlers.QueueListener(q, MyHandler())

Inserting a BOM into messages sent to a SysLogHandler

RFC 5424 [https://datatracker.ietf.org/doc/html/rfc5424.html] requires that a Unicode message be sent to a syslog daemon as a set of bytes which have the following structure: an optional pure-ASCII component, followed by a UTF-8 Byte Order Mark (BOM), followed by Unicode encoded using UTF-8. (See the **relevant section of the specification** [https://datatracker.ietf.org/doc/html/rfc5424.html#section-6].)

In Python 3.1, code was added to `SysLogHandler` to insert a BOM into the message, but unfortunately, it was implemented incorrectly, with the BOM appearing at the beginning of the message and hence not allowing any pure-ASCII component to appear before it.

As this behaviour is broken, the incorrect BOM insertion code is being removed from Python 3.2.4 and later. However, it is not being replaced, and if you want to produce **RFC 5424** [https://datatracker.ietf.org/doc/html/rfc5424.html]-compliant messages which include a BOM, an optional pure-ASCII sequence before it and arbitrary Unicode after it, encoded using UTF-8, then you need to do the following:

1. Attach a **`Formatter`** instance to your **`SysLogHandler`** instance, with a format string such as:

   ```
   'ASCII section\ufeffUnicode section'
   ```

   The Unicode code point U+FEFF, when encoded using UTF-8, will be encoded as a UTF-8 BOM – the byte-string `b'\xef\xbb\xbf'`.

2. Replace the ASCII section with whatever placeholders you like, but make sure that the data that appears in there after substitution is always ASCII (that way, it will remain unchanged after UTF-8 encoding).

3. Replace the Unicode section with whatever placeholders you like; if the data which appears there after substitution contains characters outside the ASCII range, that’s fine – it will be encoded using UTF-8.

The formatted message *will* be encoded using UTF-8 encoding by `SysLogHandler`. If you follow the above rules, you should be able to produce **RFC 5424** [https://datatracker.ietf.org/doc/html/rfc5424.html]-compliant messages. If you don’t, logging may not complain, but your messages will not be RFC 5424-compliant, and your syslog daemon may complain.

Implementing structured logging

Although most logging messages are intended for reading by humans, and thus not readily machine-parseable, there might be circumstances where you want to output messages in a structured format which *is* capable of being parsed by a program (without needing complex regular expressions to parse the log message). This is straightforward to achieve using the logging package. There are a number of ways in which this could be achieved, but the following is a simple approach which uses JSON to serialise the event in a machine-parseable manner:

```
import json
import logging

class StructuredMessage:
    def __init__(self, message, /, **kwargs):
        self.message = message
        self.kwargs = kwargs

    def __str__(self):
        return '%s >>> %s' % (self.message,
json.dumps(self.kwargs))

_ = StructuredMessage   # optional, to improve readability

logging.basicConfig(level=logging.INFO, format='%(message)s')
logging.info(_('message 1', foo='bar', bar='baz', num=123,
fnum=123.456))
```

If the above script is run, it prints:

```
message 1 >>> {"fnum": 123.456, "num": 123, "bar": "baz",
"foo": "bar"}
```

Note that the order of items might be different according to the version of Python used.

If you need more specialised processing, you can use a custom JSON encoder, as in the following complete example:

```
import json
import logging

class Encoder(json.JSONEncoder):
    def default(self, o):
        if isinstance(o, set):
            return tuple(o)
        elif isinstance(o, str):
            return o.encode('unicode_escape').decode('ascii')
        return super().default(o)

class StructuredMessage:
    def __init__(self, message, /, **kwargs):
        self.message = message
        self.kwargs = kwargs

    def __str__(self):
        s = Encoder().encode(self.kwargs)
        return '%s >>> %s' % (self.message, s)

_ = StructuredMessage   # optional, to improve readability

def main():
    logging.basicConfig(level=logging.INFO, format='%(message)s')
    logging.info(_('message 1', set_value={1, 2, 3}, snowman='\u2603'))

if __name__ == '__main__':
    main()
```

When the above script is run, it prints:

```
message 1 >>> {"snowman": "\u2603", "set_value": [1, 2, 3]}
```

Note that the order of items might be different according to the version of Python used.

Customizing handlers with `dictConfig()`

There are times when you want to customize logging handlers in particular ways, and if you use `dictConfig()` you may be able to do this without subclassing. As an example, consider that you may want to set the ownership of a log file. On POSIX, this is easily done using `shutil.chown()`, but the file handlers in the stdlib don't offer built-in support. You can customize handler creation using a plain function such as:

```
def owned_file_handler(filename, mode='a', encoding=None,
owner=None):
    if owner:
        if not os.path.exists(filename):
            open(filename, 'a').close()
        shutil.chown(filename, *owner)
    return logging.FileHandler(filename, mode, encoding)
```

You can then specify, in a logging configuration passed to `dictConfig()`, that a logging handler be created by calling this function:

```
LOGGING = {
    'version': 1,
    'disable_existing_loggers': False,
    'formatters': {
        'default': {
            'format': '%(asctime)s %(levelname)s %(name)s %
(message)s'
        },
    },
    'handlers': {
        'file':{
            # The values below are popped from this dictionary
and
            # used to create the handler, set the handler's
level and
            # its formatter.
            '()': owned_file_handler,
            'level':'DEBUG',
            'formatter': 'default',
            # The values below are passed to the handler
creator callable
            # as keyword arguments.
            'owner': ['pulse', 'pulse'],
            'filename': 'chowntest.log',
            'mode': 'w',
            'encoding': 'utf-8',
        },
    },
    'root': {
        'handlers': ['file'],
        'level': 'DEBUG',
    },
}
```

In this example I am setting the ownership using the `pulse` user and group, just for the purposes of illustration. Putting it together into a working script, `chowntest.py`:

```
import logging, logging.config, os, shutil

def owned_file_handler(filename, mode='a', encoding=None,
owner=None):
    if owner:
        if not os.path.exists(filename):
            open(filename, 'a').close()
        shutil.chown(filename, *owner)
    return logging.FileHandler(filename, mode, encoding)

LOGGING = {
    'version': 1,
    'disable_existing_loggers': False,
    'formatters': {
        'default': {
            'format': '%(asctime)s %(levelname)s %(name)s %
(message)s'
        },
    },
    'handlers': {
        'file':{
            # The values below are popped from this dictionary
and
            # used to create the handler, set the handler's
level and
            # its formatter.
            '()': owned_file_handler,
            'level':'DEBUG',
            'formatter': 'default',
            # The values below are passed to the handler
creator callable
            # as keyword arguments.
            'owner': ['pulse', 'pulse'],
            'filename': 'chowntest.log',
            'mode': 'w',
            'encoding': 'utf-8',
        },
    },
    'root': {
        'handlers': ['file'],
        'level': 'DEBUG',
    },
}

logging.config.dictConfig(LOGGING)
logger = logging.getLogger('mylogger')
logger.debug('A debug message')
```

To run this, you will probably need to run as `root`:

```
$ sudo python3.3 chowntest.py
$ cat chowntest.log
2013-11-05 09:34:51,128 DEBUG mylogger A debug message
$ ls -l chowntest.log
-rw-r--r-- 1 pulse pulse 55 2013-11-05 09:34 chowntest.log
```

Note that this example uses Python 3.3 because that’s where **`shutil.chown()`** makes an appearance. This approach should work with any Python version that supports **`dictConfig()`** - namely, Python 2.7, 3.2 or later. With pre-3.3 versions, you would need to implement the actual ownership change using e.g. **`os.chown()`**.

In practice, the handler-creating function may be in a utility module somewhere in your project. Instead of the line in the configuration:

```
'()': owned_file_handler,
```

you could use e.g.:

```
'()': 'ext://project.util.owned_file_handler',
```

where `project.util` can be replaced with the actual name of the package where the function resides. In the above working script, using `'ext://__main__.owned_file_handler'` should work. Here, the actual callable is resolved by **`dictConfig()`** from the `ext://` specification.

This example hopefully also points the way to how you could implement other types of file change - e.g. setting specific POSIX permission bits - in the same way, using **`os.chmod()`**.

Of course, the approach could also be extended to types of handler other than a **`FileHandler`** - for example, one of the rotating file handlers, or a different type of handler altogether.

Using particular formatting styles throughout your application

In Python 3.2, the **`Formatter`** gained a `style` keyword parameter which, while defaulting to `%` for backward compatibility, allowed the specification of `{` or `$` to support the formatting approaches supported by **`str.format()`** and **`string.Template`**. Note that this governs the formatting of logging messages for final output to logs, and is completely orthogonal to how an individual logging message is constructed.

Logging calls (`debug()`, `info()` etc.) only take positional parameters for the actual logging message itself, with keyword parameters used only for determining options for how to handle the logging call (e.g. the `exc_info` keyword parameter to indicate that traceback information should be logged, or the `extra` keyword parameter to indicate additional contextual information to be added to the log). So you cannot directly make logging calls using `str.format()` or `string.Template` syntax, because internally the logging package uses %-formatting to merge the format string and the variable arguments. There would be no changing this while preserving backward compatibility, since all logging calls which are out there in existing code will be using %-format strings.

There have been suggestions to associate format styles with specific loggers, but that approach also runs into backward compatibility problems because any existing code could be using a given logger name and using %-formatting.

For logging to work interoperably between any third-party libraries and your code, decisions about formatting need to be made at the level of the individual logging call. This opens up a couple of ways in which alternative formatting styles can be accommodated.

Using LogRecord factories

In Python 3.2, along with the `Formatter` changes mentioned above, the logging package gained the ability to allow users to set their own `LogRecord` subclasses, using the `setLogRecordFactory()` function. You can use this to set your own subclass of `LogRecord`, which does the Right Thing by overriding the `getMessage()` method. The base class implementation of this method is where the `msg % args` formatting happens, and where you can substitute your alternate formatting; however, you should be careful to support all formatting styles and allow %-formatting as the default, to ensure interoperability with other code. Care should also be taken to call `str(self.msg)`, just as the base implementation does.

Refer to the reference documentation on **`setLogRecordFactory()`** and **`LogRecord`** for more information.

Using custom message objects

There is another, perhaps simpler way that you can use {}- and $- formatting to construct your individual log messages. You may recall (from Using arbitrary objects as messages) that when logging you can use an arbitrary object as a message format string, and that the logging package will call **`str()`** on that object to get the actual format string. Consider the following two classes:

```
class BraceMessage:
    def __init__(self, fmt, /, *args, **kwargs):
        self.fmt = fmt
        self.args = args
        self.kwargs = kwargs

    def __str__(self):
        return self.fmt.format(*self.args, **self.kwargs)

class DollarMessage:
    def __init__(self, fmt, /, **kwargs):
        self.fmt = fmt
        self.kwargs = kwargs

    def __str__(self):
        from string import Template
        return Template(self.fmt).substitute(**self.kwargs)
```

Either of these can be used in place of a format string, to allow {}- or $-formatting to be used to build the actual “message” part which appears in the formatted log output in place of “%(message)s” or “{message}” or “$message”. If you find it a little unwieldy to use the class names whenever you want to log something, you can make it more palatable if you use an alias such as `M` or `_` for the message (or perhaps `__`, if you are using `_` for localization).

Examples of this approach are given below. Firstly, formatting with [`str.format()`](#):

```
>>> __ = BraceMessage
>>> print(__('Message with {0} {1}', 2, 'placeholders'))
Message with 2 placeholders
>>> class Point: pass
...
>>> p = Point()
>>> p.x = 0.5
>>> p.y = 0.5
>>> print(__('Message with coordinates: ({point.x:.2f},
{point.y:.2f})', point=p))
Message with coordinates: (0.50, 0.50)
```

Secondly, formatting with [`string.Template`](#):

```
>>> __ = DollarMessage
>>> print(__('Message with $num $what', num=2,
what='placeholders'))
Message with 2 placeholders
>>>
```

One thing to note is that you pay no significant performance penalty with this approach: the actual formatting happens not when you make the logging call, but when (and if) the logged message is actually about to be output to a log by a handler. So the only slightly unusual thing which might trip you up is that the parentheses go around the format string and the arguments, not just the format string. That’s because the `__` notation is just syntax sugar for a constructor call to one of the *XXX*`Message` classes shown above.

Configuring filters with `dictConfig()`

You *can* configure filters using `dictConfig()`, though it might not be obvious at first glance how to do it (hence this recipe). Since `Filter` is the only filter class included in the standard library, and it is unlikely to cater to many requirements (it’s only there as a base class), you will typically need to define your own `Filter` subclass with an overridden `filter()` method. To do this, specify the `()` key in the configuration dictionary for the filter, specifying a callable which will be used to create the filter (a class is the most obvious, but you can provide any callable which returns a `Filter` instance). Here is a complete example:

```
import logging
import logging.config
import sys

class MyFilter(logging.Filter):
    def __init__(self, param=None):
        self.param = param

    def filter(self, record):
        if self.param is None:
            allow = True
        else:
            allow = self.param not in record.msg
        if allow:
            record.msg = 'changed: ' + record.msg
        return allow

LOGGING = {
    'version': 1,
    'filters': {
        'myfilter': {
            '()': MyFilter,
            'param': 'noshow',
        }
    },
    'handlers': {
        'console': {
            'class': 'logging.StreamHandler',
            'filters': ['myfilter']
        }
    },
    'root': {
        'level': 'DEBUG',
        'handlers': ['console']
    },
}

if __name__ == '__main__':
    logging.config.dictConfig(LOGGING)
    logging.debug('hello')
    logging.debug('hello - noshow')
```

This example shows how you can pass configuration data to the callable which constructs the instance, in the form of keyword parameters. When run, the above script will print:

```
changed: hello
```

which shows that the filter is working as configured.

A couple of extra points to note:

- If you can't refer to the callable directly in the configuration (e.g. if it lives in a different module, and you can't import it directly where the configuration dictionary is), you can use the form `ext://...` as described in Access to external objects. For example, you could have used the text `'ext://__main__.MyFilter'` instead of `MyFilter` in the above example.
- As well as for filters, this technique can also be used to configure custom handlers and formatters. See User-defined objects for more information on how logging

supports using user-defined objects in its configuration, and see the other cookbook recipe Customizing handlers with dictConfig() above.

Customized exception formatting

There might be times when you want to do customized exception formatting - for argument’s sake, let’s say you want exactly one line per logged event, even when exception information is present. You can do this with a custom formatter class, as shown in the following example:

```
import logging

class OneLineExceptionFormatter(logging.Formatter):
    def formatException(self, exc_info):
        """
        Format an exception so that it prints on a single line.
        """
        result = super().formatException(exc_info)
        return repr(result)  # or format into one line however
you want to

    def format(self, record):
        s = super().format(record)
        if record.exc_text:
            s = s.replace('\n', '') + '|'
        return s

def configure_logging():
    fh = logging.FileHandler('output.txt', 'w')
    f = OneLineExceptionFormatter('%(asctime)s|%(levelname)s|%
(message)s|',
                                  '%d/%m/%Y %H:%M:%S')
    fh.setFormatter(f)
    root = logging.getLogger()
    root.setLevel(logging.DEBUG)
    root.addHandler(fh)

def main():
    configure_logging()
    logging.info('Sample message')
    try:
        x = 1 / 0
    except ZeroDivisionError as e:
        logging.exception('ZeroDivisionError: %s', e)

if __name__ == '__main__':
    main()
```

When run, this produces a file with exactly two lines:

```
28/01/2015 07:21:23|INFO|Sample message|
28/01/2015 07:21:23|ERROR|ZeroDivisionError: division by
zero|'Traceback (most recent call last):\n  File "logtest7.py",
line 30, in main\n    x = 1 / 0\nZeroDivisionError: division by
zero'|
```

While the above treatment is simplistic, it points the way to how exception information can be formatted to your liking. The **`traceback`** module may be helpful for more specialized needs.

Speaking logging messages

There might be situations when it is desirable to have logging messages rendered in an audible rather than a visible format. This is easy to do if you have text-to-speech (TTS) functionality available in your system, even if it doesn’t have a Python binding. Most TTS systems have a command line program you can run, and this can be invoked from a handler using **`subprocess`**. It’s assumed here that TTS command line programs won’t expect to interact with users or take a long time to complete, and that the frequency of logged messages will be not so high as to swamp the user with messages, and that it’s acceptable to have the messages spoken one at a time rather than concurrently, The example implementation below waits for one message to be spoken before the next is processed, and this might cause other handlers to be kept waiting. Here is a short example showing the approach, which assumes that the `espeak` TTS package is available:

```
import logging
import subprocess
import sys

class TTSHandler(logging.Handler):
    def emit(self, record):
        msg = self.format(record)
        # Speak slowly in a female English voice
        cmd = ['espeak', '-s150', '-ven+f3', msg]
        p = subprocess.Popen(cmd, stdout=subprocess.PIPE,
                             stderr=subprocess.STDOUT)
        # wait for the program to finish
        p.communicate()

def configure_logging():
    h = TTSHandler()
    root = logging.getLogger()
    root.addHandler(h)
    # the default formatter just returns the message
    root.setLevel(logging.DEBUG)

def main():
    logging.info('Hello')
    logging.debug('Goodbye')

if __name__ == '__main__':
    configure_logging()
    sys.exit(main())
```

When run, this script should say “Hello” and then “Goodbye” in a female voice.

The above approach can, of course, be adapted to other TTS systems and even other systems altogether which can process messages via external programs run from a command line.

Buffering logging messages and outputting them conditionally

There might be situations where you want to log messages in a temporary area and only output them if a certain condition occurs. For example, you may want to start logging debug events in a function, and if the function completes without errors, you don’t want to clutter the log with the collected debug information, but if there is an error, you want all the debug information to be output as well as the error.

Here is an example which shows how you could do this using a decorator for your functions where you want logging to behave this way. It makes use of the **`logging.handlers.MemoryHandler`**, which allows buffering of logged events until some condition occurs, at which point the buffered events are `flushed` - passed to another handler (the `target` handler) for processing. By default, the `MemoryHandler` flushed when its buffer gets filled up or an event whose level is greater than or equal to a specified threshold is seen. You can use this recipe with a more specialised subclass of `MemoryHandler` if you want custom flushing behavior.

The example script has a simple function, `foo`, which just cycles through all the logging levels, writing to `sys.stderr` to say what level it’s about to log at, and then actually logging a message at that level. You can pass a parameter to `foo` which, if true, will log at ERROR and CRITICAL levels - otherwise, it only logs at DEBUG, INFO and WARNING levels.

The script just arranges to decorate `foo` with a decorator which will do the conditional logging that’s required. The decorator takes a logger as a parameter and attaches a memory handler for the duration of the call to the decorated function. The decorator can be additionally parameterised using a target handler, a level at which flushing should occur, and a capacity for the buffer (number of records buffered). These default to a `StreamHandler` which writes to `sys.stderr`, `logging.ERROR` and `100` respectively.

Here's the script:

```
import logging
from logging.handlers import MemoryHandler
import sys

logger = logging.getLogger(__name__)
logger.addHandler(logging.NullHandler())

def log_if_errors(logger, target_handler=None,
flush_level=None, capacity=None):
    if target_handler is None:
        target_handler = logging.StreamHandler()
    if flush_level is None:
        flush_level = logging.ERROR
    if capacity is None:
        capacity = 100
    handler = MemoryHandler(capacity, flushLevel=flush_level,
target=target_handler)

    def decorator(fn):
        def wrapper(*args, **kwargs):
            logger.addHandler(handler)
            try:
                return fn(*args, **kwargs)
            except Exception:
                logger.exception('call failed')
                raise
            finally:
                super(MemoryHandler, handler).flush()
                logger.removeHandler(handler)
        return wrapper

    return decorator
```

```
def write_line(s):
    sys.stderr.write('%s\n' % s)

def foo(fail=False):
    write_line('about to log at DEBUG ...')
    logger.debug('Actually logged at DEBUG')
    write_line('about to log at INFO ...')
    logger.info('Actually logged at INFO')
    write_line('about to log at WARNING ...')
    logger.warning('Actually logged at WARNING')
    if fail:
        write_line('about to log at ERROR ...')
        logger.error('Actually logged at ERROR')
        write_line('about to log at CRITICAL ...')
        logger.critical('Actually logged at CRITICAL')
    return fail

decorated_foo = log_if_errors(logger)(foo)

if __name__ == '__main__':
    logger.setLevel(logging.DEBUG)
    write_line('Calling undecorated foo with False')
    assert not foo(False)
    write_line('Calling undecorated foo with True')
    assert foo(True)
    write_line('Calling decorated foo with False')
    assert not decorated_foo(False)
    write_line('Calling decorated foo with True')
    assert decorated_foo(True)
```

When this script is run, the following output should be observed:

```
Calling undecorated foo with False
about to log at DEBUG ...
about to log at INFO ...
about to log at WARNING ...
Calling undecorated foo with True
about to log at DEBUG ...
about to log at INFO ...
about to log at WARNING ...
about to log at ERROR ...
about to log at CRITICAL ...
Calling decorated foo with False
about to log at DEBUG ...
about to log at INFO ...
about to log at WARNING ...
Calling decorated foo with True
about to log at DEBUG ...
about to log at INFO ...
about to log at WARNING ...
about to log at ERROR ...
Actually logged at DEBUG
Actually logged at INFO
Actually logged at WARNING
Actually logged at ERROR
about to log at CRITICAL ...
Actually logged at CRITICAL
```

As you can see, actual logging output only occurs when an event is logged whose severity is ERROR or greater, but in that case, any previous events at lower severities are also logged.

You can of course use the conventional means of decoration:

```
@log_if_errors(logger)
def foo(fail=False):
    ...
```

Sending logging messages to email, with buffering

To illustrate how you can send log messages via email, so that a set number of messages are sent per email, you can subclass `BufferingHandler`. In the following example, which you can adapt to suit your specific needs, a simple test harness is provided which allows you to run the script with command line arguments specifying what you typically need to send things via SMTP. (Run the downloaded script with the `-h` argument to see the required and optional arguments.)

```
import logging
import logging.handlers
import smtplib

class BufferingSMTPHandler(logging.handlers.BufferingHandler):
    def __init__(self, mailhost, port, username, password,
fromaddr, toaddrs,
                 subject, capacity):
        logging.handlers.BufferingHandler.__init__(self,
capacity)
        self.mailhost = mailhost
        self.mailport = port
        self.username = username
        self.password = password
        self.fromaddr = fromaddr
        if isinstance(toaddrs, str):
            toaddrs = [toaddrs]
        self.toaddrs = toaddrs
        self.subject = subject
        self.setFormatter(logging.Formatter("%(asctime)s %
(levelname)-5s %(message)s"))

    def flush(self):
        if len(self.buffer) > 0:
            try:
                smtp = smtplib.SMTP(self.mailhost,
self.mailport)
                smtp.starttls()
                smtp.login(self.username, self.password)
                msg = "From: %s\r\nTo: %s\r\nSubject:
%s\r\n\r\n" % (self.fromaddr, ','.join(self.toaddrs),
self.subject)
                for record in self.buffer:
                    s = self.format(record)
                    msg = msg + s + "\r\n"
                smtp.sendmail(self.fromaddr, self.toaddrs, msg)
                smtp.quit()
            except Exception:
                if logging.raiseExceptions:
                    raise
            self.buffer = []

if __name__ == '__main__':
    import argparse

    ap = argparse.ArgumentParser()
    aa = ap.add_argument
    aa('host', metavar='HOST', help='SMTP server')
    aa('--port', '-p', type=int, default=587, help='SMTP port')
    aa('user', metavar='USER', help='SMTP username')
    aa('password', metavar='PASSWORD', help='SMTP password')
    aa('to', metavar='TO', help='Addressee for emails')
    aa('sender', metavar='SENDER', help='Sender email address')
    aa('--subject', '-s',
       default='Test Logging email from Python logging module
(buffering)',
       help='Subject of email')
    options = ap.parse_args()
    logger = logging.getLogger()
    logger.setLevel(logging.DEBUG)
    h = BufferingSMTPHandler(options.host, options.port,
options.user,
                             options.password, options.sender,
                             options.to, options.subject, 10)
    logger.addHandler(h)
    for i in range(102):
        logger.info("Info index = %d", i)
    h.flush()
    h.close()
```

If you run this script and your SMTP server is correctly set up, you should find that it sends eleven emails to the addressee you specify. The first ten emails will each have ten log messages, and the eleventh will have two messages. That makes up 102 messages as specified in the script.

Formatting times using UTC (GMT) via configuration

Sometimes you want to format times using UTC, which can be done using a class such as `UTCFormatter`, shown below:

```
import logging
import time

class UTCFormatter(logging.Formatter):
    converter = time.gmtime
```

and you can then use the `UTCFormatter` in your code instead of **`Formatter`**. If you want to do that via configuration, you can use the **`dictConfig()`** API with an approach illustrated by the following complete example:

```
import logging
import logging.config
import time

class UTCFormatter(logging.Formatter):
    converter = time.gmtime

LOGGING = {
    'version': 1,
    'disable_existing_loggers': False,
    'formatters': {
        'utc': {
            '()': UTCFormatter,
            'format': '%(asctime)s %(message)s',
        },
        'local': {
            'format': '%(asctime)s %(message)s',
        }
    },
    'handlers': {
        'console1': {
            'class': 'logging.StreamHandler',
            'formatter': 'utc',
        },
        'console2': {
            'class': 'logging.StreamHandler',
            'formatter': 'local',
        },
    },
    'root': {
        'handlers': ['console1', 'console2'],
   }
}

if __name__ == '__main__':
    logging.config.dictConfig(LOGGING)
    logging.warning('The local time is %s', time.asctime())
```

When this script is run, it should print something like:

```
2015-10-17 12:53:29,501 The local time is Sat Oct 17 13:53:29
2015
2015-10-17 13:53:29,501 The local time is Sat Oct 17 13:53:29
2015
```

showing how the time is formatted both as local time and UTC, one for each handler.

Using a context manager for selective logging

There are times when it would be useful to temporarily change the logging configuration and revert it back after doing something. For this, a context manager is the most obvious way of saving and restoring the logging context. Here is a simple example of such a context manager, which allows you to optionally change the logging level and add a logging handler purely in the scope of the context manager:

```
import logging
import sys

class LoggingContext:
    def __init__(self, logger, level=None, handler=None,
close=True):
        self.logger = logger
        self.level = level
        self.handler = handler
        self.close = close

    def __enter__(self):
        if self.level is not None:
            self.old_level = self.logger.level
            self.logger.setLevel(self.level)
        if self.handler:
            self.logger.addHandler(self.handler)

    def __exit__(self, et, ev, tb):
        if self.level is not None:
            self.logger.setLevel(self.old_level)
        if self.handler:
            self.logger.removeHandler(self.handler)
        if self.handler and self.close:
            self.handler.close()
        # implicit return of None => don't swallow exceptions
```

If you specify a level value, the logger’s level is set to that value in the scope of the with block covered by the context manager. If you specify a handler, it is added to the logger on entry to the block and removed on exit from the block. You can also ask the manager to close the handler for you on block exit - you could do this if you don’t need the handler any more.

To illustrate how it works, we can add the following block of code to the above:

```
if __name__ == '__main__':
    logger = logging.getLogger('foo')
    logger.addHandler(logging.StreamHandler())
    logger.setLevel(logging.INFO)
    logger.info('1. This should appear just once on stderr.')
    logger.debug('2. This should not appear.')
    with LoggingContext(logger, level=logging.DEBUG):
        logger.debug('3. This should appear once on stderr.')
    logger.debug('4. This should not appear.')
    h = logging.StreamHandler(sys.stdout)
    with LoggingContext(logger, level=logging.DEBUG, handler=h,
close=True):
        logger.debug('5. This should appear twice - once on
stderr and once on stdout.')
    logger.info('6. This should appear just once on stderr.')
    logger.debug('7. This should not appear.')
```

We initially set the logger’s level to `INFO`, so message #1 appears and message #2 doesn’t. We then change the level to `DEBUG` temporarily in the following `with` block, and so message #3 appears. After the block exits, the logger’s level is restored to `INFO` and so message #4 doesn’t appear. In the next `with` block, we set the level to `DEBUG` again but also add a handler writing to `sys.stdout`. Thus, message #5 appears twice on the console (once via `stderr` and once via `stdout`). After the `with` statement’s completion, the status is as it was before so message #6 appears (like message #1) whereas message #7 doesn’t (just like message #2).

If we run the resulting script, the result is as follows:

```
$ python logctx.py
1. This should appear just once on stderr.
3. This should appear once on stderr.
5. This should appear twice - once on stderr and once on
stdout.
5. This should appear twice - once on stderr and once on
stdout.
6. This should appear just once on stderr.
```

If we run it again, but pipe `stderr` to `/dev/null`, we see the following, which is the only message written to `stdout`:

```
$ python logctx.py 2>/dev/null
5. This should appear twice - once on stderr and once on
stdout.
```

Once again, but piping `stdout` to `/dev/null`, we get:

```
$ python logctx.py >/dev/null
1. This should appear just once on stderr.
```

```
3. This should appear once on stderr.
5. This should appear twice - once on stderr and once on
stdout.
6. This should appear just once on stderr.
```

In this case, the message #5 printed to `stdout` doesn't appear, as expected.

Of course, the approach described here can be generalised, for example to attach logging filters temporarily. Note that the above code works in Python 2 as well as Python 3.

A CLI application starter template

Here's an example which shows how you can:

- Use a logging level based on command-line arguments
- Dispatch to multiple subcommands in separate files, all logging at the same level in a consistent way
- Make use of simple, minimal configuration

Suppose we have a command-line application whose job is to stop, start or restart some services. This could be organised for the purposes of illustration as a file `app.py` that is the main script for the application, with individual commands implemented in `start.py`, `stop.py` and `restart.py`. Suppose further that we want to control the verbosity of the application via a command-line argument, defaulting to `logging.INFO`. Here's one way that `app.py` could be written:

```
import argparse
import importlib
import logging
import os
import sys

def main(args=None):
    scriptname = os.path.basename(__file__)
    parser = argparse.ArgumentParser(scriptname)
    levels = ('DEBUG', 'INFO', 'WARNING', 'ERROR', 'CRITICAL')
    parser.add_argument('--log-level', default='INFO',
choices=levels)
    subparsers = parser.add_subparsers(dest='command',
                                       help='Available
commands:')
    start_cmd = subparsers.add_parser('start', help='Start a
service')
    start_cmd.add_argument('name', metavar='NAME',
                           help='Name of service to start')
    stop_cmd = subparsers.add_parser('stop',
                                     help='Stop one or more
services')
    stop_cmd.add_argument('names', metavar='NAME', nargs='+',
                          help='Name of service to stop')
    restart_cmd = subparsers.add_parser('restart',
                                        help='Restart one or
more services')
    restart_cmd.add_argument('names', metavar='NAME',
nargs='+',
                             help='Name of service to restart')
    options = parser.parse_args()
    # the code to dispatch commands could all be in this file.
For the purposes
    # of illustration only, we implement each command in a
separate module.
    try:
        mod = importlib.import_module(options.command)
        cmd = getattr(mod, 'command')
    except (ImportError, AttributeError):
        print('Unable to find the code for command \'%s\'' %
options.command)
        return 1
    # Could get fancy here and load configuration from file or
dictionary
    logging.basicConfig(level=options.log_level,
                        format='%(levelname)s %(name)s %
(message)s')
    cmd(options)

if __name__ == '__main__':
    sys.exit(main())
```

And the `start`, `stop` and `restart` commands can be implemented in separate modules, like so for starting:

```
# start.py
import logging

logger = logging.getLogger(__name__)

def command(options):
    logger.debug('About to start %s', options.name)
    # actually do the command processing here ...
    logger.info('Started the \'%s\' service.', options.name)
```

and thus for stopping:

```
# stop.py
import logging

logger = logging.getLogger(__name__)

def command(options):
    n = len(options.names)
    if n == 1:
        plural = ''
        services = '\'%s\'' % options.names[0]
    else:
        plural = 's'
        services = ', '.join('\'%s\'' % name for name in 
options.names)
        i = services.rfind(', ')
        services = services[:i] + ' and ' + services[i + 2:]
    logger.debug('About to stop %s', services)
    # actually do the command processing here ...
    logger.info('Stopped the %s service%s.', services, plural)
```

and similarly for restarting:

```
# restart.py
import logging

logger = logging.getLogger(__name__)
```

```
def command(options):
    n = len(options.names)
    if n == 1:
        plural = ''
        services = '\'%s\'' % options.names[0]
    else:
        plural = 's'
        services = ', '.join('\'%s\'' % name for name in
options.names)
        i = services.rfind(', ')
        services = services[:i] + ' and ' + services[i + 2:]
    logger.debug('About to restart %s', services)
    # actually do the command processing here ...
    logger.info('Restarted the %s service%s.', services,
plural)
```

If we run this application with the default log level, we get output like this:

```
$ python app.py start foo
INFO start Started the 'foo' service.

$ python app.py stop foo bar
INFO stop Stopped the 'foo' and 'bar' services.

$ python app.py restart foo bar baz
INFO restart Restarted the 'foo', 'bar' and 'baz' services.
```

The first word is the logging level, and the second word is the module or package name of the place where the event was logged.

If we change the logging level, then we can change the information sent to the log. For example, if we want more information:

```
$ python app.py --log-level DEBUG start foo
DEBUG start About to start foo
INFO start Started the 'foo' service.

$ python app.py --log-level DEBUG stop foo bar
```

```
DEBUG stop About to stop 'foo' and 'bar'
INFO stop Stopped the 'foo' and 'bar' services.

$ python app.py --log-level DEBUG restart foo bar baz
DEBUG restart About to restart 'foo', 'bar' and 'baz'
INFO restart Restarted the 'foo', 'bar' and 'baz' services.
```

And if we want less:

```
$ python app.py --log-level WARNING start foo
$ python app.py --log-level WARNING stop foo bar
$ python app.py --log-level WARNING restart foo bar baz
```

In this case, the commands don’t print anything to the console, since nothing at `WARNING` level or above is logged by them.

A Qt GUI for logging

A question that comes up from time to time is about how to log to a GUI application. The Qt [https://www.qt.io/] framework is a popular cross-platform UI framework with Python bindings using PySide2 [https://pypi.org/project/PySide2/] or PyQt5 [https://pypi.org/project/PyQt5/] libraries.

The following example shows how to log to a Qt GUI. This introduces a simple `QtHandler` class which takes a callable, which should be a slot in the main thread that does GUI updates. A worker thread is also created to show how you can log to the GUI from both the UI itself (via a button for manual logging) as well as a worker thread doing work in the background (here, just logging messages at random levels with random short delays in between).

The worker thread is implemented using Qt’s `QThread` class rather than the **`threading`** module, as there are circumstances where one has to use `QThread`, which offers better integration with other `Qt` components.

The code should work with recent releases of any of `PySide6`, `PyQt6`, `PySide2` or `PyQt5`. You should be able to adapt the approach to earlier versions of Qt. Please refer to the comments in the code snippet for more detailed information.

```
import datetime
import logging
import random
import sys
import time

# Deal with minor differences between different Qt packages
try:
    from PySide6 import QtCore, QtGui, QtWidgets
    Signal = QtCore.Signal
    Slot = QtCore.Slot
except ImportError:
    try:
        from PyQt6 import QtCore, QtGui, QtWidgets
        Signal = QtCore.pyqtSignal
        Slot = QtCore.pyqtSlot
    except ImportError:
        try:
            from PySide2 import QtCore, QtGui, QtWidgets
            Signal = QtCore.Signal
            Slot = QtCore.Slot
        except ImportError:
            from PyQt5 import QtCore, QtGui, QtWidgets
            Signal = QtCore.pyqtSignal
            Slot = QtCore.pyqtSlot

logger = logging.getLogger(__name__)

#
# Signals need to be contained in a QObject or subclass in
order to be correctly
```

```
# initialized.
#
class Signaller(QtCore.QObject):
    signal = Signal(str, logging.LogRecord)

#
# Output to a Qt GUI is only supposed to happen on the main
thread. So, this
# handler is designed to take a slot function which is set up
to run in the main
# thread. In this example, the function takes a string argument
which is a
# formatted log message, and the log record which generated it.
The formatted
# string is just a convenience - you could format a string for
output any way
# you like in the slot function itself.
#
# You specify the slot function to do whatever GUI updates you
want. The handler
# doesn't know or care about specific UI elements.
#
class QtHandler(logging.Handler):
    def __init__(self, slotfunc, *args, **kwargs):
        super().__init__(*args, **kwargs)
        self.signaller = Signaller()
        self.signaller.signal.connect(slotfunc)

    def emit(self, record):
        s = self.format(record)
        self.signaller.signal.emit(s, record)

#
# This example uses QThreads, which means that the threads at
the Python level
# are named something like "Dummy-1". The function below gets
the Qt name of the
# current thread.
#
def ctname():
    return QtCore.QThread.currentThread().objectName()
```

```
#
# Used to generate random levels for logging.
#
LEVELS = (logging.DEBUG, logging.INFO, logging.WARNING, 
logging.ERROR,
          logging.CRITICAL)

#
# This worker class represents work that is done in a thread 
separate to the
# main thread. The way the thread is kicked off to do work is 
via a button press
# that connects to a slot in the worker.
#
# Because the default threadName value in the LogRecord isn't 
much use, we add
# a qThreadName which contains the QThread name as computed 
above, and pass that
# value in an "extra" dictionary which is used to update the 
LogRecord with the
# QThread name.
#
# This example worker just outputs messages sequentially, 
interspersed with
# random delays of the order of a few seconds.
#
class Worker(QtCore.QObject):
    @Slot()
    def start(self):
        extra = {'qThreadName': ctname() }
        logger.debug('Started work', extra=extra)
        i = 1
        # Let the thread run until interrupted. This allows 
reasonably clean
        # thread termination.
        while not 
QtCore.QThread.currentThread().isInterruptionRequested():
            delay = 0.5 + random.random() * 2
            time.sleep(delay)
            try:
                if random.random() < 0.1:
                    raise ValueError('Exception raised: %d' % 
i)
```

```
                else:
                    level = random.choice(LEVELS)
                    logger.log(level, 'Message after delay of
%3.1f: %d', delay, i, extra=extra)
            except ValueError as e:
                logger.exception('Failed: %s', e, extra=extra)
            i += 1

#
# Implement a simple UI for this cookbook example. This
contains:
#
# * A read-only text edit window which holds formatted log
messages
# * A button to start work and log stuff in a separate thread
# * A button to log something from the main thread
# * A button to clear the log window
#
class Window(QtWidgets.QWidget):

        rc = app.exec_()
    sys.exit(rc)

if __name__=='__main__':
    main()
```

Logging to syslog with RFC5424 support

Although **RFC 5424** [https://datatracker.ietf.org/doc/html/rfc5424.html] dates from 2009, most syslog servers are configured by default to use the older **RFC 3164** [https://datatracker.ietf.org/doc/html/rfc3164.html], which hails from 2001. When `logging` was added to Python in 2003, it supported the earlier (and only existing) protocol at the time. Since RFC5424 came out, as there has not been widespread deployment of it in syslog servers, the **`SysLogHandler`** functionality has not been updated.

RFC 5424 contains some useful features such as support for structured data, and if you need to be able to log to a syslog server with support for it, you can do so with a subclassed handler which looks something like this:

```
import datetime
import logging.handlers
import re
import socket
import time

class SysLogHandler5424(logging.handlers.SysLogHandler):

    tz_offset = re.compile(r'([+-]\d{2})(\d{2})$')
    escaped = re.compile(r'([\]"\\])')

    def __init__(self, *args, **kwargs):
        self.msgid = kwargs.pop('msgid', None)
        self.appname = kwargs.pop('appname', None)
        super().__init__(*args, **kwargs)

    def format(self, record):
        version = 1
        asctime =
datetime.datetime.fromtimestamp(record.created).isoformat()
        m = self.tz_offset.match(time.strftime('%z'))
        has_offset = False
        if m and time.timezone:
            hrs, mins = m.groups()
            if int(hrs) or int(mins):
                has_offset = True
        if not has_offset:
            asctime += 'Z'
        else:
            asctime += f'{hrs}:{mins}'
        try:
            hostname = socket.gethostname()
        except Exception:
            hostname = '-'
        appname = self.appname or '-'
        procid = record.process
        msgid = '-'
        msg = super().format(record)
        sdata = '-'
        if hasattr(record, 'structured_data'):
            sd = record.structured_data
            # This should be a dict where the keys are SD-ID
and the value is a
            # dict mapping PARAM-NAME to PARAM-VALUE (refer to
the RFC for what these
            # mean)
            # There's no error checking here - it's purely for
```

```
illustration, and you
            # can adapt this code for use in production
environments
            parts = []

            def replacer(m):
                g = m.groups()
                return '\\' + g[0]

            for sdid, dv in sd.items():
                part = f'[{sdid}'
                for k, v in dv.items():
                    s = str(v)
                    s = self.escaped.sub(replacer, s)
                    part += f' {k}="{s}"'
                part += ']'
                parts.append(part)
            sdata = ''.join(parts)
        return f'{version} {asctime} {hostname} {appname}
{procid} {msgid} {sdata} {msg}'
```

You’ll need to be familiar with RFC 5424 to fully understand the above code, and it may be that you have slightly different needs (e.g. for how you pass structural data to the log). Nevertheless, the above should be adaptable to your speciric needs. With the above handler, you’d pass structured data using something like this:

```
sd = {
    'foo@12345': {'bar': 'baz', 'baz': 'bozz', 'fizz':
r'buzz'},
    'foo@54321': {'rab': 'baz', 'zab': 'bozz', 'zzif': r'buzz'}
}
extra = {'structured_data': sd}
i = 1
logger.debug('Message %d', i, extra=extra)
```

How to treat a logger like an output stream

Sometimes, you need to interface to a third-party API which expects a file-like object to write to, but you want to direct the API’s output to a logger. You can do this using a class which wraps a logger with a file-like API. Here’s a short script illustrating such a class:

```
import logging

class LoggerWriter:
    def __init__(self, logger, level):
        self.logger = logger
        self.level = level

    def write(self, message):
        if message != '\n':  # avoid printing bare newlines, if
you like
            self.logger.log(self.level, message)

    def flush(self):
        # doesn't actually do anything, but might be expected
of a file-like
        # object - so optional depending on your situation
        pass

    def close(self):
        # doesn't actually do anything, but might be expected
of a file-like
        # object - so optional depending on your situation. You
might want
        # to set a flag so that later calls to write raise an
exception
        pass

def main():
    logging.basicConfig(level=logging.DEBUG)
    logger = logging.getLogger('demo')
    info_fp = LoggerWriter(logger, logging.INFO)
    debug_fp = LoggerWriter(logger, logging.DEBUG)
    print('An INFO message', file=info_fp)
    print('A DEBUG message', file=debug_fp)
```

```
if __name__ == "__main__":
    main()
```

When this script is run, it prints

```
INFO:demo:An INFO message
DEBUG:demo:A DEBUG message
```

You could also use `LoggerWriter` to redirect `sys.stdout` and `sys.stderr` by doing something like this:

```
import sys

sys.stdout = LoggerWriter(logger, logging.INFO)
sys.stderr = LoggerWriter(logger, logging.WARNING)
```

You should do this *after* configuring logging for your needs. In the above example, the **`basicConfig()`** call does this (using the `sys.stderr` value *before* it is overwritten by a `LoggerWriter` instance). Then, you'd get this kind of result:

```
>>> print('Foo')
INFO:demo:Foo
>>> print('Bar', file=sys.stderr)
WARNING:demo:Bar
>>>
```

Of course, the examples above show output according to the format used by **`basicConfig()`**, but you can use a different formatter when you configure logging.

Note that with the above scheme, you are somewhat at the mercy of buffering and the sequence of write calls which you are intercepting. For example, with the definition of `LoggerWriter` above, if you have the snippet

```
sys.stderr = LoggerWriter(logger, logging.WARNING)
1 / 0
```

then running the script results in

```
WARNING:demo:Traceback (most recent call last):

WARNING:demo:  File "/home/runner/cookbook-
loggerwriter/test.py", line 53, in <module>

WARNING:demo:
WARNING:demo:main()
WARNING:demo:  File "/home/runner/cookbook-
loggerwriter/test.py", line 49, in main

WARNING:demo:
WARNING:demo:1 / 0
WARNING:demo:ZeroDivisionError
WARNING:demo::
WARNING:demo:division by zero
```

As you can see, this output isn’t ideal. That’s because the underlying code which writes to `sys.stderr` makes multiple writes, each of which results in a separate logged line (for example, the last three lines above). To get around this problem, you need to buffer things and only output log lines when newlines are seen. Let’s use a slightly better implementation of `LoggerWriter`:

```
class BufferingLoggerWriter(LoggerWriter):
    def __init__(self, logger, level):
        super().__init__(logger, level)
        self.buffer = ''

    def write(self, message):
        if '\n' not in message:
            self.buffer += message
        else:
            parts = message.split('\n')
            if self.buffer:
                s = self.buffer + parts.pop(0)
                self.logger.log(self.level, s)
            self.buffer = parts.pop()
            for part in parts:
                self.logger.log(self.level, part)
```

This just buffers up stuff until a newline is seen, and then logs complete lines. With this approach, you get better output:

```
WARNING:demo:Traceback (most recent call last):
WARNING:demo:  File "/home/runner/cookbook-
loggerwriter/main.py", line 55, in <module>
WARNING:demo:    main()
WARNING:demo:  File "/home/runner/cookbook-
loggerwriter/main.py", line 52, in main
WARNING:demo:    1/0
WARNING:demo:ZeroDivisionError: division by zero
```

How to uniformly handle newlines in logging output

Usually, messages that are logged (say to console or file) consist of a single line of text. However, sometimes there is a need to handle messages with multiple lines - whether because a logging format string contains newlines, or logged data contains newlines. If you want to handle such messages uniformly, so that each line in the logged message appears uniformly formatted as if it was logged separately, you can do this using a handler mixin, as in the following snippet:

```
# Assume this is in a module mymixins.py
import copy

class MultilineMixin:
    def emit(self, record):
        s = record.getMessage()
        if '\n' not in s:
            super().emit(record)
        else:
            lines = s.splitlines()
            rec = copy.copy(record)
            rec.args = None
            for line in lines:
                rec.msg = line
                super().emit(rec)
```

You can use the mixin as in the following script:

```
import logging

from mymixins import MultilineMixin

logger = logging.getLogger(__name__)

class StreamHandler(MultilineMixin, logging.StreamHandler):
    pass

if __name__ == '__main__':
    logging.basicConfig(level=logging.DEBUG, format='%
(asctime)s %(levelname)-9s %(message)s',
                        handlers = [StreamHandler()])
    logger.debug('Single line')
    logger.debug('Multiple lines:\nfool me once ...')
    logger.debug('Another single line')
    logger.debug('Multiple lines:\n%s', 'fool me ...\ncan\'t
get fooled again')
```

The script, when run, prints something like:

```
2025-07-02 13:54:47,234 DEBUG     Single line
2025-07-02 13:54:47,234 DEBUG     Multiple lines:
2025-07-02 13:54:47,234 DEBUG     fool me once ...
2025-07-02 13:54:47,234 DEBUG     Another single line
2025-07-02 13:54:47,234 DEBUG     Multiple lines:
2025-07-02 13:54:47,234 DEBUG     fool me ...
2025-07-02 13:54:47,234 DEBUG     can't get fooled again
```

If, on the other hand, you are concerned about log injection [https://owasp.org/www-community/attacks/Log_Injection], you can use a formatter which escapes newlines, as per the following example:

```
import logging

logger = logging.getLogger(__name__)
```

```
class EscapingFormatter(logging.Formatter):
    def format(self, record):
        s = super().format(record)
        return s.replace('\n', r'\n')

if __name__ == '__main__':
    h = logging.StreamHandler()
    h.setFormatter(EscapingFormatter('%(asctime)s %
(levelname)-9s %(message)s'))
    logging.basicConfig(level=logging.DEBUG, handlers = [h])
    logger.debug('Single line')
    logger.debug('Multiple lines:\nfool me once ...')
    logger.debug('Another single line')
    logger.debug('Multiple lines:\n%s', 'fool me ...\ncan\'t
get fooled again')
```

You can, of course, use whatever escaping scheme makes the most sense for you. The script, when run, should produce output like this:

```
2025-07-09 06:47:33,783 DEBUG     Single line
2025-07-09 06:47:33,783 DEBUG     Multiple lines:\nfool me once
...
2025-07-09 06:47:33,783 DEBUG     Another single line
2025-07-09 06:47:33,783 DEBUG     Multiple lines:\nfool me
...\ncan't get fooled again
```

Escaping behaviour can’t be the stdlib default , as it would break backwards compatibility.

Patterns to avoid

Although the preceding sections have described ways of doing things you might need to do or deal with, it is worth mentioning some usage patterns which are *unhelpful*, and which should therefore be avoided in most cases. The following sections are in no particular order.

Opening the same log file multiple times

On Windows, you will generally not be able to open the same file multiple times as this will lead to a “file is in use by another process” error. However, on POSIX platforms you’ll not get any errors if you open the same file multiple times. This could be done accidentally, for example by:

- Adding a file handler more than once which references the same file (e.g. by a copy/paste/forget-to-change error).
- Opening two files that look different, as they have different names, but are the same because one is a symbolic link to the other.
- Forking a process, following which both parent and child have a reference to the same file. This might be through use of the `multiprocessing` module, for example.

Opening a file multiple times might *appear* to work most of the time, but can lead to a number of problems in practice:

- Logging output can be garbled because multiple threads or processes try to write to the same file. Although logging guards against concurrent use of the same handler instance by multiple threads, there is no such protection if concurrent writes are attempted by two different threads using two different handler instances which happen to point to the same file.
- An attempt to delete a file (e.g. during file rotation) silently fails, because there is another reference pointing to it. This can lead to confusion and wasted debugging time - log entries end up in unexpected places, or are lost altogether. Or a file that was supposed to be moved remains in place, and grows in size unexpectedly despite size-based rotation being supposedly in place.

Use the techniques outlined in Logging to a single file from multiple processes to circumvent such issues.

Using loggers as attributes in a class or passing them as parameters

While there might be unusual cases where you’ll need to do this, in general there is no point because loggers are singletons. Code can always access a given logger instance by name using `logging.getLogger(name)`, so passing instances around and holding them as instance attributes is pointless. Note that in other languages such as Java and C#, loggers are often static class attributes. However, this pattern doesn’t make sense in Python, where the module (and not the class) is the unit of software decomposition.

Adding handlers other than `NullHandler` to a logger in a library

Configuring logging by adding handlers, formatters and filters is the responsibility of the application developer, not the library developer. If you are maintaining a library, ensure that you don’t add handlers to any of your loggers other than a **`NullHandler`** instance.

Creating a lot of loggers

Loggers are singletons that are never freed during a script execution, and so creating lots of loggers will use up memory which can’t then be freed. Rather than create a logger per e.g. file processed or network connection made, use the existing mechanisms for passing contextual information into your logs and restrict the loggers created to those describing areas within your application (generally modules, but occasionally slightly more fine-grained than that).

Basic Tutorial

Advanced Tutorial

Regular Expression HOWTO

Author:: A.M. Kuchling <amk@amk.ca>

Abstract

This document is an introductory tutorial to using regular expressions in Python with the **re** module. It provides a gentler introduction than the corresponding section in the Library Reference.

Introduction

Regular expressions (called REs, or regexes, or regex patterns) are essentially a tiny, highly specialized programming language embedded inside Python and made available through the **re** module. Using this little language, you specify the rules for the set of possible strings that you want to match; this set might contain English sentences, or e-mail addresses, or TeX commands, or anything you like. You can then ask questions such as “Does this string match the pattern?”, or “Is there a match for the pattern anywhere in this string?”. You can also use REs to modify a string or to split it apart in various ways.

Regular expression patterns are compiled into a series of bytecodes which are then executed by a matching engine written in C. For advanced use, it may be necessary to pay careful attention to how the engine will execute a given RE, and write the RE in a certain way in order to produce bytecode that runs faster. Optimization isn't covered in this document, because it requires that you have a good understanding of the matching engine's internals.

The regular expression language is relatively small and restricted, so not all possible string processing tasks can be done using regular expressions. There are also tasks that *can* be done with regular expressions, but the expressions turn out to be very complicated. In these cases, you may be better off writing Python code to do the processing; while Python code will be slower than an elaborate regular expression, it will also probably be more understandable.

Simple Patterns

We'll start by learning about the simplest possible regular expressions. Since regular expressions are used to operate on strings, we'll begin with the most common task: matching characters.

For a detailed explanation of the computer science underlying regular expressions (deterministic and non-deterministic finite automata), you can refer to almost any textbook on writing compilers.

Matching Characters

Most letters and characters will simply match themselves. For example, the regular expression `test` will match the string `test` exactly. (You can enable a case-insensitive mode that would let this RE match `Test` or `TEST` as well; more about this later.)

There are exceptions to this rule; some characters are special *metacharacters*, and don't match themselves. Instead, they signal that some out-of-the-ordinary thing should be matched, or they affect other portions of the RE by repeating them or changing their meaning. Much of this document is devoted to discussing various metacharacters and what they do.

Here’s a complete list of the metacharacters; their meanings will be discussed in the rest of this HOWTO.

```
. ^ $ * + ? { } [ ] \ | ( )
```

The first metacharacters we’ll look at are `[` and `]`. They’re used for specifying a character class, which is a set of characters that you wish to match. Characters can be listed individually, or a range of characters can be indicated by giving two characters and separating them by a `'-'`. For example, `[abc]` will match any of the characters `a`, `b`, or `c`; this is the same as `[a-c]`, which uses a range to express the same set of characters. If you wanted to match only lowercase letters, your RE would be `[a-z]`.

Metacharacters (except `\`) are not active inside classes. For example, `[akm$]` will match any of the characters `'a'`, `'k'`, `'m'`, or `'$'`; `'$'` is usually a metacharacter, but inside a character class it’s stripped of its special nature.

You can match the characters not listed within the class by *complementing* the set. This is indicated by including a `'^'` as the first character of the class. For example, `[^5]` will match any character except `'5'`. If the caret appears elsewhere in a character class, it does not have special meaning. For example: `[5^]` will match either a `'5'` or a `'^'`.

Perhaps the most important metacharacter is the backslash, `\`. As in Python string literals, the backslash can be followed by various characters to signal various special sequences. It’s also used to escape all the metacharacters so you can still match them in patterns; for example, if you need to match a `[` or `\`, you can precede them with a backslash to remove their special meaning: `\[` or `\\`.

Some of the special sequences beginning with `'\'` represent predefined sets of characters that are often useful, such as the set of digits, the set of letters, or the set of anything that isn’t whitespace.

Let’s take an example: `\w` matches any alphanumeric character. If the regex pattern is expressed in bytes, this is equivalent to the class `[a-zA-Z0-9_]`. If the regex pattern is a string, `\w` will match all the characters marked as letters in the Unicode database provided by the **`unicodedata`** module. You can use the more restricted definition of `\w` in a string pattern by supplying the **`re.ASCII`** flag when compiling the regular expression.

The following list of special sequences isn’t complete. For a complete list of sequences and expanded class definitions for Unicode string patterns, see the last part of Regular Expression Syntax in the Standard Library reference. In general, the Unicode versions match any character that’s in the appropriate category in the Unicode database.

`\d`

Matches any decimal digit; this is equivalent to the class `[0-9]`.

`\D`

Matches any non-digit character; this is equivalent to the class `[^0-9]`.

`\s`

Matches any whitespace character; this is equivalent to the class `[ \t\n\r\f\v]`.

`\S`

Matches any non-whitespace character; this is equivalent to the class `[^ \t\n\r\f\v]`.

`\w`

Matches any alphanumeric character; this is equivalent to the class `[a-zA-Z0-9_]`.

`\W`

Matches any non-alphanumeric character; this is equivalent to the class `[^a-zA-Z0-9_]`.

These sequences can be included inside a character class. For example, `[\s,.]` is a character class that will match any whitespace character, or `','` or `'.'`.

The final metacharacter in this section is `.`. It matches anything except a newline character, and there's an alternate mode (**`re.DOTALL`**) where it will match even a newline. `.` is often used where you want to match "any character".

Repeating Things

Being able to match varying sets of characters is the first thing regular expressions can do that isn't already possible with the methods available on strings. However, if that was the only additional capability of regexes, they wouldn't be much of an advance. Another capability is that you can specify that portions of the RE must be repeated a certain number of times.

The first metacharacter for repeating things that we'll look at is `*`. `*` doesn't match the literal character `'*'`; instead, it specifies that the previous character can be matched zero or more times, instead of exactly once.

For example, `ca*t` will match `'ct'` (0 `'a'` characters), `'cat'` (1 `'a'`), `'caaat'` (3 `'a'` characters), and so forth.

Repetitions such as `*` are *greedy*; when repeating a RE, the matching engine will try to repeat it as many times as possible. If later portions of the pattern don’t match, the matching engine will then back up and try again with fewer repetitions.

A step-by-step example will make this more obvious. Let’s consider the expression `a[bcd]*b`. This matches the letter `'a'`, zero or more letters from the class `[bcd]`, and finally ends with a `'b'`. Now imagine matching this RE against the string `'abcbd'`.

Step	**Matched**	**Explanation**
1	`a`	The `a` in the RE matches.
2	`abcbd`	The engine matches `[bcd]*`, going as far as it can, which is to the end of the string.
3	*Failure*	The engine tries to match `b`, but the current position is at the end of the string, so it fails.
4	`abcb`	Back up, so that `[bcd]*` matches one less character.
5	*Failure*	Try `b` again, but the current position is at the last character, which is a `'d'`.

Step	Matched	Explanation
6	`abc`	Back up again, so that `[bcd]*` is only matching `bc`.
6	`abcb`	Try `b` again. This time the character at the current position is `'b'`, so it succeeds.

The end of the RE has now been reached, and it has matched `'abcb'`. This demonstrates how the matching engine goes as far as it can at first, and if no match is found it will then progressively back up and retry the rest of the RE again and again. It will back up until it has tried zero matches for `[bcd]*`, and if that subsequently fails, the engine will conclude that the string doesn’t match the RE at all.

Another repeating metacharacter is `+`, which matches one or more times. Pay careful attention to the difference between `*` and `+`; `*` matches *zero* or more times, so whatever’s being repeated may not be present at all, while `+` requires at least *one* occurrence. To use a similar example, `ca+t` will match `'cat'` (1 `'a'`), `'caaat'` (3 `'a'`s), but won’t match `'ct'`.

There are two more repeating operators or quantifiers. The question mark character, `?`, matches either once or zero times; you can think of it as marking something as being optional. For example, `home-?brew` matches either `'homebrew'` or `'home-brew'`.

The most complicated quantifier is `{m,n}`, where *m* and *n* are decimal integers. This quantifier means there must be at least *m* repetitions, and at most *n*. For example, `a/{1,3}b` will match `'a/b'`, `'a//b'`, and `'a///b'`. It won't match `'ab'`, which has no slashes, or `'a////b'`, which has four.

You can omit either *m* or *n*; in that case, a reasonable value is assumed for the missing value. Omitting *m* is interpreted as a lower limit of 0, while omitting *n* results in an upper bound of infinity.

The simplest case `{m}` matches the preceding item exactly *m* times. For example, `a/{2}b` will only match `'a//b'`.

Readers of a reductionist bent may notice that the three other quantifiers can all be expressed using this notation. `{0,}` is the same as `*`, `{1,}` is equivalent to `+`, and `{0,1}` is the same as `?`. It's better to use `*`, `+`, or `?` when you can, simply because they're shorter and easier to read.

Using Regular Expressions

Now that we've looked at some simple regular expressions, how do we actually use them in Python? The **`re`** module provides an interface to the regular expression engine, allowing you to compile REs into objects and then perform matches with them.

Compiling Regular Expressions

Regular expressions are compiled into pattern objects, which have methods for various operations such as searching for pattern matches or performing string substitutions.

```
>>> import re
>>> p = re.compile('ab*')
>>> p
re.compile('ab*')
```

`re.compile()` also accepts an optional *flags* argument, used to enable various special features and syntax variations. We'll go over the available settings later, but for now a single example will do:

```
>>> p = re.compile('ab*', re.IGNORECASE)
```

The RE is passed to `re.compile()` as a string. REs are handled as strings because regular expressions aren't part of the core Python language, and no special syntax was created for expressing them. (There are applications that don't need REs at all, so there's no need to bloat the language specification by including them.) Instead, the `re` module is simply a C extension module included with Python, just like the `socket` or `zlib` modules.

Putting REs in strings keeps the Python language simpler, but has one disadvantage which is the topic of the next section.

The Backslash Plague

As stated earlier, regular expressions use the backslash character (`'\'`) to indicate special forms or to allow special characters to be used without invoking their special meaning. This conflicts with Python's usage of the same character for the same purpose in string literals.

Let's say you want to write a RE that matches the string `\section`, which might be found in a LaTeX file. To figure out what to write in the program code, start with the desired string to be matched. Next, you must escape any backslashes and other metacharacters by preceding them with a backslash, resulting in the string `\\section`. The resulting string that must be passed to `re.compile()` must be

`\\section`. However, to express this as a Python string literal, both backslashes must be escaped *again*.

Characters	Stage
`\section`	Text string to be matched
`\\section`	Escaped backslash for `re.compile()`
`"\\\\section"`	Escaped backslashes for a string literal

In short, to match a literal backslash, one has to write `'\\\\'` as the RE string, because the regular expression must be `\\`, and each backslash must be expressed as `\\` inside a regular Python string literal. In REs that feature backslashes repeatedly, this leads to lots of repeated backslashes and makes the resulting strings difficult to understand.

The solution is to use Python's raw string notation for regular expressions; backslashes are not handled in any special way in a string literal prefixed with `'r'`, so `r"\n"` is a two-character string containing `'\'` and `'n'`, while `"\n"` is a one-character string containing a newline. Regular expressions will often be written in Python code using this raw string notation.

In addition, special escape sequences that are valid in regular expressions, but not valid as Python string literals, now result in a `DeprecationWarning` and will eventually become a `SyntaxError`, which means the sequences will be invalid if raw string notation or escaping the backslashes isn't used.

Regular String	Raw string
`"ab*"`	`r"ab*"`
`"\\\\section"`	`r"\\section"`
`"\\w+\\s+\\1"`	`r"\w+\s+\1"`

Performing Matches

Once you have an object representing a compiled regular expression, what do you do with it? Pattern objects have several methods and attributes. Only the most significant ones will be covered here; consult the `re` docs for a complete listing.

Method/Attribute	Purpose
`match()`	Determine if the RE matches at the beginning of the string.
`search()`	Scan through a string, looking for any location where this RE matches.
`findall()`	Find all substrings where the RE matches, and returns them as a list.

Method/Attribute	Purpose
`finditer()`	Find all substrings where the RE matches, and returns them as an iterator.

`match()` and **`search()`** return `None` if no match can be found. If they're successful, a match object instance is returned, containing information about the match: where it starts and ends, the substring it matched, and more.

You can learn about this by interactively experimenting with the **`re`** module.

This HOWTO uses the standard Python interpreter for its examples. First, run the Python interpreter, import the **`re`** module, and compile a RE:

```
>>> import re
>>> p = re.compile('[a-z]+')
>>> p
re.compile('[a-z]+')
```

Now, you can try matching various strings against the RE `[a-z]+`. An empty string shouldn't match at all, since `+` means 'one or more repetitions'. **`match()`** should return `None` in this case, which will cause the interpreter to print no output. You can explicitly print the result of **`match()`** to make this clear.

```
>>> p.match("")
>>> print(p.match(""))
None
```

Now, let's try it on a string that it should match, such as `tempo`. In this case, **`match()`** will return a match object, so you should store the result in a variable for later use.

```
>>> m = p.match('tempo')
>>> m
<re.Match object; span=(0, 5), match='tempo'>
```

Now you can query the match object for information about the matching string. Match object instances also have several methods and attributes; the most important ones are:

Method/Attribute	Purpose
`group()`	Return the string matched by the RE
`start()`	Return the starting position of the match
`end()`	Return the ending position of the match
`span()`	Return a tuple containing the (start, end) positions of the match

Trying these methods will soon clarify their meaning:

```
>>> m.group()
'tempo'
>>> m.start(), m.end()
(0, 5)
>>> m.span()
(0, 5)
```

`group()` returns the substring that was matched by the RE. **`start()`** and **`end()`** return the starting and ending index of the match. **`span()`** returns both start and end indexes in a single tuple. Since the **`match()`** method only checks if the RE matches at the start of a string, **`start()`** will always be zero. However, the **`search()`** method of patterns scans through the string, so the match may not start at zero in that case.

```
>>> print(p.match('::: message'))
None
>>> m = p.search('::: message'); print(m)
<re.Match object; span=(4, 11), match='message'>
>>> m.group()
'message'
>>> m.span()
(4, 11)
```

In actual programs, the most common style is to store the match object in a variable, and then check if it was `None`. This usually looks like:

```
p = re.compile( ... )
m = p.match( 'string goes here' )
if m:
    print('Match found: ', m.group())
else:
    print('No match')
```

Two pattern methods return all of the matches for a pattern. **`findall()`** returns a list of matching strings:

```
>>> p = re.compile(r'\d+')
>>> p.findall('12 drummers drumming, 11 pipers piping, 10 lords
a-leaping')
['12', '11', '10']
```

The `r` prefix, making the literal a raw string literal, is needed in this example because escape sequences in a normal “cooked” string literal that are not recognized by Python, as opposed to regular expressions, now result in a

`DeprecationWarning` and will eventually become a **`SyntaxError`**. See The Backslash Plague.

`findall()` has to create the entire list before it can be returned as the result. The **`finditer()`** method returns a sequence of match object instances as an iterator:

```
>>> iterator = p.finditer('12 drummers drumming, 11 ... 10
...')
>>> iterator
<callable_iterator object at 0x...>
>>> for match in iterator:
...     print(match.span())
...
(0, 2)
(22, 24)
(29, 31)
```

Module-Level Functions

You don't have to create a pattern object and call its methods; the **`re`** module also provides top-level functions called **`match()`**, **`search()`**, **`findall()`**, **`sub()`**, and so forth. These functions take the same arguments as the corresponding pattern method with the RE string added as the first argument, and still return either `None` or a match object instance.

```
>>> print(re.match(r'From\s+', 'Fromage amk'))
None
>>> re.match(r'From\s+', 'From amk Thu May 14 19:12:10 1998')
<re.Match object; span=(0, 5), match='From '>
```

Under the hood, these functions simply create a pattern object for you and call the appropriate method on it. They also store the compiled object in a cache, so future calls using the same RE won't need to parse the pattern again and again.

Should you use these module-level functions, or should you get the pattern and call its methods yourself? If you’re accessing a regex within a loop, pre-compiling it will save a few function calls. Outside of loops, there’s not much difference thanks to the internal cache.

Compilation Flags

Compilation flags let you modify some aspects of how regular expressions work. Flags are available in the `re` module under two names, a long name such as `IGNORECASE` and a short, one-letter form such as `I`. (If you’re familiar with Perl’s pattern modifiers, the one-letter forms use the same letters; the short form of `re.VERBOSE` is `re.X`, for example.) Multiple flags can be specified by bitwise OR-ing them; `re.I | re.M` sets both the `I` and `M` flags, for example.

Here’s a table of the available flags, followed by a more detailed explanation of each one.

Flag	Meaning
`ASCII`, `A`	Makes several escapes like `\w`, `\b`, `\s` and `\d` match only on ASCII characters with the respective property.
`DOTALL`, `S`	Make `.` match any character, including newlines.
`IGNORECASE`, `I`	Do case-insensitive matches.
`LOCALE`, `L`	Do a locale-aware match.

Flag	**Meaning**
`MULTILINE`, `M`	Multi-line matching, affecting `^` and `$`.
`VERBOSE`, `X` (for ‘extended’)	Enable verbose REs, which can be organized more cleanly and understandably.

re.I
re.IGNORECASE

Perform case-insensitive matching; character class and literal strings will match letters by ignoring case. For example, `[A-Z]` will match lowercase letters, too. Full Unicode matching also works unless the `ASCII` flag is used to disable non-ASCII matches. When the Unicode patterns `[a-z]` or `[A-Z]` are used in combination with the `IGNORECASE` flag, they will match the 52 ASCII letters and 4 additional non-ASCII letters: ‘İ’ (U+0130, Latin capital letter I with dot above), ‘ı’ (U+0131, Latin small letter dotless i), ‘ſ’ (U+017F, Latin small letter long s) and ‘K’ (U+212A, Kelvin sign). `Spam` will match `'Spam'`, `'spam'`, `'spAM'`, or `'ſpam'` (the latter is matched only in Unicode mode). This lowercasing doesn’t take the current locale into account; it will if you also set the `LOCALE` flag.

re.L
re.LOCALE

Make `\w`, `\W`, `\b`, `\B` and case-insensitive matching dependent on the current locale instead of the Unicode database.

Locales are a feature of the C library intended to help in writing programs that take account of language differences. For example, if you're processing encoded French text, you'd want to be able to write `\w+` to match words, but `\w` only matches the character class `[A-Za-z]` in bytes patterns; it won't match bytes corresponding to `é` or `ç`. If your system is configured properly and a French locale is selected, certain C functions will tell the program that the byte corresponding to `é` should also be considered a letter. Setting the **`LOCALE`** flag when compiling a regular expression will cause the resulting compiled object to use these C functions for `\w`; this is slower, but also enables `\w+` to match French words as you'd expect. The use of this flag is discouraged in Python 3 as the locale mechanism is very unreliable, it only handles one "culture" at a time, and it only works with 8-bit locales. Unicode matching is already enabled by default in Python 3 for Unicode (str) patterns, and it is able to handle different locales/languages.

re.M
re.MULTILINE

(`^` and `$` haven't been explained yet; they'll be introduced in section More Metacharacters.)

Usually `^` matches only at the beginning of the string, and `$` matches only at the end of the string and immediately before the newline (if any) at the end of the string. When this flag is specified, `^` matches at the beginning of the string and at the beginning of each line within the string, immediately following each newline. Similarly, the `$` metacharacter matches either at the end of the string and at the end of each line (immediately preceding each newline).

re.S

re.DOTALL

Makes the `'.'` special character match any character at all, including a newline; without this flag, `'.'` will match anything *except* a newline.

re.A
re.ASCII

Make `\w`, `\W`, `\b`, `\B`, `\s` and `\S` perform ASCII-only matching instead of full Unicode matching. This is only meaningful for Unicode patterns, and is ignored for byte patterns.

re.X
re.VERBOSE

This flag allows you to write regular expressions that are more readable by granting you more flexibility in how you can format them. When this flag has been specified, whitespace within the RE string is ignored, except when the whitespace is in a character class or preceded by an unescaped backslash; this lets you organize and indent the RE more clearly. This flag also lets you put comments within a RE that will be ignored by the engine; comments are marked by a `'#'` that's neither in a character class or preceded by an unescaped backslash.

For example, here's a RE that uses **`re.VERBOSE`**; see how much easier it is to read?

```
charref = re.compile(r"""
 &[#]                # Start of a numeric entity reference
 (
     0[0-7]+         # Octal form
   | [0-9]+          # Decimal form
   | x[0-9a-fA-F]+   # Hexadecimal form
 )
 ;                   # Trailing semicolon
""", re.VERBOSE)
```

Without the verbose setting, the RE would look like this:

```
charref = re.compile("&#(0[0-7]+"
                     "|[0-9]+"
                     "|x[0-9a-fA-F]+);")
```

In the above example, Python’s automatic concatenation of string literals has been used to break up the RE into smaller pieces, but it’s still more difficult to understand than the version using **`re.VERBOSE`**.

More Pattern Power

So far we’ve only covered a part of the features of regular expressions. In this section, we’ll cover some new metacharacters, and how to use groups to retrieve portions of the text that was matched.

More Metacharacters

There are some metacharacters that we haven’t covered yet. Most of them will be covered in this section.

Some of the remaining metacharacters to be discussed are *zero-width assertions*. They don’t cause the engine to advance through the string; instead, they consume no characters at all, and simply succeed or fail. For example, `\b` is an assertion that the current position is located at a word boundary; the position isn’t changed by the `\b` at all. This means that zero-width assertions should never be repeated, because if they match once at a given location, they can obviously be matched an infinite number of times.

`|`

Alternation, or the “or” operator. If *A* and *B* are regular expressions, `A|B` will match any string that matches either *A* or *B*. `|` has very low precedence in order to make it work reasonably when you’re alternating multi-character strings. `Crow|Servo` will match either `'Crow'` or `'Servo'`, not `'Cro'`, a `'w'` or an `'S'`, and `'ervo'`.

To match a literal `'|'`, use `\|`, or enclose it inside a character class, as in `[|]`.

`^`

Matches at the beginning of lines. Unless the **`MULTILINE`** flag has been set, this will only match at the beginning of the string. In **`MULTILINE`** mode, this also matches immediately after each newline within the string.

For example, if you wish to match the word `From` only at the beginning of a line, the RE to use is `^From`.

```
>>> print(re.search('^From', 'From Here to Eternity'))
<re.Match object; span=(0, 4), match='From'>
>>> print(re.search('^From', 'Reciting From Memory'))
None
```

To match a literal `'^'`, use `\^`.

`$`

Matches at the end of a line, which is defined as either the end of the string, or any location followed by a newline character.

```
>>> print(re.search('}$', '{block}'))
<re.Match object; span=(6, 7), match='}'>
>>> print(re.search('}$', '{block} '))
None
>>> print(re.search('}$', '{block}\n'))
<re.Match object; span=(6, 7), match='}'>
```

To match a literal `'$'`, use `\$` or enclose it inside a character class, as in `[$]`.

`\A`

Matches only at the start of the string. When not in **`MULTILINE`** mode, `\A` and `^` are effectively the same. In **`MULTILINE`** mode, they're different: `\A` still matches only at the beginning of the string, but `^` may match at any location inside the string that follows a newline character.

`\z`

Matches only at the end of the string.

`\Z`

The same as `\z`. For compatibility with old Python versions.

`\b`

Word boundary. This is a zero-width assertion that matches only at the beginning or end of a word. A word is defined as a sequence of alphanumeric characters, so the end of a word is indicated by whitespace or a non-alphanumeric character.

The following example matches `class` only when it's a complete word; it won't match when it's contained inside another word.

```
>>> p = re.compile(r'\bclass\b')
>>> print(p.search('no class at all'))
<re.Match object; span=(3, 8), match='class'>
>>> print(p.search('the declassified algorithm'))
None
>>> print(p.search('one subclass is'))
None
```

There are two subtleties you should remember when using this special sequence. First, this is the worst collision between Python's string literals and regular expression sequences. In Python's string literals, `\b` is the backspace character, ASCII value 8. If you're not using raw strings, then Python will convert the `\b` to a backspace, and your RE won’t match as you expect it to. The following example looks the same as our previous RE, but omits the `'r'` in front of the RE string.

```
>>> p = re.compile('\bclass\b')
>>> print(p.search('no class at all'))
None
>>> print(p.search('\b' + 'class' + '\b'))
<re.Match object; span=(0, 7), match='\x08class\x08'>
```

Second, inside a character class, where there’s no use for this assertion, `\b` represents the backspace character, for compatibility with Python’s string literals.

`\B`

Another zero-width assertion, this is the opposite of `\b`, only matching when the current position is not at a word boundary.

Grouping

Frequently you need to obtain more information than just whether the RE matched or not. Regular expressions are often used to dissect strings by writing a RE divided into several subgroups which match different components of interest. For example, an RFC-822 header line is divided into a header name and a value, separated by a `':'`, like this:

```
From: author@example.com
User-Agent: Thunderbird 1.5.0.9 (X11/20061227)
MIME-Version: 1.0
To: editor@example.com
```

This can be handled by writing a regular expression which matches an entire header line, and has one group which matches the header name, and another group which matches the header’s value.

Groups are marked by the `'('`, `')'` metacharacters. `'('` and `')'` have much the same meaning as they do in mathematical expressions; they group together the expressions contained inside them, and you can repeat the contents of a group with a quantifier, such as `*`, `+`, `?`, or `{m,n}`. For example, `(ab)*` will match zero or more repetitions of `ab`.

```
>>> p = re.compile('(ab)*')
>>> print(p.match('ababababab').span())
(0, 10)
```

Groups indicated with `'('`, `')'` also capture the starting and ending index of the text that they match; this can be retrieved by passing an argument to **`group()`**, **`start()`**, **`end()`**, and **`span()`**. Groups are numbered starting with 0. Group 0 is always present; it's the whole RE, so match object methods all have group 0 as their default argument. Later we'll see how to express groups that don't capture the span of text that they match.

```
>>> p = re.compile('(a)b')
>>> m = p.match('ab')
>>> m.group()
'ab'
>>> m.group(0)
'ab'
```

Subgroups are numbered from left to right, from 1 upward. Groups can be nested; to determine the number, just count the opening parenthesis characters, going from left to right.

```
>>> p = re.compile('(a(b)c)d')
>>> m = p.match('abcd')
>>> m.group(0)
'abcd'
>>> m.group(1)
'abc'
>>> m.group(2)
'b'
```

`group()` can be passed multiple group numbers at a time, in which case it will return a tuple containing the corresponding values for those groups.

```
>>> m.group(2,1,2)
('b', 'abc', 'b')
```

The `groups()` method returns a tuple containing the strings for all the subgroups, from 1 up to however many there are.

```
>>> m.groups()
('abc', 'b')
```

Backreferences in a pattern allow you to specify that the contents of an earlier capturing group must also be found at the current location in the string. For example, `\1` will succeed if the exact contents of group 1 can be found at the current position, and fails otherwise. Remember that Python’s string literals also use a backslash followed by numbers to allow including arbitrary characters in a string, so be sure to use a raw string when incorporating backreferences in a RE.

For example, the following RE detects doubled words in a string.

```
>>> p = re.compile(r'\b(\w+)\s+\1\b')
>>> p.search('Paris in the the spring').group()
'the the'
```

Backreferences like this aren’t often useful for just searching through a string — there are few text formats which repeat data in this way — but you’ll soon find out that they’re *very* useful when performing string substitutions.

Non-capturing and Named Groups

Elaborate REs may use many groups, both to capture substrings of interest, and to group and structure the RE itself. In complex REs, it becomes difficult to keep track of the group numbers. There are two features which help with this problem. Both of them use a common syntax for regular expression extensions, so we'll look at that first.

Perl 5 is well known for its powerful additions to standard regular expressions. For these new features the Perl developers couldn't choose new single-keystroke metacharacters or new special sequences beginning with `\` without making Perl's regular expressions confusingly different from standard REs. If they chose `&` as a new metacharacter, for example, old expressions would be assuming that `&` was a regular character and wouldn't have escaped it by writing `\&` or `[&]`.

The solution chosen by the Perl developers was to use `(?...)` as the extension syntax. `?` immediately after a parenthesis was a syntax error because the `?` would have nothing to repeat, so this didn't introduce any compatibility problems. The characters immediately after the `?` indicate what extension is being used, so `(?=foo)` is one thing (a positive lookahead assertion) and `(?:foo)` is something else (a non-capturing group containing the subexpression `foo`).

Python supports several of Perl's extensions and adds an extension syntax to Perl's extension syntax. If the first character after the question mark is a `P`, you know that it's an extension that's specific to Python.

Now that we've looked at the general extension syntax, we can return to the features that simplify working with groups in complex REs.

Sometimes you’ll want to use a group to denote a part of a regular expression, but aren’t interested in retrieving the group’s contents. You can make this fact explicit by using a non-capturing group: `(?:...)`, where you can replace the `...` with any other regular expression.

```
>>> m = re.match("([abc])+", "abc")
>>> m.groups()
('c',)
>>> m = re.match("(?:[abc])+", "abc")
>>> m.groups()
()
```

Except for the fact that you can’t retrieve the contents of what the group matched, a non-capturing group behaves exactly the same as a capturing group; you can put anything inside it, repeat it with a repetition metacharacter such as `*`, and nest it within other groups (capturing or non-capturing). `(?:...)` is particularly useful when modifying an existing pattern, since you can add new groups without changing how all the other groups are numbered. It should be mentioned that there’s no performance difference in searching between capturing and non-capturing groups; neither form is any faster than the other.

A more significant feature is named groups: instead of referring to them by numbers, groups can be referenced by a name.

The syntax for a named group is one of the Python-specific extensions: `(?P<name>...)`. *name* is, obviously, the name of the group. Named groups behave exactly like capturing groups, and additionally associate a name with a group. The match object methods that deal with capturing groups all accept either integers that refer to the group by number or strings that contain the desired group’s name. Named groups are still given numbers, so you can retrieve information about a group in two ways:

```
>>> p = re.compile(r'(?P<word>\b\w+\b)')
>>> m = p.search( '(((( Lots of punctuation )))' )
>>> m.group('word')
'Lots'
>>> m.group(1)
'Lots'
```

Additionally, you can retrieve named groups as a dictionary with **`groupdict()`**:

```
>>> m = re.match(r'(?P<first>\w+) (?P<last>\w+)', 'Jane Doe')
>>> m.groupdict()
{'first': 'Jane', 'last': 'Doe'}
```

Named groups are handy because they let you use easily remembered names, instead of having to remember numbers. Here’s an example RE from the **`imaplib`** module:

```
InternalDate = re.compile(r'INTERNALDATE "'
        r'(?P<day>[ 123][0-9])-(?P<mon>[A-Z][a-z][a-z])-'
        r'(?P<year>[0-9][0-9][0-9][0-9])'
        r' (?P<hour>[0-9][0-9]):(?P<min>[0-9][0-9]):(?P<sec>[0-
9][0-9])'
        r' (?P<zonen>[-+])(?P<zoneh>[0-9][0-9])(?P<zonem>[0-9]
[0-9])'
        r'"')
```

It’s obviously much easier to retrieve `m.group('zonem')`, instead of having to remember to retrieve group 9.

The syntax for backreferences in an expression such as `(...)\1` refers to the number of the group. There’s naturally a variant that uses the group name instead of the number. This is another Python extension: `(?P=name)` indicates that the contents of the group called *name* should again be matched at the current point. The regular expression for finding doubled words, `\b(\w+)\s+\1\b` can also be written as `\b(?P<word>\w+)\s+(?P=word)\b`:

```
>>> p = re.compile(r'\b(?P<word>\w+)\s+(?P=word)\b')
>>> p.search('Paris in the the spring').group()
'the the'
```

Lookahead Assertions

Another zero-width assertion is the lookahead assertion. Lookahead assertions are available in both positive and negative form, and look like this:

`(?=...)`
: Positive lookahead assertion. This succeeds if the contained regular expression, represented here by `...`, successfully matches at the current location, and fails otherwise. But, once the contained expression has been tried, the matching engine doesn't advance at all; the rest of the pattern is tried right where the assertion started.

`(?!...)`
: Negative lookahead assertion. This is the opposite of the positive assertion; it succeeds if the contained expression *doesn't* match at the current position in the string.

To make this concrete, let's look at a case where a lookahead is useful. Consider a simple pattern to match a filename and split it apart into a base name and an extension, separated by a `.`. For example, in `news.rc`, `news` is the base name, and `rc` is the filename's extension.

The pattern to match this is quite simple:

```
.*[.].*$
```

Notice that the `.` needs to be treated specially because it's a metacharacter, so it's inside a character class to only match that specific character. Also notice the trailing `$`; this is added to ensure that all the rest of the string must be included in the extension. This regular expression matches `foo.bar` and `autoexec.bat` and `sendmail.cf` and `printers.conf`.

Now, consider complicating the problem a bit; what if you want to match filenames where the extension is not `bat`? Some incorrect attempts:

```
.*[.][^b].*$
```

The first attempt above tries to exclude `bat` by requiring that the first character of the extension is not a `b`. This is wrong, because the pattern also doesn't match `foo.bar`.

```
.*[.]([^b]..|.[^a].|..[^t])$
```

The expression gets messier when you try to patch up the first solution by requiring one of the following cases to match: the first character of the extension isn't `b`; the second character isn't `a`; or the third character isn't `t`. This accepts `foo.bar` and rejects `autoexec.bat`, but it requires a three-letter extension and won't accept a filename with a two-letter extension such as `sendmail.cf`. We'll complicate the pattern again in an effort to fix it.

```
.*[.]([^b].?.?|.[^a]?.?|..?[^t]?)$
```

In the third attempt, the second and third letters are all made optional in order to allow matching extensions shorter than three characters, such as `sendmail.cf`.

The pattern's getting really complicated now, which makes it hard to read and understand. Worse, if the problem changes and you want to exclude both `bat` and `exe` as extensions, the pattern would get even more complicated and confusing.

A negative lookahead cuts through all this confusion:

```
.*[.](?!bat$)[^.]*$
```

The negative lookahead means: if the expression `bat` doesn't match at this point, try the rest of the pattern; if `bat$` does match, the whole pattern will fail. The trailing `$` is required to ensure that something like `sample.batch`, where the extension only starts with `bat`, will be allowed. The `[^.]*` makes sure that the pattern works when there are multiple dots in the filename.

Excluding another filename extension is now easy; simply add it as an alternative inside the assertion. The following pattern excludes filenames that end in either `bat` or `exe`:

```
.*[.](?!bat$|exe$)[^.]*$
```

Modifying Strings

Up to this point, we've simply performed searches against a static string. Regular expressions are also commonly used to modify strings in various ways, using the following pattern methods:

Method/Attribute	Purpose
`split()`	Split the string into a list, splitting it wherever the RE matches

Method/Attribute	Purpose
`sub()`	Find all substrings where the RE matches, and replace them with a different string
`subn()`	Does the same thing as **`sub()`**, but returns the new string and the number of replacements

Splitting Strings

The `split()` method of a pattern splits a string apart wherever the RE matches, returning a list of the pieces. It’s similar to the `split()` method of strings but provides much more generality in the delimiters that you can split by; string **`split()`** only supports splitting by whitespace or by a fixed string. As you’d expect, there’s a module-level `re.split()` function, too.

.split(*string*[, *maxsplit=0*])

> Split *string* by the matches of the regular expression. If capturing parentheses are used in the RE, then their contents will also be returned as part of the resulting list. If *maxsplit* is nonzero, at most *maxsplit* splits are performed.

You can limit the number of splits made, by passing a value for *maxsplit*. When *maxsplit* is nonzero, at most *maxsplit* splits will be made, and the remainder of the string is returned as the final element of the list. In the following example, the delimiter is any sequence of non-alphanumeric characters.

```
>>> p = re.compile(r'\W+')
>>> p.split('This is a test, short and sweet, of split().')
['This', 'is', 'a', 'test', 'short', 'and', 'sweet', 'of',
'split', '']
>>> p.split('This is a test, short and sweet, of split().', 3)
['This', 'is', 'a', 'test, short and sweet, of split().']
```

Sometimes you’re not only interested in what the text between delimiters is, but also need to know what the delimiter was. If capturing parentheses are used in the RE, then their values are also returned as part of the list. Compare the following calls:

```
>>> p = re.compile(r'\W+')
>>> p2 = re.compile(r'(\W+)')
>>> p.split('This... is a test.')
['This', 'is', 'a', 'test', '']
>>> p2.split('This... is a test.')
['This', '... ', 'is', ' ', 'a', ' ', 'test', '.', '']
```

The module-level function `re.split()` adds the RE to be used as the first argument, but is otherwise the same.

```
>>> re.split(r'[\W]+', 'Words, words, words.')
['Words', 'words', 'words', '']
>>> re.split(r'([\W]+)', 'Words, words, words.')
['Words', ', ', 'words', ', ', 'words', '.', '']
>>> re.split(r'[\W]+', 'Words, words, words.', 1)
['Words', 'words, words.']
```

Search and Replace

Another common task is to find all the matches for a pattern, and replace them with a different string. The `sub()` method takes a replacement value, which can be either a string or a function, and the string to be processed.

.sub(*replacement*, *string*[, *count=0*])

Returns the string obtained by replacing the leftmost non-overlapping occurrences of the RE in *string* by the replacement *replacement*. If the pattern isn’t found, *string* is returned unchanged.

The optional argument *count* is the maximum number of pattern occurrences to be replaced; *count* must be a non-negative integer. The default value of 0 means to replace all occurrences.

Here’s a simple example of using the **`sub()`** method. It replaces colour names with the word `colour`:

```
>>> p = re.compile('(blue|white|red)')
>>> p.sub('colour', 'blue socks and red shoes')
'colour socks and colour shoes'
>>> p.sub('colour', 'blue socks and red shoes', count=1)
'colour socks and red shoes'
```

The **`subn()`** method does the same work, but returns a 2-tuple containing the new string value and the number of replacements that were performed:

```
>>> p = re.compile('(blue|white|red)')
>>> p.subn('colour', 'blue socks and red shoes')
('colour socks and colour shoes', 2)
>>> p.subn('colour', 'no colours at all')
('no colours at all', 0)
```

Empty matches are replaced only when they’re not adjacent to a previous empty match.

```
>>> p = re.compile('x*')
>>> p.sub('-', 'abxd')
'-a-b--d-'
```

If *replacement* is a string, any backslash escapes in it are processed. That is, `\n` is converted to a single newline character, `\r` is converted to a carriage return, and so forth. Unknown escapes such as `\&` are left alone. Backreferences, such as `\6`, are replaced with the substring matched by the corresponding group in the RE. This lets you incorporate portions of the original text in the resulting replacement string.

This example matches the word `section` followed by a string enclosed in `{`, `}`, and changes `section` to `subsection`:

```
>>> p = re.compile('section{ ( [^}]* ) }', re.VERBOSE)
>>> p.sub(r'subsection{\1}','section{First} section{second}')
'subsection{First} subsection{second}'
```

There's also a syntax for referring to named groups as defined by the `(?P<name>...)` syntax. `\g<name>` will use the substring matched by the group named `name`, and `\g<number>` uses the corresponding group number. `\g<2>` is therefore equivalent to `\2`, but isn't ambiguous in a replacement string such as `\g<2>0`. (`\20` would be interpreted as a reference to group 20, not a reference to group 2 followed by the literal character `'0'`.) The following substitutions are all equivalent, but use all three variations of the replacement string.

```
>>> p = re.compile('section{ (?P<name> [^}]* ) }', re.VERBOSE)
>>> p.sub(r'subsection{\1}','section{First}')
'subsection{First}'
>>> p.sub(r'subsection{\g<1>}','section{First}')
'subsection{First}'
>>> p.sub(r'subsection{\g<name>}','section{First}')
'subsection{First}'
```

replacement can also be a function, which gives you even more control. If *replacement* is a function, the function is called for every non-overlapping occurrence of *pattern*. On each call, the function is passed a match object argument for the match and can use this information to compute the desired replacement string and return it.

In the following example, the replacement function translates decimals into hexadecimal:

```
>>> def hexrepl(match):
...     "Return the hex string for a decimal number"
...     value = int(match.group())
...     return hex(value)
...
>>> p = re.compile(r'\d+')
>>> p.sub(hexrepl, 'Call 65490 for printing, 49152 for user
code.')
'Call 0xffd2 for printing, 0xc000 for user code.'
```

When using the module-level `re.sub()` function, the pattern is passed as the first argument. The pattern may be provided as an object or as a string; if you need to specify regular expression flags, you must either use a pattern object as the first parameter, or use embedded modifiers in the pattern string, e.g. `sub("(?i)b+", "x", "bbbb BBBB")` returns `'x x'`.

Common Problems

Regular expressions are a powerful tool for some applications, but in some ways their behaviour isn’t intuitive and at times they don’t behave the way you may expect them to. This section will point out some of the most common pitfalls.

Use String Methods

Sometimes using the `re` module is a mistake. If you’re matching a fixed string, or a single character class, and you’re not using any `re` features such as the `IGNORECASE` flag, then the full power of regular expressions may not be required. Strings have several methods for performing operations with fixed strings and they’re usually much faster, because the implementation is a single small C loop that’s been optimized for the purpose, instead of the large, more generalized regular expression engine.

One example might be replacing a single fixed string with another one; for example, you might replace `word` with `deed`. **`re.sub()`** seems like the function to use for this, but consider the **`replace()`** method. Note that **`replace()`** will also replace `word` inside words, turning `swordfish` into `sdeedfish`, but the naive RE `word` would have done that, too. (To avoid performing the substitution on parts of words, the pattern would have to be `\bword\b`, in order to require that `word` have a word boundary on either side. This takes the job beyond **`replace()`**’s abilities.)

Another common task is deleting every occurrence of a single character from a string or replacing it with another single character. You might do this with something like `re.sub('\n', ' ', S)`, but **`translate()`** is capable of doing both tasks and will be faster than any regular expression operation can be.

In short, before turning to the **`re`** module, consider whether your problem can be solved with a faster and simpler string method.

match() versus search()

The **`match()`** function only checks if the RE matches at the beginning of the string while **`search()`** will scan forward through the string for a match. It’s important to keep this distinction in mind. Remember, **`match()`** will only report a successful match which will start at 0; if the match wouldn’t start at zero, **`match()`** will *not* report it.

```
>>> print(re.match('super', 'superstition').span())
(0, 5)
>>> print(re.match('super', 'insuperable'))
None
```

On the other hand, `search()` will scan forward through the string, reporting the first match it finds.

```
>>> print(re.search('super', 'superstition').span())
(0, 5)
>>> print(re.search('super', 'insuperable').span())
(2, 7)
```

Sometimes you’ll be tempted to keep using `re.match()`, and just add `.*` to the front of your RE. Resist this temptation and use `re.search()` instead. The regular expression compiler does some analysis of REs in order to speed up the process of looking for a match. One such analysis figures out what the first character of a match must be; for example, a pattern starting with `Crow` must match starting with a `'C'`. The analysis lets the engine quickly scan through the string looking for the starting character, only trying the full match if a `'C'` is found.

Adding `.*` defeats this optimization, requiring scanning to the end of the string and then backtracking to find a match for the rest of the RE. Use `re.search()` instead.

Greedy versus Non-Greedy

When repeating a regular expression, as in `a*`, the resulting action is to consume as much of the pattern as possible. This fact often bites you when you’re trying to match a pair of balanced delimiters, such as the angle brackets surrounding an HTML tag. The naive pattern for matching a single HTML tag doesn't work because of the greedy nature of `.*`.

```
>>> s = '<html><head><title>Title</title>'
>>> len(s)
32
>>> print(re.match('<.*>', s).span())
(0, 32)
>>> print(re.match('<.*>', s).group())
<html><head><title>Title</title>
```

The RE matches the `'<'` in `'<html>'`, and the `.*` consumes the rest of the string. There's still more left in the RE, though, and the `>` can't match at the end of the string, so the regular expression engine has to backtrack character by character until it finds a match for the `>`. The final match extends from the `'<'` in `'<html>'` to the `'>'` in `'</title>'`, which isn't what you want.

In this case, the solution is to use the non-greedy quantifiers `*?`, `+?`, `??`, or `{m,n}?`, which match as *little* text as possible. In the above example, the `'>'` is tried immediately after the first `'<'` matches, and when it fails, the engine advances a character at a time, retrying the `'>'` at every step. This produces just the right result:

```
>>> print(re.match('<.*?>', s).group())
<html>
```

(Note that parsing HTML or XML with regular expressions is painful. Quick-and-dirty patterns will handle common cases, but HTML and XML have special cases that will break the obvious regular expression; by the time you've written a regular expression that handles all of the possible cases, the patterns will be *very* complicated. Use an HTML or XML parser module for such tasks.)

Using re.VERBOSE

By now you’ve probably noticed that regular expressions are a very compact notation, but they’re not terribly readable. REs of moderate complexity can become lengthy collections of backslashes, parentheses, and metacharacters, making them difficult to read and understand.

For such REs, specifying the `re.VERBOSE` flag when compiling the regular expression can be helpful, because it allows you to format the regular expression more clearly.

The `re.VERBOSE` flag has several effects. Whitespace in the regular expression that *isn’t* inside a character class is ignored. This means that an expression such as `dog | cat` is equivalent to the less readable `dog|cat`, but `[a b]` will still match the characters `'a'`, `'b'`, or a space. In addition, you can also put comments inside a RE; comments extend from a `#` character to the next newline. When used with triple-quoted strings, this enables REs to be formatted more neatly:

```
pat = re.compile(r"""
 \s*                 # Skip leading whitespace
 (?P<header>[^:]+)   # Header name
 \s* :               # Whitespace, and a colon
 (?P<value>.*?)      # The header's value -- *? used to
                     # lose the following trailing whitespace
 \s*$                # Trailing whitespace to end-of-line
""", re.VERBOSE)
```

This is far more readable than:

```
pat = re.compile(r"\s*(?P<header>[^:]+)\s*:(?P<value>.*?)\s*$")
```

Feedback

Regular expressions are a complicated topic. Did this document help you understand them? Were there parts that were unclear, or Problems you encountered that weren’t covered here? If so, please send suggestions for improvements to the author.

The most complete book on regular expressions is almost certainly Jeffrey Friedl’s Mastering Regular Expressions, published by O’Reilly. Unfortunately, it exclusively concentrates on Perl and Java’s flavours of regular expressions, and doesn’t contain any Python material at all, so it won’t be useful as a reference for programming in Python. (The first edition covered Python’s now-removed `regex` module, which won’t help you much.) Consider checking it out from your library.

Socket Programming HOWTO

Author:: Gordon McMillan

Abstract

Sockets are used nearly everywhere, but are one of the most severely misunderstood technologies around. This is a 10,000 foot overview of sockets. It’s not really a tutorial - you’ll still have work to do in getting things operational. It doesn’t cover the fine points (and there are a lot of them), but I hope it will give you enough background to begin using them decently.

Sockets

I’m only going to talk about INET (i.e. IPv4) sockets, but they account for at least 99% of the sockets in use. And I’ll only talk about STREAM (i.e. TCP) sockets - unless you really know what you’re doing (in which case this HOWTO isn’t for you!), you’ll get better behavior and performance from a STREAM socket than anything else. I will try to clear up the mystery of what a socket is, as well as some hints on how to work with blocking and non-blocking sockets. But I’ll start by talking about blocking sockets. You’ll need to know how they work before dealing with non-blocking sockets.

Part of the trouble with understanding these things is that “socket” can mean a number of subtly different things, depending on context. So first, let’s make a distinction between a “client” socket - an endpoint of a conversation, and a “server” socket, which is more like a switchboard operator. The client application (your browser, for example) uses “client” sockets exclusively; the web server it’s talking to uses both “server” sockets and “client” sockets.

History

Of the various forms of IPC, sockets are by far the most popular. On any given platform, there are likely to be other forms of IPC that are faster, but for cross-platform communication, sockets are about the only game in town.

They were invented in Berkeley as part of the BSD flavor of Unix. They spread like wildfire with the internet. With good reason — the combination of sockets with INET makes talking to arbitrary machines around the world unbelievably easy (at least compared to other schemes).

Creating a Socket

Roughly speaking, when you clicked on the link that brought you to this page, your browser did something like the following:

```
# create an INET, STREAMing socket
s = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
# now connect to the web server on port 80 - the normal http
port
s.connect(("www.python.org", 80))
```

When the `connect` completes, the socket `s` can be used to send in a request for the text of the page. The same socket will read the reply, and then be destroyed. That’s right, destroyed. Client sockets are normally only used for one exchange (or a small set of sequential exchanges).

What happens in the web server is a bit more complex. First, the web server creates a “server socket”:

```
# create an INET, STREAMing socket
serversocket = socket.socket(socket.AF_INET,
socket.SOCK_STREAM)
# bind the socket to a public host, and a well-known port
serversocket.bind((socket.gethostname(), 80))
# become a server socket
serversocket.listen(5)
```

A couple things to notice: we used `socket.gethostname()` so that the socket would be visible to the outside world. If we had used `s.bind(('localhost', 80))` or `s.bind(('127.0.0.1', 80))` we would still have a “server” socket, but one that was only visible within the same machine. `s.bind(('', 80))` specifies that the socket is reachable by any address the machine happens to have.

A second thing to note: low number ports are usually reserved for “well known” services (HTTP, SNMP etc). If you’re playing around, use a nice high number (4 digits).

Finally, the argument to `listen` tells the socket library that we want it to queue up as many as 5 connect requests (the normal max) before refusing outside connections. If the rest of the code is written properly, that should be plenty.

Now that we have a “server” socket, listening on port 80, we can enter the mainloop of the web server:

```
while True:
    # accept connections from outside
    (clientsocket, address) = serversocket.accept()
    # now do something with the clientsocket
    # in this case, we'll pretend this is a threaded server
    ct = make_client_thread(clientsocket)
    ct.start()
```

There’s actually 3 general ways in which this loop could work - dispatching a thread to handle `clientsocket`, create a new process to handle `clientsocket`, or restructure this app to use non-blocking sockets, and multiplex between our “server” socket and any active `clientsocket`s using `select`. More about that later. The important thing to understand now is this: this is *all* a “server” socket does. It doesn’t send any data. It doesn’t receive any data. It just produces “client” sockets. Each `clientsocket` is created in response to some *other* “client” socket doing a `connect()` to the host and port we’re bound to. As soon as we’ve created that `clientsocket`, we go back to listening for more connections. The two “clients” are free to chat it up - they are using some dynamically allocated port which will be recycled when the conversation ends.

IPC

If you need fast IPC between two processes on one machine, you should look into pipes or shared memory. If you do decide to use AF_INET sockets, bind the “server” socket to `'localhost'`. On most platforms, this will take a shortcut around a couple of layers of network code and be quite a bit faster.

See also

The **`multiprocessing`** integrates cross-platform IPC into a higher-level API.

Using a Socket

The first thing to note, is that the web browser’s “client” socket and the web server’s “client” socket are identical beasts. That is, this is a “peer to peer” conversation. Or to put it another way, *as the designer, you will have to decide what the rules of etiquette are for a conversation*. Normally, the `connect`ing socket starts the conversation, by sending in a request, or perhaps a signon. But that’s a design decision - it’s not a rule of sockets.

Now there are two sets of verbs to use for communication. You can use `send` and `recv`, or you can transform your client socket into a file-like beast and use `read` and `write`. The latter is the way Java presents its sockets. I’m not going to talk about it here, except to warn you that you need to use `flush` on sockets. These are buffered “files”, and a common mistake is to `write` something, and then `read` for a reply. Without a `flush` in there, you may wait forever for the reply, because the request may still be in your output buffer.

Now we come to the major stumbling block of sockets - `send` and `recv` operate on the network buffers. They do not necessarily handle all the bytes you hand them (or expect from them), because their major focus is handling the network buffers. In general, they return when the associated network buffers have been filled (`send`) or emptied (`recv`). They then tell you how many bytes they handled. It is *your* responsibility to call them again until your message has been completely dealt with.

When a `recv` returns 0 bytes, it means the other side has closed (or is in the process of closing) the connection. You will not receive any more data on this connection. Ever. You may be able to send data successfully; I’ll talk more about this later.

A protocol like HTTP uses a socket for only one transfer. The client sends a request, then reads a reply. That’s it. The socket is discarded. This means that a client can detect the end of the reply by receiving 0 bytes.

But if you plan to reuse your socket for further transfers, you need to realize that *there is no* EOT *on a socket.* I repeat: if a socket `send` or `recv` returns after handling 0 bytes, the connection has been broken. If the connection has *not* been broken, you may wait on a `recv` forever, because the socket will *not* tell you that there’s nothing more to read (for now). Now if you think about that a bit, you’ll come to realize a fundamental truth of sockets: *messages must either be fixed length* (yuck), *or be delimited* (shrug), *or indicate how long they are* (much better), *or end by shutting down the connection*. The choice is entirely yours, (but some ways are righter than others).

Assuming you don’t want to end the connection, the simplest solution is a fixed length message:

```
class MySocket:
    """demonstration class only
      - coded for clarity, not efficiency
    """

    def __init__(self, sock=None):
        if sock is None:
            self.sock = socket.socket(
                            socket.AF_INET, socket.SOCK_STREAM)
        else:
            self.sock = sock

    def connect(self, host, port):
        self.sock.connect((host, port))

    def mysend(self, msg):
        totalsent = 0
        while totalsent < MSGLEN:
            sent = self.sock.send(msg[totalsent:])
            if sent == 0:
                raise RuntimeError("socket connection broken")
            totalsent = totalsent + sent

    def myreceive(self):
        chunks = []
        bytes_recd = 0
        while bytes_recd < MSGLEN:
            chunk = self.sock.recv(min(MSGLEN - bytes_recd,
2048))
            if chunk == b'':
                raise RuntimeError("socket connection broken")
            chunks.append(chunk)
            bytes_recd = bytes_recd + len(chunk)
        return b''.join(chunks)
```

The sending code here is usable for almost any messaging scheme - in Python you send strings, and you can use `len()` to determine its length (even if it has embedded `\0` characters). It’s mostly the receiving code that gets more complex. (And in C, it’s not much worse, except you can’t use `strlen` if the message has embedded `\0`s.)

The easiest enhancement is to make the first character of the message an indicator of message type, and have the type determine the length. Now you have two `recv`s - the first to get (at least) that first character so you can look up the length, and the second in a loop to get the rest. If you decide to go the delimited route, you’ll be receiving in some arbitrary chunk size, (4096 or 8192 is frequently a good match for network buffer sizes), and scanning what you’ve received for a delimiter.

One complication to be aware of: if your conversational protocol allows multiple messages to be sent back to back (without some kind of reply), and you pass `recv` an arbitrary chunk size, you may end up reading the start of a following message. You’ll need to put that aside and hold onto it, until it’s needed.

Prefixing the message with its length (say, as 5 numeric characters) gets more complex, because (believe it or not), you may not get all 5 characters in one `recv`. In playing around, you'll get away with it; but in high network loads, your code will very quickly break unless you use two `recv` loops - the first to determine the length, the second to get the data part of the message. Nasty. This is also when you'll discover that `send` does not always manage to get rid of everything in one pass. And despite having read this, you will eventually get bit by it!

In the interests of space, building your character, (and preserving my competitive position), these enhancements are left as an exercise for the reader. Lets move on to cleaning up.

Binary Data

It is perfectly possible to send binary data over a socket. The major problem is that not all machines use the same formats for binary data. For example, network byte order [https://en.wikipedia.org/wiki/Endianness#Networking] is big-endian, with the most significant byte first, so a 16 bit integer with the value `1` would be the two hex bytes `00 01`. However, most common processors (x86/AMD64, ARM, RISC-V), are little-endian, with the least significant byte first - that same `1` would be `01 00`.

Socket libraries have calls for converting 16 and 32 bit integers - `ntohl, htonl, ntohs, htons` where "n" means *network* and "h" means *host*, "s" means *short* and "l" means *long*. Where network order is host order, these do nothing, but where the machine is byte-reversed, these swap the bytes around appropriately.

In these days of 64-bit machines, the ASCII representation of binary data is frequently smaller than the binary representation. That’s because a surprising amount of the time, most integers have the value 0, or maybe 1. The string `"0"` would be two bytes, while a full 64-bit integer would be 8. Of course, this doesn’t fit well with fixed-length messages. Decisions, decisions.

Disconnecting

Strictly speaking, you’re supposed to use `shutdown` on a socket before you `close` it. The `shutdown` is an advisory to the socket at the other end. Depending on the argument you pass it, it can mean “I’m not going to send anymore, but I’ll still listen”, or “I’m not listening, good riddance!”. Most socket libraries, however, are so used to programmers neglecting to use this piece of etiquette that normally a `close` is the same as `shutdown(); close()`. So in most situations, an explicit `shutdown` is not needed.

One way to use `shutdown` effectively is in an HTTP-like exchange. The client sends a request and then does a `shutdown(1)`. This tells the server “This client is done sending, but can still receive.” The server can detect “EOF” by a receive of 0 bytes. It can assume it has the complete request. The server sends a reply. If the `send` completes successfully then, indeed, the client was still receiving.

Python takes the automatic shutdown a step further, and says that when a socket is garbage collected, it will automatically do a `close` if it’s needed. But relying on this is a very bad habit. If your socket just disappears without doing a `close`, the socket at the other end may hang indefinitely, thinking you’re just being slow. *Please* `close` your sockets when you’re done.

When Sockets Die

Probably the worst thing about using blocking sockets is what happens when the other side comes down hard (without doing a `close`). Your socket is likely to hang. TCP is a reliable protocol, and it will wait a long, long time before giving up on a connection. If you're using threads, the entire thread is essentially dead. There's not much you can do about it. As long as you aren't doing something dumb, like holding a lock while doing a blocking read, the thread isn't really consuming much in the way of resources. Do *not* try to kill the thread - part of the reason that threads are more efficient than processes is that they avoid the overhead associated with the automatic recycling of resources. In other words, if you do manage to kill the thread, your whole process is likely to be screwed up.

Non-blocking Sockets

If you've understood the preceding, you already know most of what you need to know about the mechanics of using sockets. You'll still use the same calls, in much the same ways. It's just that, if you do it right, your app will be almost inside-out.

In Python, you use `socket.setblocking(False)` to make it non-blocking. In C, it's more complex, (for one thing, you'll need to choose between the BSD flavor `O_NONBLOCK` and the almost indistinguishable POSIX flavor `O_NDELAY`, which is completely different from `TCP_NODELAY`), but it's the exact same idea. You do this after creating the socket, but before using it. (Actually, if you're nuts, you can switch back and forth.)

The major mechanical difference is that `send`, `recv`, `connect` and `accept` can return without having done anything. You have (of course) a number of choices. You can check return code and error codes and generally drive yourself crazy. If you don’t believe me, try it sometime. Your app will grow large, buggy and suck CPU. So let’s skip the brain-dead solutions and do it right.

Use `select`.

In C, coding `select` is fairly complex. In Python, it’s a piece of cake, but it’s close enough to the C version that if you understand `select` in Python, you’ll have little trouble with it in C:

```
ready_to_read, ready_to_write, in_error = \
               select.select(
                  potential_readers,
                  potential_writers,
                  potential_errs,
                  timeout)
```

You pass `select` three lists: the first contains all sockets that you might want to try reading; the second all the sockets you might want to try writing to, and the last (normally left empty) those that you want to check for errors. You should note that a socket can go into more than one list. The `select` call is blocking, but you can give it a timeout. This is generally a sensible thing to do - give it a nice long timeout (say a minute) unless you have good reason to do otherwise.

In return, you will get three lists. They contain the sockets that are actually readable, writable and in error. Each of these lists is a subset (possibly empty) of the corresponding list you passed in.

If a socket is in the output readable list, you can be as-close-to-certain-as-we-ever-get-in-this-business that a `recv` on that socket will return *something*. Same idea for the writable list.

You’ll be able to send *something*. Maybe not all you want to, but *something* is better than nothing. (Actually, any reasonably healthy socket will return as writable - it just means outbound network buffer space is available.)

If you have a “server” socket, put it in the potential_readers list. If it comes out in the readable list, your `accept` will (almost certainly) work. If you have created a new socket to `connect` to someone else, put it in the potential_writers list. If it shows up in the writable list, you have a decent chance that it has connected.

Actually, `select` can be handy even with blocking sockets. It’s one way of determining whether you will block - the socket returns as readable when there’s something in the buffers. However, this still doesn’t help with the problem of determining whether the other end is done, or just busy with something else.

Portability alert: On Unix, `select` works both with the sockets and files. Don’t try this on Windows. On Windows, `select` works with sockets only. Also note that in C, many of the more advanced socket options are done differently on Windows. In fact, on Windows I usually use threads (which work very, very well) with my sockets.

Sorting Techniques

Author:: Andrew Dalke and Raymond Hettinger

Python lists have a built-in `list.sort()` method that modifies the list in-place. There is also a `sorted()` built-in function that builds a new sorted list from an iterable.

In this document, we explore the various techniques for sorting data using Python.

Sorting Basics

A simple ascending sort is very easy: just call the `sorted()` function. It returns a new sorted list:

```
>>> sorted([5, 2, 3, 1, 4])
[1, 2, 3, 4, 5]
```

You can also use the `list.sort()` method. It modifies the list in-place (and returns `None` to avoid confusion). Usually it’s less convenient than `sorted()` - but if you don’t need the original list, it’s slightly more efficient.

```
>>> a = [5, 2, 3, 1, 4]
>>> a.sort()
>>> a
[1, 2, 3, 4, 5]
```

Another difference is that the `list.sort()` method is only defined for lists. In contrast, the `sorted()` function accepts any iterable.

```
>>> sorted({1: 'D', 2: 'B', 3: 'B', 4: 'E', 5: 'A'})
[1, 2, 3, 4, 5]
```

Key Functions

The `list.sort()` method and the functions `sorted()`, `min()`, `max()`, `heapq.nsmallest()`, and `heapq.nlargest()` have a *key* parameter to specify a function (or other callable) to be called on each list element prior to making comparisons.

For example, here's a case-insensitive string comparison using `str.casefold()`:

```
>>> sorted("This is a test string from Andrew".split(),
key=str.casefold)
['a', 'Andrew', 'from', 'is', 'string', 'test', 'This']
```

The value of the *key* parameter should be a function (or other callable) that takes a single argument and returns a key to use for sorting purposes. This technique is fast because the key function is called exactly once for each input record.

A common pattern is to sort complex objects using some of the object's indices as keys. For example:

```
>>> student_tuples = [
...     ('john', 'A', 15),
...     ('jane', 'B', 12),
...     ('dave', 'B', 10),
... ]
>>> sorted(student_tuples, key=lambda student: student[2])   #
sort by age
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]
```

The same technique works for objects with named attributes. For example:

```
>>> class Student:
...     def __init__(self, name, grade, age):
...         self.name = name
...         self.grade = grade
...         self.age = age
...     def __repr__(self):
...         return repr((self.name, self.grade, self.age))

>>> student_objects = [
...     Student('john', 'A', 15),
...     Student('jane', 'B', 12),
...     Student('dave', 'B', 10),
... ]
>>> sorted(student_objects, key=lambda student: student.age)
# sort by age
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]
```

Objects with named attributes can be made by a regular class as shown above, or they can be instances of **`dataclass`** or a named tuple.

Operator Module Functions and Partial Function Evaluation

The key function patterns shown above are very common, so Python provides convenience functions to make accessor functions easier and faster. The **`operator`** module has **`itemgetter()`**, **`attrgetter()`**, and a **`methodcaller()`** function.

Using those functions, the above examples become simpler and faster:

```
>>> from operator import itemgetter, attrgetter

>>> sorted(student_tuples, key=itemgetter(2))
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]

>>> sorted(student_objects, key=attrgetter('age'))
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]
```

The operator module functions allow multiple levels of sorting. For example, to sort by *grade* then by *age*:

```
>>> sorted(student_tuples, key=itemgetter(1,2))
[('john', 'A', 15), ('dave', 'B', 10), ('jane', 'B', 12)]

>>> sorted(student_objects, key=attrgetter('grade', 'age'))
[('john', 'A', 15), ('dave', 'B', 10), ('jane', 'B', 12)]
```

The [`functools`] module provides another helpful tool for making key-functions. The [`partial()`] function can reduce the arity [https://en.wikipedia.org/wiki/Arity] of a multi-argument function making it suitable for use as a key-function.

```
>>> from functools import partial
>>> from unicodedata import normalize

>>> names = 'Zoë Åbjørn Núñez Élana Zeke Abe Nubia
Eloise'.split()

>>> sorted(names, key=partial(normalize, 'NFD'))
['Abe', 'Åbjørn', 'Eloise', 'Élana', 'Nubia', 'Núñez', 'Zeke',
'Zoë']

>>> sorted(names, key=partial(normalize, 'NFC'))
['Abe', 'Eloise', 'Nubia', 'Núñez', 'Zeke', 'Zoë', 'Åbjørn',
'Élana']
```

Ascending and Descending

Both `list.sort()` and `sorted()` accept a *reverse* parameter with a boolean value. This is used to flag descending sorts. For example, to get the student data in reverse *age* order:

```
>>> sorted(student_tuples, key=itemgetter(2), reverse=True)
[('john', 'A', 15), ('jane', 'B', 12), ('dave', 'B', 10)]

>>> sorted(student_objects, key=attrgetter('age'),
reverse=True)
[('john', 'A', 15), ('jane', 'B', 12), ('dave', 'B', 10)]
```

Sort Stability and Complex Sorts

Sorts are guaranteed to be stable [https://en.wikipedia.org/wiki/Sorting_algorithm#Stability]. That means that when multiple records have the same key, their original order is preserved.

```
>>> data = [('red', 1), ('blue', 1), ('red', 2), ('blue', 2)]
>>> sorted(data, key=itemgetter(0))
[('blue', 1), ('blue', 2), ('red', 1), ('red', 2)]
```

Notice how the two records for *blue* retain their original order so that `('blue', 1)` is guaranteed to precede `('blue', 2)`.

This wonderful property lets you build complex sorts in a series of sorting steps. For example, to sort the student data by descending *grade* and then ascending *age*, do the *age* sort first and then sort again using *grade*:

```
>>> s = sorted(student_objects, key=attrgetter('age'))     # 
sort on secondary key
>>> sorted(s, key=attrgetter('grade'), reverse=True)       # 
now sort on primary key, descending
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]
```

This can be abstracted out into a wrapper function that can take a list and tuples of field and order to sort them on multiple passes.

```
>>> def multisort(xs, specs):
...     for key, reverse in reversed(specs):
...         xs.sort(key=attrgetter(key), reverse=reverse)
...     return xs

>>> multisort(list(student_objects), (('grade', True), ('age', 
False)))
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]
```

The Timsort [https://en.wikipedia.org/wiki/Timsort] algorithm used in Python does multiple sorts efficiently because it can take advantage of any ordering already present in a dataset.

Decorate-Sort-Undecorate

This idiom is called Decorate-Sort-Undecorate after its three steps:

- First, the initial list is decorated with new values that control the sort order.
- Second, the decorated list is sorted.
- Finally, the decorations are removed, creating a list that contains only the initial values in the new order.

For example, to sort the student data by *grade* using the DSU approach:

```
>>> decorated = [(student.grade, i, student) for i, student in
enumerate(student_objects)]
>>> decorated.sort()
>>> [student for grade, i, student in decorated]
# undecorate
[('john', 'A', 15), ('jane', 'B', 12), ('dave', 'B', 10)]
```

This idiom works because tuples are compared lexicographically; the first items are compared; if they are the same then the second items are compared, and so on.

It is not strictly necessary in all cases to include the index *i* in the decorated list, but including it gives two benefits:

- The sort is stable – if two items have the same key, their order will be preserved in the sorted list.
- The original items do not have to be comparable because the ordering of the decorated tuples will be determined by at most the first two items. So for example the original list could contain complex numbers which cannot be sorted directly.

Another name for this idiom is Schwartzian transform [https://en.wikipedia.org/wiki/Schwartzian_transform], after Randal L. Schwartz, who popularized it among Perl programmers.

Now that Python sorting provides key-functions, this technique is not often needed.

Comparison Functions

Unlike key functions that return an absolute value for sorting, a comparison function computes the relative ordering for two inputs.

For example, a balance scale [https://upload.wikimedia.org/wikipedia/commons/1/17/Balance_à_tabac_1850.JPG] compares two samples giving a relative ordering: lighter, equal, or heavier. Likewise, a comparison function such as `cmp(a, b)` will return a negative value for less-than, zero if the inputs are equal, or a positive value for greater-than.

It is common to encounter comparison functions when translating algorithms from other languages. Also, some libraries provide comparison functions as part of their API. For example, **`locale.strcoll()`** is a comparison function.

To accommodate those situations, Python provides **`functools.cmp_to_key`** to wrap the comparison function to make it usable as a key function:

```
sorted(words, key=cmp_to_key(strcoll))  # locale-aware sort
order
```

Strategies For Unorderable Types and Values

A number of type and value issues can arise when sorting. Here are some strategies that can help:

- Convert non-comparable input types to strings prior to sorting:

```
>>> data = ['twelve', '11', 10]
>>> sorted(map(str, data))
['10', '11', 'twelve']
```

This is needed because most cross-type comparisons raise a `TypeError`.

- Remove special values prior to sorting:

```
>>> from math import isnan
>>> from itertools import filterfalse
>>> data = [3.3, float('nan'), 1.1, 2.2]
>>> sorted(filterfalse(isnan, data))
[1.1, 2.2, 3.3]
```

This is needed because the IEEE-754 standard [https://en.wikipedia.org/wiki/IEEE_754] specifies that, “Every NaN shall compare unordered with everything, including itself.”

Likewise, `None` can be stripped from datasets as well:

```
>>> data = [3.3, None, 1.1, 2.2]
>>> sorted(x for x in data if x is not None)
[1.1, 2.2, 3.3]
```

This is needed because `None` is not comparable to other types.

- Convert mapping types into sorted item lists before sorting:

```
>>> data = [{'a': 1}, {'b': 2}]
>>> sorted(data, key=lambda d: sorted(d.items()))
[{'a': 1}, {'b': 2}]
```

This is needed because dict-to-dict comparisons raise a `TypeError`.

- Convert set types into sorted lists before sorting:

```
>>> data = [{'a', 'b', 'c'}, {'b', 'c', 'd'}]
>>> sorted(map(sorted, data))
[['a', 'b', 'c'], ['b', 'c', 'd']]
```

This is needed because the elements contained in set types do not have a deterministic order. For example, `list({'a', 'b'})` may produce either `['a', 'b']` or `['b', 'a']`.

Odds and Ends

- For locale aware sorting, use `locale.strxfrm()` for a key function or `locale.strcoll()` for a comparison function. This is necessary because “alphabetical” sort orderings can vary across cultures even if the underlying alphabet is the same.

- The *reverse* parameter still maintains sort stability (so that records with equal keys retain the original order). Interestingly, that effect can be simulated without the parameter by using the builtin `reversed()` function twice:

  ```
  >>> data = [('red', 1), ('blue', 1), ('red', 2), ('blue', 2)]
  >>> standard_way = sorted(data, key=itemgetter(0), reverse=True)
  >>> double_reversed = list(reversed(sorted(reversed(data), key=itemgetter(0))))
  >>> assert standard_way == double_reversed
  >>> standard_way
  [('red', 1), ('red', 2), ('blue', 1), ('blue', 2)]
  ```

- The sort routines use `<` when making comparisons between two objects. So, it is easy to add a standard sort order to a class by defining an `__lt__()` method:

```
>>> Student.__lt__ = lambda self, other: self.age <
other.age
>>> sorted(student_objects)
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]
```

However, note that < can fall back to using `__gt__()` if `__lt__()` is not implemented (see `object.__lt__()` for details on the mechanics). To avoid surprises, **PEP 8** [https://peps.python.org/pep-0008/] recommends that all six comparison methods be implemented. The `total_ordering()` decorator is provided to make that task easier.

- Key functions need not depend directly on the objects being sorted. A key function can also access external resources. For instance, if the student grades are stored in a dictionary, they can be used to sort a separate list of student names:

```
>>> students = ['dave', 'john', 'jane']
>>> newgrades = {'john': 'F', 'jane':'A', 'dave': 'C'}
>>> sorted(students, key=newgrades.__getitem__)
['jane', 'dave', 'john']
```

Partial Sorts

Some applications require only some of the data to be ordered. The standard library provides several tools that do less work than a full sort:

- `min()` and `max()` return the smallest and largest values, respectively. These functions make a single pass over the input data and require almost no auxiliary memory.
- `heapq.nsmallest()` and `heapq.nlargest()` return the *n* smallest and largest values, respectively. These

functions make a single pass over the data keeping only *n* elements in memory at a time. For values of *n* that are small relative to the number of inputs, these functions make far fewer comparisons than a full sort.

- **`heapq.heappush()`** and **`heapq.heappop()`** create and maintain a partially sorted arrangement of data that keeps the smallest element at position `0`. These functions are suitable for implementing priority queues which are commonly used for task scheduling.

Unicode HOWTO

Release:: 1.12

This HOWTO discusses Python's support for the Unicode specification for representing textual data, and explains various problems that people commonly encounter when trying to work with Unicode.

Introduction to Unicode

Definitions

Today's programs need to be able to handle a wide variety of characters. Applications are often internationalized to display messages and output in a variety of user-selectable languages; the same program might need to output an error message in English, French, Japanese, Hebrew, or Russian. Web content can be written in any of these languages and can also include a variety of emoji symbols. Python's string type uses the Unicode Standard for representing characters, which lets Python programs work with all these different possible characters.

Unicode (https://www.unicode.org/) is a specification that aims to list every character used by human languages and give each character its own unique code. The Unicode specifications are continually revised and updated to add new languages and symbols.

A **character** is the smallest possible component of a text. 'A', 'B', 'C', etc., are all different characters. So are 'È' and 'Í'. Characters vary depending on the language or context you’re talking about. For example, there’s a character for “Roman Numeral One”, ‘Ⅰ’, that’s separate from the uppercase letter ‘I’. They’ll usually look the same, but these are two different characters that have different meanings.

The Unicode standard describes how characters are represented by **code points**. A code point value is an integer in the range 0 to 0x10FFFF (about 1.1 million values, the actual number assigned [https://www.unicode.org/versions/latest/#Summary] is less than that). In the standard and in this document, a code point is written using the notation `U+265E` to mean the character with value `0x265e` (9,822 in decimal).

The Unicode standard contains a lot of tables listing characters and their corresponding code points:

```
0061    'a'; LATIN SMALL LETTER A
0062    'b'; LATIN SMALL LETTER B
0063    'c'; LATIN SMALL LETTER C
...
007B    '{'; LEFT CURLY BRACKET
...
2167    'Ⅷ'; ROMAN NUMERAL EIGHT
2168    'Ⅸ'; ROMAN NUMERAL NINE
...
265E    '♞'; BLACK CHESS KNIGHT
265F    '♟'; BLACK CHESS PAWN
...
1F600   '😀'; GRINNING FACE
1F609   '😉'; WINKING FACE
...
```

Strictly, these definitions imply that it’s meaningless to say ‘this is character `U+265E`’. `U+265E` is a code point, which represents some particular character; in this case, it represents the character ‘BLACK CHESS KNIGHT’, ‘♞’. In informal contexts, this distinction between code points and characters will sometimes be forgotten.

A character is represented on a screen or on paper by a set of graphical elements that’s called a **glyph**. The glyph for an uppercase A, for example, is two diagonal strokes and a horizontal stroke, though the exact details will depend on the font being used. Most Python code doesn’t need to worry about glyphs; figuring out the correct glyph to display is generally the job of a GUI toolkit or a terminal’s font renderer.

Encodings

To summarize the previous section: a Unicode string is a sequence of code points, which are numbers from 0 through `0x10FFFF` (1,114,111 decimal). This sequence of code points needs to be represented in memory as a set of **code units**, and **code units** are then mapped to 8-bit bytes. The rules for translating a Unicode string into a sequence of bytes are called a **character encoding**, or just an **encoding**.

The first encoding you might think of is using 32-bit integers as the code unit, and then using the CPU’s representation of 32-bit integers. In this representation, the string “Python” might look like this:

```
   P           y           t           h           o
n
0x50 00 00 00 79 00 00 00 74 00 00 00 68 00 00 00 6f 00 00 00
6e 00 00 00
   0  1  2  3  4  5  6  7  8  9 10 11 12 13 14 15 16 17 18 19
20 21 22 23
```

This representation is straightforward but using it presents a number of problems.

1. It’s not portable; different processors order the bytes differently.

2. It’s very wasteful of space. In most texts, the majority of the code points are less than 127, or less than 255, so a lot of space is occupied by `0x00` bytes. The above string takes 24 bytes compared to the 6 bytes needed for an ASCII representation. Increased RAM usage doesn’t matter too much (desktop computers have gigabytes of RAM, and strings aren’t usually that large), but expanding our usage of disk and network bandwidth by a factor of 4 is intolerable.
3. It’s not compatible with existing C functions such as `strlen()`, so a new family of wide string functions would need to be used.

Therefore this encoding isn’t used very much, and people instead choose other encodings that are more efficient and convenient, such as UTF-8.

UTF-8 is one of the most commonly used encodings, and Python often defaults to using it. UTF stands for “Unicode Transformation Format”, and the ‘8’ means that 8-bit values are used in the encoding. (There are also UTF-16 and UTF-32 encodings, but they are less frequently used than UTF-8.) UTF-8 uses the following rules:

1. If the code point is < 128, it’s represented by the corresponding byte value.
2. If the code point is >= 128, it’s turned into a sequence of two, three, or four bytes, where each byte of the sequence is between 128 and 255.

UTF-8 has several convenient properties:

1. It can handle any Unicode code point.
2. A Unicode string is turned into a sequence of bytes that contains embedded zero bytes only where they represent the null character (U+0000). This means that

UTF-8 strings can be processed by C functions such as `strcpy()` and sent through protocols that can't handle zero bytes for anything other than end-of-string markers.
3. A string of ASCII text is also valid UTF-8 text.
4. UTF-8 is fairly compact; the majority of commonly used characters can be represented with one or two bytes.
5. If bytes are corrupted or lost, it's possible to determine the start of the next UTF-8-encoded code point and resynchronize. It's also unlikely that random 8-bit data will look like valid UTF-8.
6. UTF-8 is a byte oriented encoding. The encoding specifies that each character is represented by a specific sequence of one or more bytes. This avoids the byte-ordering issues that can occur with integer and word oriented encodings, like UTF-16 and UTF-32, where the sequence of bytes varies depending on the hardware on which the string was encoded.

The Unicode Consortium site [https://www.unicode.org] has character charts, a glossary, and PDF versions of the Unicode specification. Be prepared for some difficult reading. A chronology [https://www.unicode.org/history/] of the origin and development of Unicode is also available on the site.

On the Computerphile Youtube channel, Tom Scott briefly discusses the history of Unicode and UTF-8 [https://www.youtube.com/watch?v=MijmeoH9LT4] (9 minutes 36 seconds).

To help understand the standard, Jukka Korpela has written an introductory guide [https://jkorpela.fi/unicode/guide.html] to reading the Unicode character tables.

Another good introductory article [https://www.joelonsoftware.com/2003/10/08/the-absolute-minimum-every-software-developer-absolutely-positively-must-know-about-unicode-and-character-sets-no-excuses/] was written by Joel Spolsky. If this introduction didn’t make things clear to you, you should try reading this alternate article before continuing.

Wikipedia entries are often helpful; see the entries for “character encoding [https://en.wikipedia.org/wiki/Character_encoding]” and UTF-8 [https://en.wikipedia.org/wiki/UTF-8], for example.

Python’s Unicode Support

Now that you’ve learned the rudiments of Unicode, we can look at Python’s Unicode features.

The String Type

Since Python 3.0, the language’s **`str`** type contains Unicode characters, meaning any string created using `"unicode rocks!"`, `'unicode rocks!'`, or the triple-quoted string syntax is stored as Unicode.

The default encoding for Python source code is UTF-8, so you can simply include a Unicode character in a string literal:

```
try:
    with open('/tmp/input.txt', 'r') as f:
        ...
except OSError:
    # 'File not found' error message.
    print("Fichier non trouvé")
```

Side note: Python 3 also supports using Unicode characters in identifiers:

```
répertoire = "/tmp/records.log"
with open(répertoire, "w") as f:
    f.write("test\n")
```

If you can't enter a particular character in your editor or want to keep the source code ASCII-only for some reason, you can also use escape sequences in string literals. (Depending on your system, you may see the actual capital-delta glyph instead of a u escape.)

```
>>> "\N{GREEK CAPITAL LETTER DELTA}"  # Using the character
name
'\u0394'
>>> "\u0394"                          # Using a 16-bit hex
value
'\u0394'
>>> "\U00000394"                      # Using a 32-bit hex
value
'\u0394'
```

In addition, one can create a string using the `decode()` method of `bytes`. This method takes an *encoding* argument, such as `UTF-8`, and optionally an *errors* argument.

The *errors* argument specifies the response when the input string can't be converted according to the encoding's rules. Legal values for this argument are `'strict'` (raise a `UnicodeDecodeError` exception), `'replace'` (use `U+FFFD`, `REPLACEMENT CHARACTER`), `'ignore'` (just leave the character out of the Unicode result), or `'backslashreplace'` (inserts a `\xNN` escape sequence). The following examples show the differences:

```
>>> b'\x80abc'.decode("utf-8", "strict")
Traceback (most recent call last):
    ...
UnicodeDecodeError: 'utf-8' codec can't decode byte 0x80 in
position 0:
  invalid start byte
>>> b'\x80abc'.decode("utf-8", "replace")
```

```
'\ufffdabc'
>>> b'\x80abc'.decode("utf-8", "backslashreplace")
'\\x80abc'
>>> b'\x80abc'.decode("utf-8", "ignore")
'abc'
```

Encodings are specified as strings containing the encoding’s name. Python comes with roughly 100 different encodings; see the Python Library Reference at Standard Encodings for a list. Some encodings have multiple names; for example, `'latin-1'`, `'iso_8859_1'` and `'8859`’ are all synonyms for the same encoding.

One-character Unicode strings can also be created with the **`chr()`** built-in function, which takes integers and returns a Unicode string of length 1 that contains the corresponding code point. The reverse operation is the built-in **`ord()`** function that takes a one-character Unicode string and returns the code point value:

```
>>> chr(57344)
'\ue000'
>>> ord('\ue000')
57344
```

Converting to Bytes

The opposite method of **`bytes.decode()`** is **`str.encode()`**, which returns a **`bytes`** representation of the Unicode string, encoded in the requested *encoding*.

The *errors* parameter is the same as the parameter of the **`decode()`** method but supports a few more possible handlers. As well as `'strict'`, `'ignore'`, and `'replace'` (which in this case inserts a question mark instead of the unencodable character), there is also `'xmlcharrefreplace'` (inserts an XML character reference), `backslashreplace` (inserts a `\uNNNN` escape sequence) and `namereplace` (inserts a `\N{...}` escape sequence).

The following example shows the different results:

```
>>> u = chr(40960) + 'abcd' + chr(1972)
>>> u.encode('utf-8')
b'\xea\x80\x80abcd\xde\xb4'
>>> u.encode('ascii')
Traceback (most recent call last):
    ...
UnicodeEncodeError: 'ascii' codec can't encode character
'\ua000' in
  position 0: ordinal not in range(128)
>>> u.encode('ascii', 'ignore')
b'abcd'
>>> u.encode('ascii', 'replace')
b'?abcd?'
>>> u.encode('ascii', 'xmlcharrefreplace')
b'&#40960;abcd&#1972;'
>>> u.encode('ascii', 'backslashreplace')
b'\\ua000abcd\\u07b4'
>>> u.encode('ascii', 'namereplace')
b'\\N{YI SYLLABLE IT}abcd\\u07b4'
```

The low-level routines for registering and accessing the available encodings are found in the `codecs` module. Implementing new encodings also requires understanding the `codecs` module. However, the encoding and decoding functions returned by this module are usually more low-level than is comfortable, and writing new encodings is a specialized task, so the module won’t be covered in this HOWTO.

Unicode Literals in Python Source Code

In Python source code, specific Unicode code points can be written using the `\u` escape sequence, which is followed by four hex digits giving the code point. The `\U` escape sequence is similar, but expects eight hex digits, not four:

```
>>> s = "a\xac\u1234\u20ac\U00008000"
... #     ^^^^ two-digit hex escape
... #         ^^^^^^ four-digit Unicode escape
... #                     ^^^^^^^^^^ eight-digit Unicode escape
>>> [ord(c) for c in s]
[97, 172, 4660, 8364, 32768]
```

Using escape sequences for code points greater than 127 is fine in small doses, but becomes an annoyance if you're using many accented characters, as you would in a program with messages in French or some other accent-using language. You can also assemble strings using the `chr()` built-in function, but this is even more tedious.

Ideally, you'd want to be able to write literals in your language's natural encoding. You could then edit Python source code with your favorite editor which would display the accented characters naturally, and have the right characters used at runtime.

Python supports writing source code in UTF-8 by default, but you can use almost any encoding if you declare the encoding being used. This is done by including a special comment as either the first or second line of the source file:

```
#!/usr/bin/env python
# -*- coding: latin-1 -*-

u = 'abcdé'
print(ord(u[-1]))
```

The syntax is inspired by Emacs's notation for specifying variables local to a file. Emacs supports many different variables, but Python only supports 'coding'. The `-*-` symbols indicate to Emacs that the comment is special;

they have no significance to Python but are a convention. Python looks for `coding: name` or `coding=name` in the comment.

If you don’t include such a comment, the default encoding used will be UTF-8 as already mentioned. See also **PEP 263** [https://peps.python.org/pep-0263/] for more information.

Unicode Properties

The Unicode specification includes a database of information about code points. For each defined code point, the information includes the character’s name, its category, the numeric value if applicable (for characters representing numeric concepts such as the Roman numerals, fractions such as one-third and four-fifths, etc.). There are also display-related properties, such as how to use the code point in bidirectional text.

The following program displays some information about several characters, and prints the numeric value of one particular character:

```
import unicodedata

u = chr(233) + chr(0x0bf2) + chr(3972) + chr(6000) + chr(13231)

for i, c in enumerate(u):
    print(i, '%04x' % ord(c), unicodedata.category(c), end=" ")
    print(unicodedata.name(c))

# Get numeric value of second character
print(unicodedata.numeric(u[1]))
```

When run, this prints:

```
0 00e9 Ll LATIN SMALL LETTER E WITH ACUTE
1 0bf2 No TAMIL NUMBER ONE THOUSAND
2 0f84 Mn TIBETAN MARK HALANTA
3 1770 Lo TAGBANWA LETTER SA
```

```
4 33af So SQUARE RAD OVER S SQUARED
1000.0
```

The category codes are abbreviations describing the nature of the character. These are grouped into categories such as “Letter”, “Number”, “Punctuation”, or “Symbol”, which in turn are broken up into subcategories. To take the codes from the above output, `'Ll'` means ‘Letter, lowercase’, `'No'` means “Number, other”, `'Mn'` is “Mark, nonspacing”, and `'So'` is “Symbol, other”. See the General Category Values section of the Unicode Character Database documentation [https://www.unicode.org/reports/tr44/#General_Category_Values] for a list of category codes.

Comparing Strings

Unicode adds some complication to comparing strings, because the same set of characters can be represented by different sequences of code points. For example, a letter like ‘ê’ can be represented as a single code point U+00EA, or as U+0065 U+0302, which is the code point for ‘e’ followed by a code point for ‘COMBINING CIRCUMFLEX ACCENT’. These will produce the same output when printed, but one is a string of length 1 and the other is of length 2.

One tool for a case-insensitive comparison is the **`casefold()`** string method that converts a string to a case-insensitive form following an algorithm described by the Unicode Standard. This algorithm has special handling for characters such as the German letter ‘ß’ (code point U+00DF), which becomes the pair of lowercase letters ‘ss’.

```
>>> street = 'Gürzenichstraße'
>>> street.casefold()
'gürzenichstrasse'
```

A second tool is the `unicodedata` module's `normalize()` function that converts strings to one of several normal forms, where letters followed by a combining character are replaced with single characters. `normalize()` can be used to perform string comparisons that won't falsely report inequality if two strings use combining characters differently:

```
import unicodedata

def compare_strs(s1, s2):
    def NFD(s):
        return unicodedata.normalize('NFD', s)

    return NFD(s1) == NFD(s2)

single_char = 'ê'
multiple_chars = '\N{LATIN SMALL LETTER E}\N{COMBINING
CIRCUMFLEX ACCENT}'
print('length of first string=', len(single_char))
print('length of second string=', len(multiple_chars))
print(compare_strs(single_char, multiple_chars))
```

When run, this outputs:

```
$ python compare-strs.py
length of first string= 1
length of second string= 2
True
```

The first argument to the `normalize()` function is a string giving the desired normalization form, which can be one of 'NFC', 'NFKC', 'NFD', and 'NFKD'.

The Unicode Standard also specifies how to do caseless comparisons:

```
import unicodedata

def compare_caseless(s1, s2):
    def NFD(s):
        return unicodedata.normalize('NFD', s)

    return NFD(NFD(s1).casefold()) == NFD(NFD(s2).casefold())

# Example usage
single_char = 'ê'
multiple_chars = '\N{LATIN CAPITAL LETTER E}\N{COMBINING
CIRCUMFLEX ACCENT}'

print(compare_caseless(single_char, multiple_chars))
```

This will print `True`. (Why is **`NFD()`** invoked twice? Because there are a few characters that make **`casefold()`** return a non-normalized string, so the result needs to be normalized again. See section 3.13 of the Unicode Standard for a discussion and an example.)

Unicode Regular Expressions

The regular expressions supported by the **`re`** module can be provided either as bytes or strings. Some of the special character sequences such as `\d` and `\w` have different meanings depending on whether the pattern is supplied as bytes or a string. For example, `\d` will match the characters `[0-9]` in bytes but in strings will match any character that’s in the `'Nd'` category.

The string in this example has the number 57 written in both Thai and Arabic numerals:

```
import re
p = re.compile(r'\d+')

s = "Over \u0e55\u0e57 57 flavours"
m = p.search(s)
print(repr(m.group()))
```

When executed, `\d+` will match the Thai numerals and print them out. If you supply the **`re.ASCII`** flag to **`compile()`**, `\d+` will match the substring “57” instead.

Similarly, `\w` matches a wide variety of Unicode characters but only `[a-zA-Z0-9_]` in bytes or if **`re.ASCII`** is supplied, and `\s` will match either Unicode whitespace characters or `[ \t\n\r\f\v]`.

Marc-André Lemburg gave a presentation titled “Python and Unicode” (PDF slides) [https://downloads.egenix.com/python/Unicode-EPC2002-Talk.pdf] at EuroPython 2002. The slides are an excellent overview of the design of Python 2’s Unicode features (where the Unicode string type is called `unicode` and literals start with `u`).

Reading and Writing Unicode Data

Once you’ve written some code that works with Unicode data, the next problem is input/output. How do you get

Unicode strings into your program, and how do you convert Unicode into a form suitable for storage or transmission?

It’s possible that you may not need to do anything depending on your input sources and output destinations; you should check whether the libraries used in your application support Unicode natively. XML parsers often return Unicode data, for example. Many relational databases also support Unicode-valued columns and can return Unicode values from an SQL query.

Unicode data is usually converted to a particular encoding before it gets written to disk or sent over a socket. It’s possible to do all the work yourself: open a file, read an 8-bit bytes object from it, and convert the bytes with `bytes.decode(encoding)`. However, the manual approach is not recommended.

One problem is the multi-byte nature of encodings; one Unicode character can be represented by several bytes. If you want to read the file in arbitrary-sized chunks (say, 1024 or 4096 bytes), you need to write error-handling code to catch the case where only part of the bytes encoding a single Unicode character are read at the end of a chunk. One solution would be to read the entire file into memory and then perform the decoding, but that prevents you from working with files that are extremely large; if you need to read a 2 GiB file, you need 2 GiB of RAM. (More, really, since for at least a moment you’d need to have both the encoded string and its Unicode version in memory.)

The solution would be to use the low-level decoding interface to catch the case of partial coding sequences. The work of implementing this has already been done for you: the built-in `open()` function can return a file-like object that assumes the file’s contents are in a specified encoding and accepts Unicode parameters for methods such as `read()` and `write()`. This works through `open()`'s *encoding* and *errors* parameters which are interpreted just like those in `str.encode()` and `bytes.decode()`.

Reading Unicode from a file is therefore simple:

```
with open('unicode.txt', encoding='utf-8') as f:
    for line in f:
        print(repr(line))
```

It’s also possible to open files in update mode, allowing both reading and writing:

```
with open('test', encoding='utf-8', mode='w+') as f:
    f.write('\u4500 blah blah blah\n')
    f.seek(0)
    print(repr(f.readline()[:1]))
```

The Unicode character `U+FEFF` is used as a byte-order mark (BOM), and is often written as the first character of a file in order to assist with autodetection of the file’s byte ordering. Some encodings, such as UTF-16, expect a BOM to be present at the start of a file; when such an encoding is used, the BOM will be automatically written as the first character and will be silently dropped when the file is read. There are variants of these encodings, such as ‘utf-16-le’ and ‘utf-16-be’ for little-endian and big-endian encodings, that specify one particular byte ordering and don’t skip the BOM.

In some areas, it is also convention to use a “BOM” at the start of UTF-8 encoded files; the name is misleading since UTF-8 is not byte-order dependent. The mark simply announces that the file is encoded in UTF-8. For reading such files, use the ‘utf-8-sig’ codec to automatically skip the mark if present.

Unicode filenames

Most of the operating systems in common use today support filenames that contain arbitrary Unicode characters. Usually this is implemented by converting the Unicode string into some encoding that varies depending on the system. Today Python is converging on using UTF-8: Python on MacOS has used UTF-8 for several versions, and Python 3.6 switched to using UTF-8 on Windows as well. On Unix systems, there will only be a filesystem encoding. if you've set the `LANG` or `LC_CTYPE` environment variables; if you haven't, the default encoding is again UTF-8.

The **`sys.getfilesystemencoding()`** function returns the encoding to use on your current system, in case you want to do the encoding manually, but there's not much reason to bother. When opening a file for reading or writing, you can usually just provide the Unicode string as the filename, and it will be automatically converted to the right encoding for you:

```
filename = 'filename\u4500abc'
with open(filename, 'w') as f:
    f.write('blah\n')
```

Functions in the **`os`** module such as **`os.stat()`** will also accept Unicode filenames.

The **`os.listdir()`** function returns filenames, which raises an issue: should it return the Unicode version of filenames, or should it return bytes containing the encoded versions? **`os.listdir()`** can do both, depending on whether you provided the directory path as bytes or a Unicode string. If you pass a Unicode string as the path, filenames will be decoded using the filesystem's encoding and a list of Unicode strings will be returned, while passing a byte path will return the filenames as bytes. For example, assuming the default filesystem encoding is UTF-8, running the following program:

```
fn = 'filename\u4500abc'
f = open(fn, 'w')
f.close()

import os
print(os.listdir(b'.'))
print(os.listdir('.'))
```

will produce the following output:

```
$ python listdir-test.py
[b'filename\xe4\x94\x80abc', ...]
['filename\u4500abc', ...]
```

The first list contains UTF-8-encoded filenames, and the second list contains the Unicode versions.

Note that on most occasions, you should can just stick with using Unicode with these APIs. The bytes APIs should only be used on systems where undecodable file names can be present; that’s pretty much only Unix systems now.

Tips for Writing Unicode-aware Programs

This section provides some suggestions on writing software that deals with Unicode.

The most important tip is:

> Software should only work with Unicode strings internally, decoding the input data as soon as possible and encoding the output only at the end.

If you attempt to write processing functions that accept both Unicode and byte strings, you will find your program vulnerable to bugs wherever you combine the two different kinds of strings. There is no automatic encoding or decoding: if you do e.g. `str + bytes`, a **`TypeError`** will be raised.

When using data coming from a web browser or some other untrusted source, a common technique is to check for illegal characters in a string before using the string in a generated command line or storing it in a database. If you’re doing this, be careful to check the decoded string, not the encoded bytes data; some encodings may have interesting properties, such as not being bijective or not being fully ASCII-compatible. This is especially true if the input data also specifies the encoding, since the attacker can then choose a clever way to hide malicious text in the encoded bytestream.

Converting Between File Encodings

The **`StreamRecoder`** class can transparently convert between encodings, taking a stream that returns data in encoding #1 and behaving like a stream returning data in encoding #2.

For example, if you have an input file *f* that’s in Latin-1, you can wrap it with a **`StreamRecoder`** to return bytes encoded in UTF-8:

```
new_f = codecs.StreamRecoder(f,
    # en/decoder: used by read() to encode its results and
    # by write() to decode its input.
    codecs.getencoder('utf-8'), codecs.getdecoder('utf-8'),

    # reader/writer: used to read and write to the stream.
    codecs.getreader('latin-1'), codecs.getwriter('latin-1') )
```

Files in an Unknown Encoding

What can you do if you need to make a change to a file, but don’t know the file’s encoding? If you know the encoding is

ASCII-compatible and only want to examine or modify the ASCII parts, you can open the file with the `surrogateescape` error handler:

```
with open(fname, 'r', encoding="ascii",
errors="surrogateescape") as f:
    data = f.read()

# make changes to the string 'data'

with open(fname + '.new', 'w',
          encoding="ascii", errors="surrogateescape") as f:
    f.write(data)
```

The `surrogateescape` error handler will decode any non-ASCII bytes as code points in a special range running from U+DC80 to U+DCFF. These code points will then turn back into the same bytes when the `surrogateescape` error handler is used to encode the data and write it back out.

HOWTO Fetch Internet Resources Using The urllib Package

Author:: Michael Foord [https://agileabstractions.com/]

Introduction

Related Articles

You may also find useful the following article on fetching web resources with Python:

- Basic Authentication [https://web.archive.org/web/20201215133350/http://www.voidspace.org.uk/python/articles/authentication.shtml]

  A tutorial on *Basic Authentication*, with examples in Python.

urllib.request is a Python module for fetching URLs (Uniform Resource Locators). It offers a very simple interface, in the form of the *urlopen* function. This is capable of fetching URLs using a variety of different protocols. It also offers a slightly more complex interface for handling common situations - like basic authentication, cookies, proxies and so on. These are provided by objects called handlers and openers.

urllib.request supports fetching URLs for many “URL schemes” (identified by the string before the `":"` in URL - for example `"ftp"` is the URL scheme of `"ftp://python.org/"`) using their associated network protocols (e.g. FTP, HTTP). This tutorial focuses on the most common case, HTTP.

For straightforward situations *urlopen* is very easy to use. But as soon as you encounter errors or non-trivial cases when opening HTTP URLs, you will need some understanding of the HyperText Transfer Protocol. The most comprehensive and authoritative reference to HTTP is **RFC 2616** [https://datatracker.ietf.org/doc/html/rfc2616.html]. This is a technical document and not intended to be easy to read. This HOWTO aims to illustrate using *urllib*, with enough detail about HTTP to help you through. It is not intended to replace the **`urllib.request`** docs, but is supplementary to them.

Fetching URLs

The simplest way to use urllib.request is as follows:

```
import urllib.request
with urllib.request.urlopen('http://python.org/') as response:
   html = response.read()
```

If you wish to retrieve a resource via URL and store it in a temporary location, you can do so via the **`shutil.copyfileobj()`** and **`tempfile.NamedTemporaryFile()`** functions:

```
import shutil
import tempfile
import urllib.request

with urllib.request.urlopen('http://python.org/') as response:
    with tempfile.NamedTemporaryFile(delete=False) as tmp_file:
        shutil.copyfileobj(response, tmp_file)

with open(tmp_file.name) as html:
    pass
```

Many uses of urllib will be that simple (note that instead of an ‘http:’ URL we could have used a URL starting with ‘ftp:’, ‘file:’, etc.). However, it’s the purpose of this tutorial to explain the more complicated cases, concentrating on HTTP.

HTTP is based on requests and responses - the client makes requests and servers send responses. urllib.request mirrors this with a `Request` object which represents the HTTP request you are making. In its simplest form you create a Request object that specifies the URL you want to fetch. Calling `urlopen` with this Request object returns a response object for the URL requested. This response is a file-like object, which means you can for example call `.read()` on the response:

```
import urllib.request

req = urllib.request.Request('http://python.org/')
with urllib.request.urlopen(req) as response:
   the_page = response.read()
```

Note that urllib.request makes use of the same Request interface to handle all URL schemes. For example, you can make an FTP request like so:

```
req = urllib.request.Request('ftp://example.com/')
```

In the case of HTTP, there are two extra things that Request objects allow you to do: First, you can pass data to be sent to the server. Second, you can pass extra information (“metadata”) *about* the data or about the request itself, to the server - this information is sent as HTTP “headers”. Let’s look at each of these in turn.

Data

Sometimes you want to send data to a URL (often the URL will refer to a CGI (Common Gateway Interface) script or other web application). With HTTP, this is often done using what's known as a **POST** request. This is often what your browser does when you submit a HTML form that you filled in on the web. Not all POSTs have to come from forms: you can use a POST to transmit arbitrary data to your own application. In the common case of HTML forms, the data needs to be encoded in a standard way, and then passed to the Request object as the `data` argument. The encoding is done using a function from the **`urllib.parse`** library.

```
import urllib.parse
import urllib.request

url = 'http://www.someserver.com/cgi-bin/register.cgi'
values = {'name' : 'Michael Foord',
          'location' : 'Northampton',
          'language' : 'Python' }

data = urllib.parse.urlencode(values)
data = data.encode('ascii') # data should be bytes
req = urllib.request.Request(url, data)
with urllib.request.urlopen(req) as response:
   the_page = response.read()
```

Note that other encodings are sometimes required (e.g. for file upload from HTML forms - see HTML Specification, Form Submission [https://www.w3.org/TR/REC-html40/interact/forms.html#h-17.13] for more details).

If you do not pass the `data` argument, urllib uses a **GET** request. One way in which GET and POST requests differ is that POST requests often have "side-effects": they change the state of the system in some way (for example by placing an order with the website for a hundredweight of tinned spam to be delivered to your door). Though the HTTP standard makes it clear that POSTs are intended to *always* cause side-effects, and GET requests *never* to cause side-effects, nothing prevents a GET request from having side-effects, nor a POST requests from having no side-effects. Data can also be passed in an HTTP GET request by encoding it in the URL itself.

This is done as follows:

```
>>> import urllib.request
>>> import urllib.parse
>>> data = {}
>>> data['name'] = 'Somebody Here'
>>> data['location'] = 'Northampton'
>>> data['language'] = 'Python'
>>> url_values = urllib.parse.urlencode(data)
>>> print(url_values)  # The order may differ from below.
name=Somebody+Here&language=Python&location=Northampton
>>> url = 'http://www.example.com/example.cgi'
>>> full_url = url + '?' + url_values
>>> data = urllib.request.urlopen(full_url)
```

Notice that the full URL is created by adding a `?` to the URL, followed by the encoded values.

Headers

We’ll discuss here one particular HTTP header, to illustrate how to add headers to your HTTP request.

Some websites [[1]] dislike being browsed by programs, or send different versions to different browsers [[2]]. By default urllib identifies itself as `Python-urllib/x.y` (where `x` and `y` are the major and minor version numbers of the Python release, e.g. `Python-urllib/2.5`), which may confuse the site, or just plain not work. The way a browser identifies itself is through the `User-Agent` header [[3]]. When you create a Request object you can pass a dictionary of headers in. The following example makes the same request as above, but identifies itself as a version of Internet Explorer [[4]].

```
import urllib.parse
import urllib.request

url = 'http://www.someserver.com/cgi-bin/register.cgi'
user_agent = 'Mozilla/5.0 (Windows NT 6.1; Win64; x64)'
values = {'name': 'Michael Foord',
          'location': 'Northampton',
          'language': 'Python' }
headers = {'User-Agent': user_agent}

data = urllib.parse.urlencode(values)
data = data.encode('ascii')
req = urllib.request.Request(url, data, headers)
with urllib.request.urlopen(req) as response:
   the_page = response.read()
```

The response also has two useful methods. See the section on info and geturl which comes after we have a look at what happens when things go wrong.

Handling Exceptions

urlopen raises `URLError` when it cannot handle a response (though as usual with Python APIs, built-in exceptions such as `ValueError`, `TypeError` etc. may also be raised).

`HTTPError` is the subclass of `URLError` raised in the specific case of HTTP URLs.

The exception classes are exported from the `urllib.error` module.

URLError

Often, URLError is raised because there is no network connection (no route to the specified server), or the specified server doesn’t exist. In this case, the exception raised will have a ‘reason’ attribute, which is a tuple containing an error code and a text error message.

e.g.

```
>>> req =
urllib.request.Request('http://www.pretend_server.org')
>>> try: urllib.request.urlopen(req)
... except urllib.error.URLError as e:
...     print(e.reason)
...
(4, 'getaddrinfo failed')
```

HTTPError

Every HTTP response from the server contains a numeric “status code”. Sometimes the status code indicates that the server is unable to fulfil the request. The default handlers will handle some of these responses for you (for example, if the response is a “redirection” that requests the client fetch the document from a different URL, urllib will handle that for you). For those it can’t handle, urlopen will raise an `HTTPError`. Typical errors include ‘404’ (page not found), ‘403’ (request forbidden), and ‘401’ (authentication required).

See section 10 of **RFC 2616** [https://datatracker.ietf.org/doc/html/rfc2616.html] for a reference on all the HTTP error codes.

The `HTTPError` instance raised will have an integer ‘code’ attribute, which corresponds to the error sent by the server.

Error Codes

Because the default handlers handle redirects (codes in the 300 range), and codes in the 100–299 range indicate success, you will usually only see error codes in the 400–599 range.

`http.server.BaseHTTPRequestHandler.responses` is a useful dictionary of response codes that shows all the response codes used by **RFC 2616** [https://datatracker.ietf.org/doc/html/rfc2616.html]. An excerpt from the dictionary is shown below

```
responses = {
    ...
    <HTTPStatus.OK: 200>: ('OK', 'Request fulfilled, document
follows'),
    ...
    <HTTPStatus.FORBIDDEN: 403>: ('Forbidden',
                                  'Request forbidden --
authorization will '
                                  'not help'),
    <HTTPStatus.NOT_FOUND: 404>: ('Not Found',
                                  'Nothing matches the given
URI'),
    ...
    <HTTPStatus.IM_A_TEAPOT: 418>: ("I'm a Teapot",
                                    'Server refuses to brew
coffee because '
                                    'it is a teapot'),
    ...
    <HTTPStatus.SERVICE_UNAVAILABLE: 503>: ('Service
Unavailable',
                                            'The server cannot
process the '
                                            'request due to a
high load'),
    ...
    }
```

When an error is raised the server responds by returning an HTTP error code *and* an error page. You can use the `HTTPError` instance as a response on the page returned. This means that as well as the code attribute, it also has read, geturl, and info, methods as returned by the `urllib.response` module:

```
>>> req =
urllib.request.Request('http://www.python.org/fish.html')
>>> try:
...     urllib.request.urlopen(req)
... except urllib.error.HTTPError as e:
...     print(e.code)
...     print(e.read())
...
404
b'<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0
Transitional//EN"
  "http://www.w3.org/TR/xhtml1/DTD/xhtml1-
transitional.dtd">\n\n\n<html
  ...
  <title>Page Not Found</title>\n
  ...
```

Wrapping it Up

So if you want to be prepared for **`HTTPError`** *or* **`URLError`** there are two basic approaches. I prefer the second approach.

Number 1

```
from urllib.request import Request, urlopen
from urllib.error import URLError, HTTPError
req = Request(someurl)
try:
    response = urlopen(req)
except HTTPError as e:
    print('The server couldn\'t fulfill the request.')
    print('Error code: ', e.code)
except URLError as e:
    print('We failed to reach a server.')
    print('Reason: ', e.reason)
else:
    # everything is fine
```

Note

The `except HTTPError` *must* come first, otherwise `except URLError` will *also* catch an `HTTPError`.

Number 2

```
from urllib.request import Request, urlopen
from urllib.error import URLError
req = Request(someurl)
try:
    response = urlopen(req)
except URLError as e:
    if hasattr(e, 'reason'):
        print('We failed to reach a server.')
        print('Reason: ', e.reason)
    elif hasattr(e, 'code'):
        print('The server couldn\'t fulfill the request.')
        print('Error code: ', e.code)
else:
    # everything is fine
```

info and geturl

The response returned by urlopen (or the `HTTPError` instance) has two useful methods **`info()`** and **`geturl()`** and is defined in the module `urllib.response`.

- **geturl** - this returns the real URL of the page fetched. This is useful because `urlopen` (or the opener object used) may have followed a redirect. The URL of the page fetched may not be the same as the URL requested.
- **info** - this returns a dictionary-like object that describes the page fetched, particularly the headers sent by the server. It is currently an `http.client.HTTPMessage` instance.

Typical headers include ‘Content-length’, ‘Content-type’, and so on. See the Quick Reference to HTTP Headers [https://jkorpela.fi/http.html] for a useful listing of HTTP headers with brief explanations of their meaning and use.

Openers and Handlers

When you fetch a URL you use an opener (an instance of the perhaps confusingly named **`urllib.request.OpenerDirector`**). Normally we have been using the default opener - via `urlopen` - but you can create custom openers. Openers use handlers. All the “heavy lifting” is done by the handlers. Each handler knows how to open URLs for a particular URL scheme (http, ftp, etc.), or how to handle an aspect of URL opening, for example HTTP redirections or HTTP cookies.

You will want to create openers if you want to fetch URLs with specific handlers installed, for example to get an opener that handles cookies, or to get an opener that does not handle redirections.

To create an opener, instantiate an `OpenerDirector`, and then call `.add_handler(some_handler_instance)` repeatedly.

Alternatively, you can use `build_opener`, which is a convenience function for creating opener objects with a single function call. `build_opener` adds several handlers by default, but provides a quick way to add more and/or override the default handlers.

Other sorts of handlers you might want to can handle proxies, authentication, and other common but slightly specialised situations.

`install_opener` can be used to make an `opener` object the (global) default opener. This means that calls to `urlopen` will use the opener you have installed.

Opener objects have an `open` method, which can be called directly to fetch urls in the same way as the `urlopen` function: there’s no need to call `install_opener`, except as a convenience.

Basic Authentication

To illustrate creating and installing a handler we will use the `HTTPBasicAuthHandler`. For a more detailed discussion of this subject – including an explanation of how Basic Authentication works - see the Basic Authentication Tutorial [https://web.archive.org/web/20201215133350/http://www.voidspace.org.uk/python/articles/authentication.shtml].

When authentication is required, the server sends a header (as well as the 401 error code) requesting authentication. This specifies the authentication scheme and a ‘realm’. The header looks like: `WWW-Authenticate: SCHEME realm="REALM"`.

e.g.

```
WWW-Authenticate: Basic realm="cPanel Users"
```

The client should then retry the request with the appropriate name and password for the realm included as a header in the request. This is ‘basic authentication’. In order to simplify this process we can create an instance of `HTTPBasicAuthHandler` and an opener to use this handler.

The `HTTPBasicAuthHandler` uses an object called a password manager to handle the mapping of URLs and realms to passwords and usernames. If you know what the realm is (from the authentication header sent by the server), then you can use a `HTTPPasswordMgr`. Frequently one doesn’t care what the realm is. In that case, it is convenient to use `HTTPPasswordMgrWithDefaultRealm`. This allows you to specify a default username and password for a URL. This will be supplied in the absence of you providing an alternative combination for a specific realm. We indicate this by providing `None` as the realm argument to the `add_password` method.

The top-level URL is the first URL that requires authentication. URLs “deeper” than the URL you pass to .add_password() will also match.

```
# create a password manager
password_mgr = urllib.request.HTTPPasswordMgrWithDefaultRealm()

# Add the username and password.
# If we knew the realm, we could use it instead of None.
top_level_url = "http://example.com/foo/"
password_mgr.add_password(None, top_level_url, username,
password)

handler = urllib.request.HTTPBasicAuthHandler(password_mgr)

# create "opener" (OpenerDirector instance)
opener = urllib.request.build_opener(handler)

# use the opener to fetch a URL
opener.open(a_url)

# Install the opener.
# Now all calls to urllib.request.urlopen use our opener.
urllib.request.install_opener(opener)
```

Note

In the above example we only supplied our `HTTPBasicAuthHandler` to `build_opener`. By default openers have the handlers for normal situations – `ProxyHandler` (if a proxy setting such as an **`http_proxy`** environment variable is set), `UnknownHandler`, `HTTPHandler`, `HTTPDefaultErrorHandler`, `HTTPRedirectHandler`, `FTPHandler`, `FileHandler`, `DataHandler`, `HTTPErrorProcessor`.

`top_level_url` is in fact *either* a full URL (including the 'http:' scheme component and the hostname and optionally the port number) e.g. `"http://example.com/"` *or* an "authority" (i.e. the hostname, optionally including the port number) e.g. `"example.com"` or `"example.com:8080"` (the latter example includes a port number). The authority, if present, must NOT contain the "userinfo" component - for example `"joe:password@example.com"` is not correct.

Proxies

urllib will auto-detect your proxy settings and use those. This is through the `ProxyHandler`, which is part of the normal handler chain when a proxy setting is detected. Normally that's a good thing, but there are occasions when it may not be helpful [[5]]. One way to do this is to setup our own `ProxyHandler`, with no proxies defined. This is done using similar steps to setting up a Basic Authentication handler:

```
>>> proxy_support = urllib.request.ProxyHandler({})
>>> opener = urllib.request.build_opener(proxy_support)
>>> urllib.request.install_opener(opener)
```

Note

Currently `urllib.request` *does not* support fetching of `https` locations through a proxy. However, this can be enabled by extending urllib.request as shown in the recipe [[6]].

Note

`HTTP_PROXY` will be ignored if a variable `REQUEST_METHOD` is set; see the documentation on `getproxies()`.

Sockets and Layers

The Python support for fetching resources from the web is layered. urllib uses the `http.client` library, which in turn uses the socket library.

As of Python 2.3 you can specify how long a socket should wait for a response before timing out. This can be useful in applications which have to fetch web pages. By default the socket module has *no timeout* and can hang. Currently, the socket timeout is not exposed at the http.client or urllib.request levels. However, you can set the default timeout globally for all sockets using

```
import socket
import urllib.request

# timeout in seconds
timeout = 10
socket.setdefaulttimeout(timeout)

# this call to urllib.request.urlopen now uses the default
timeout
# we have set in the socket module
req = urllib.request.Request('http://www.voidspace.org.uk')
response = urllib.request.urlopen(req)
```

Footnotes

This document was reviewed and revised by John Lee.

[1]

Google for example.
[2]

Browser sniffing is a very bad practice for website design - building sites using web standards is much more sensible. Unfortunately a lot of sites still send different versions to different browsers.

[3]

The user agent for MSIE 6 is *‘Mozilla/4.0 (compatible; MSIE 6.0; Windows NT 5.1; SV1; .NET CLR 1.1.4322)’*

[4]

For details of more HTTP request headers, see Quick Reference to HTTP Headers [https://jkorpela.fi/http.html].

[5]

In my case I have to use a proxy to access the internet at work. If you attempt to fetch *localhost* URLs through this proxy it blocks them. IE is set to use the proxy, which urllib picks up on. In order to test scripts with a localhost server, I have to prevent urllib from using the proxy.

An introduction to the ipaddress module

author:: Peter Moody
author:: Nick Coghlan

Overview

This document aims to provide a gentle introduction to the `ipaddress` module. It is aimed primarily at users that aren't already familiar with IP networking terminology, but may also be useful to network engineers wanting an overview of how `ipaddress` represents IP network addressing concepts.

Creating Address/Network/Interface objects

Since `ipaddress` is a module for inspecting and manipulating IP addresses, the first thing you'll want to do is create some objects. You can use `ipaddress` to create objects from strings and integers.

A Note on IP Versions

For readers that aren't particularly familiar with IP addressing, it's important to know that the Internet Protocol (IP) is currently in the process of moving from version 4 of the protocol to version 6. This transition is occurring largely because version 4 of the protocol doesn't provide enough addresses to handle the needs of the whole world, especially given the increasing number of devices with direct connections to the internet.

Explaining the details of the differences between the two versions of the protocol is beyond the scope of this introduction, but readers need to at least be aware that these two versions exist, and it will sometimes be necessary to force the use of one version or the other.

IP Host Addresses

Addresses, often referred to as “host addresses” are the most basic unit when working with IP addressing. The simplest way to create addresses is to use the `ipaddress.ip_address()` factory function, which automatically determines whether to create an IPv4 or IPv6 address based on the passed in value:

```
>>> ipaddress.ip_address('192.0.2.1')
IPv4Address('192.0.2.1')
>>> ipaddress.ip_address('2001:DB8::1')
IPv6Address('2001:db8::1')
```

Addresses can also be created directly from integers. Values that will fit within 32 bits are assumed to be IPv4 addresses:

```
>>> ipaddress.ip_address(3221225985)
IPv4Address('192.0.2.1')
>>>
ipaddress.ip_address(42540766411282592856903984951653826561)
IPv6Address('2001:db8::1')
```

To force the use of IPv4 or IPv6 addresses, the relevant classes can be invoked directly. This is particularly useful to force creation of IPv6 addresses for small integers:

```
>>> ipaddress.ip_address(1)
IPv4Address('0.0.0.1')
>>> ipaddress.IPv4Address(1)
IPv4Address('0.0.0.1')
>>> ipaddress.IPv6Address(1)
IPv6Address('::1')
```

Defining Networks

Host addresses are usually grouped together into IP networks, so **`ipaddress`** provides a way to create, inspect and manipulate network definitions. IP network objects are constructed from strings that define the range of host addresses that are part of that network. The simplest form for that information is a “network address/network prefix” pair, where the prefix defines the number of leading bits that are compared to determine whether or not an address is part of the network and the network address defines the expected value of those bits.

As for addresses, a factory function is provided that determines the correct IP version automatically:

```
>>> ipaddress.ip_network('192.0.2.0/24')
IPv4Network('192.0.2.0/24')
>>> ipaddress.ip_network('2001:db8::0/96')
IPv6Network('2001:db8::/96')
```

Network objects cannot have any host bits set. The practical effect of this is that `192.0.2.1/24` does not describe a network. Such definitions are referred to as interface objects since the ip-on-a-network notation is commonly used to describe network interfaces of a computer on a given network and are described further in the next section.

By default, attempting to create a network object with host bits set will result in **`ValueError`** being raised. To request that the additional bits instead be coerced to zero, the flag `strict=False` can be passed to the constructor:

```
>>> ipaddress.ip_network('192.0.2.1/24')
Traceback (most recent call last):
   ...
ValueError: 192.0.2.1/24 has host bits set
>>> ipaddress.ip_network('192.0.2.1/24', strict=False)
IPv4Network('192.0.2.0/24')
```

While the string form offers significantly more flexibility, networks can also be defined with integers, just like host addresses. In this case, the network is considered to contain only the single address identified by the integer, so the network prefix includes the entire network address:

```
>>> ipaddress.ip_network(3221225984)
IPv4Network('192.0.2.0/32')
>>>
ipaddress.ip_network(42540766411282592856903984951653826560)
IPv6Network('2001:db8::/128')
```

As with addresses, creation of a particular kind of network can be forced by calling the class constructor directly instead of using the factory function.

Host Interfaces

As mentioned just above, if you need to describe an address on a particular network, neither the address nor the network classes are sufficient. Notation like `192.0.2.1/24` is commonly used by network engineers and the people who write tools for firewalls and routers as shorthand for “the host `192.0.2.1` on the network `192.0.2.0/24`”, Accordingly, **`ipaddress`** provides a set of hybrid classes that associate an address with a particular network. The interface for creation is identical to that for defining network objects, except that the address portion isn’t constrained to being a network address.

```
>>> ipaddress.ip_interface('192.0.2.1/24')
IPv4Interface('192.0.2.1/24')
>>> ipaddress.ip_interface('2001:db8::1/96')
IPv6Interface('2001:db8::1/96')
```

Integer inputs are accepted (as with networks), and use of a particular IP version can be forced by calling the relevant constructor directly.

Inspecting Address/Network/Interface Objects

You’ve gone to the trouble of creating an IPv(4|6) (Address|Network|Interface) object, so you probably want to get information about it. **`ipaddress`** tries to make doing this easy and intuitive.

Extracting the IP version:

```
>>> addr4 = ipaddress.ip_address('192.0.2.1')
>>> addr6 = ipaddress.ip_address('2001:db8::1')
>>> addr6.version
6
>>> addr4.version
4
```

Obtaining the network from an interface:

```
>>> host4 = ipaddress.ip_interface('192.0.2.1/24')
>>> host4.network
IPv4Network('192.0.2.0/24')
>>> host6 = ipaddress.ip_interface('2001:db8::1/96')
>>> host6.network
IPv6Network('2001:db8::/96')
```

Finding out how many individual addresses are in a network:

```
>>> net4 = ipaddress.ip_network('192.0.2.0/24')
>>> net4.num_addresses
```

```
256
>>> net6 = ipaddress.ip_network('2001:db8::0/96')
>>> net6.num_addresses
4294967296
```

Iterating through the “usable” addresses on a network:

```
>>> net4 = ipaddress.ip_network('192.0.2.0/24')
>>> for x in net4.hosts():
...     print(x)
192.0.2.1
192.0.2.2
192.0.2.3
192.0.2.4
...
192.0.2.252
192.0.2.253
192.0.2.254
```

Obtaining the netmask (i.e. set bits corresponding to the network prefix) or the hostmask (any bits that are not part of the netmask):

```
>>> net4 = ipaddress.ip_network('192.0.2.0/24')
>>> net4.netmask
IPv4Address('255.255.255.0')
>>> net4.hostmask
IPv4Address('0.0.0.255')
>>> net6 = ipaddress.ip_network('2001:db8::0/96')
>>> net6.netmask
IPv6Address('ffff:ffff:ffff:ffff:ffff:ffff::')
>>> net6.hostmask
IPv6Address('::ffff:ffff')
```

Exploding or compressing the address:

```
>>> addr6.exploded
'2001:0db8:0000:0000:0000:0000:0000:0001'
>>> addr6.compressed
'2001:db8::1'
>>> net6.exploded
'2001:0db8:0000:0000:0000:0000:0000:0000/96'
```

```
>>> net6.compressed
'2001:db8::/96'
```

While IPv4 doesn’t support explosion or compression, the associated objects still provide the relevant properties so that version neutral code can easily ensure the most concise or most verbose form is used for IPv6 addresses while still correctly handling IPv4 addresses.

Networks as lists of Addresses

It’s sometimes useful to treat networks as lists. This means it is possible to index them like this:

```
>>> net4[1]
IPv4Address('192.0.2.1')
>>> net4[-1]
IPv4Address('192.0.2.255')
>>> net6[1]
IPv6Address('2001:db8::1')
>>> net6[-1]
IPv6Address('2001:db8::ffff:ffff')
```

It also means that network objects lend themselves to using the list membership test syntax like this:

```
if address in network:
    # do something
```

Containment testing is done efficiently based on the network prefix:

```
>>> addr4 = ipaddress.ip_address('192.0.2.1')
>>> addr4 in ipaddress.ip_network('192.0.2.0/24')
True
>>> addr4 in ipaddress.ip_network('192.0.3.0/24')
False
```

Comparisons

`ipaddress` provides some simple, hopefully intuitive ways to compare objects, where it makes sense:

```
>>> ipaddress.ip_address('192.0.2.1') <
ipaddress.ip_address('192.0.2.2')
True
```

A **`TypeError`** exception is raised if you try to compare objects of different versions or different types.

Using IP Addresses with other modules

Other modules that use IP addresses (such as **`socket`**) usually won’t accept objects from this module directly. Instead, they must be coerced to an integer or string that the other module will accept:

```
>>> addr4 = ipaddress.ip_address('192.0.2.1')
>>> str(addr4)
'192.0.2.1'
>>> int(addr4)
3221225985
```

Getting more detail when instance creation fails

When creating address/network/interface objects using the version-agnostic factory functions, any errors will be reported as **`ValueError`** with a generic error message that simply says the passed in value was not recognized as an object of that type. The lack of a specific error is because it’s necessary to know whether the value is *supposed* to be IPv4 or IPv6 in order to provide more detail on why it has been rejected.

To support use cases where it is useful to have access to this additional detail, the individual class constructors actually raise the `ValueError` subclasses `ipaddress.AddressValueError` and `ipaddress.NetmaskValueError` to indicate exactly which part of the definition failed to parse correctly.

The error messages are significantly more detailed when using the class constructors directly. For example:

```
>>> ipaddress.ip_address("192.168.0.256")
Traceback (most recent call last):
  ...
ValueError: '192.168.0.256' does not appear to be an IPv4 or
IPv6 address
>>> ipaddress.IPv4Address("192.168.0.256")
Traceback (most recent call last):
  ...
ipaddress.AddressValueError: Octet 256 (> 255) not permitted in
'192.168.0.256'

>>> ipaddress.ip_network("192.168.0.1/64")
Traceback (most recent call last):
  ...
ValueError: '192.168.0.1/64' does not appear to be an IPv4 or
IPv6 network
>>> ipaddress.IPv4Network("192.168.0.1/64")
Traceback (most recent call last):
  ...
ipaddress.NetmaskValueError: '64' is not a valid netmask
```

However, both of the module specific exceptions have `ValueError` as their parent class, so if you’re not concerned with the particular type of error, you can still write code like the following:

```
try:
    network = ipaddress.IPv4Network(address)
except ValueError:
    print('address/netmask is invalid for IPv4:', address)
```

Instrumenting CPython with DTrace and SystemTap

author:: David Malcolm
author:: Łukasz Langa

DTrace and SystemTap are monitoring tools, each providing a way to inspect what the processes on a computer system are doing. They both use domain-specific languages allowing a user to write scripts which:

- filter which processes are to be observed
- gather data from the processes of interest
- generate reports on the data

As of Python 3.6, CPython can be built with embedded “markers”, also known as “probes”, that can be observed by a DTrace or SystemTap script, making it easier to monitor what the CPython processes on a system are doing.

CPython implementation detail: DTrace markers are implementation details of the CPython interpreter. No guarantees are made about probe compatibility between versions of CPython. DTrace scripts can stop working or work incorrectly without warning when changing CPython versions.

Enabling the static markers

macOS comes with built-in support for DTrace. On Linux, in order to build CPython with the embedded markers for

SystemTap, the SystemTap development tools must be installed.

On a Linux machine, this can be done via:

```
$ yum install systemtap-sdt-devel
```

or:

```
$ sudo apt-get install systemtap-sdt-dev
```

CPython must then be **configured with the `--with-dtrace` option**:

```
checking for --with-dtrace... yes
```

On macOS, you can list available DTrace probes by running a Python process in the background and listing all probes made available by the Python provider:

```
$ python3.6 -q &
$ sudo dtrace -l -P python$!  # or: dtrace -l -m python3.6

   ID   PROVIDER            MODULE
FUNCTION NAME
29564 python18035        python3.6
_PyEval_EvalFrameDefault function-entry
29565 python18035        python3.6
dtrace_function_entry function-entry
29566 python18035        python3.6
_PyEval_EvalFrameDefault function-return
29567 python18035        python3.6
dtrace_function_return function-return
29568 python18035        python3.6
collect gc-done
29569 python18035        python3.6
collect gc-start
29570 python18035        python3.6
_PyEval_EvalFrameDefault line
29571 python18035        python3.6
maybe_dtrace_line line
```

On Linux, you can verify if the SystemTap static markers are present in the built binary by seeing if it contains a “.note.stapsdt” section.

```
$ readelf -S ./python | grep .note.stapsdt
[30] .note.stapsdt        NOTE         0000000000000000
00308d78
```

If you’ve built Python as a shared library (with the [`--enable-shared`]() configure option), you need to look instead within the shared library. For example:

```
$ readelf -S libpython3.3dm.so.1.0 | grep .note.stapsdt
[29] .note.stapsdt        NOTE         0000000000000000
00365b68
```

Sufficiently modern readelf can print the metadata:

```
$ readelf -n ./python

Semaphore: 0x00000000008d6bea
        Arguments: 8@%rbp 8@%r12 -4@%eax
```

The above metadata contains information for SystemTap describing how it can patch strategically placed machine code instructions to enable the tracing hooks used by a SystemTap script.

Static DTrace probes

The following example DTrace script can be used to show the call/return hierarchy of a Python script, only tracing within the invocation of a function called “start”. In other words, import-time function invocations are not going to be listed:

```
self int indent;
```

```
python$target:::function-entry
/copyinstr(arg1) == "start"/
{
        self->trace = 1;
}

python$target:::function-entry
/self->trace/
{
        printf("%d\t%*s:", timestamp, 15, probename);
        printf("%*s", self->indent, "");
        printf("%s:%s:%d\n", basename(copyinstr(arg0)),
copyinstr(arg1), arg2);
        self->indent++;
}

python$target:::function-return
/self->trace/
{
        self->indent--;
        printf("%d\t%*s:", timestamp, 15, probename);
        printf("%*s", self->indent, "");
        printf("%s:%s:%d\n", basename(copyinstr(arg0)),
copyinstr(arg1), arg2);
}

python$target:::function-return
/copyinstr(arg1) == "start"/
{
        self->trace = 0;
}
```

It can be invoked like this:

```
$ sudo dtrace -q -s call_stack.d -c "python3.6 script.py"
```

The output looks like this:

```
156641360502280  function-entry:call_stack.py:start:23
156641360518804  function-entry: call_stack.py:function_1:1
156641360532797  function-entry:  call_stack.py:function_3:9
156641360546807 function-return:  call_stack.py:function_3:10
```

```
156641360563367 function-return: call_stack.py:function_1:2
156641360578365  function-entry: call_stack.py:function_2:5
156641360591757  function-entry:  call_stack.py:function_1:1
156641360605556  function-entry:   call_stack.py:function_3:9
156641360617482 function-return:   call_stack.py:function_3:10
156641360629814 function-return:  call_stack.py:function_1:2
156641360642285 function-return: call_stack.py:function_2:6
156641360656770  function-entry: call_stack.py:function_3:9
156641360669707 function-return: call_stack.py:function_3:10
156641360687853  function-entry: call_stack.py:function_4:13
156641360700719 function-return: call_stack.py:function_4:14
156641360719640  function-entry: call_stack.py:function_5:18
156641360732567 function-return: call_stack.py:function_5:21
156641360747370 function-return:call_stack.py:start:28
```

Static SystemTap markers

The low-level way to use the SystemTap integration is to use the static markers directly. This requires you to explicitly state the binary file containing them.

For example, this SystemTap script can be used to show the call/return hierarchy of a Python script:

```
probe process("python").mark("function__entry") {
     filename = user_string($arg1);
     funcname = user_string($arg2);
     lineno = $arg3;

     printf("%s => %s in %s:%d\\n",
            thread_indent(1), funcname, filename, lineno);
}

probe process("python").mark("function__return") {
    filename = user_string($arg1);
    funcname = user_string($arg2);
    lineno = $arg3;

    printf("%s <= %s in %s:%d\\n",
           thread_indent(-1), funcname, filename, lineno);
}
```

It can be invoked like this:

```
$ stap \
  show-call-hierarchy.stp \
  -c "./python test.py"
```

The output looks like this:

```
11408 python(8274):        => __contains__ in
Lib/_abcoll.py:362
11414 python(8274):         => __getitem__ in Lib/os.py:425
11418 python(8274):          => encode in Lib/os.py:490
11424 python(8274):          <= encode in Lib/os.py:493
11428 python(8274):         <= __getitem__ in Lib/os.py:426
11433 python(8274):        <= __contains__ in
Lib/_abcoll.py:366
```

where the columns are:

- time in microseconds since start of script
- name of executable
- PID of process

and the remainder indicates the call/return hierarchy as the script executes.

For a **`--enable-shared`** build of CPython, the markers are contained within the libpython shared library, and the probe’s dotted path needs to reflect this. For example, this line from the above example:

```
probe process("python").mark("function__entry") {
```

should instead read:

```
probe
process("python").library("libpython3.6dm.so.1.0").mark("functi
on__entry") {
```

(assuming a debug build of CPython 3.6)

Available static markers

function__entry(str filename, str funcname, int lineno)

This marker indicates that execution of a Python function has begun. It is only triggered for pure-Python (bytecode) functions.

The filename, function name, and line number are provided back to the tracing script as positional arguments, which must be accessed using `$arg1`, `$arg2`, `$arg3`:

- `$arg1` : `(const char *)` filename, accessible using `user_string($arg1)`
- `$arg2` : `(const char *)` function name, accessible using `user_string($arg2)`
- `$arg3` : `int` line number

function__return(str filename, str funcname, int lineno)

This marker is the converse of **`function__entry()`**, and indicates that execution of a Python function has ended (either via `return`, or via an exception). It is only triggered for pure-Python (bytecode) functions.

The arguments are the same as for **`function__entry()`**

line(str filename, str funcname, int lineno)

This marker indicates a Python line is about to be executed. It is the equivalent of line-by-line tracing with a Python profiler. It is not triggered within C functions.

The arguments are the same as for **`function__entry()`**.

gc__start(int generation)

Fires when the Python interpreter starts a garbage collection cycle. `arg0` is the generation to scan, like `gc.collect()`.

gc__done(long collected)

Fires when the Python interpreter finishes a garbage collection cycle. `arg0` is the number of collected objects.

import__find__load__start(str modulename)

Fires before `importlib` attempts to find and load the module. `arg0` is the module name.

Added in version 3.7.

import__find__load__done(str modulename, int found)

Fires after `importlib`'s find_and_load function is called. `arg0` is the module name, `arg1` indicates if module was successfully loaded.

Added in version 3.7.

audit(str event, void *tuple)

Fires when `sys.audit()` or `PySys_Audit()` is called. `arg0` is the event name as C string, `arg1` is a `PyObject` pointer to a tuple object.

Added in version 3.8.

SystemTap Tapsets

The higher-level way to use the SystemTap integration is to use a “tapset”: SystemTap’s equivalent of a library, which hides some of the lower-level details of the static markers.

Here is a tapset file, based on a non-shared build of CPython:

```
/*
   Provide a higher-level wrapping around the function__entry
and
   function__return markers:
 \*/
probe python.function.entry =
process("python").mark("function__entry")
{
    filename = user_string($arg1);
    funcname = user_string($arg2);
    lineno = $arg3;
    frameptr = $arg4
}
probe python.function.return =
process("python").mark("function__return")
{
    filename = user_string($arg1);
    funcname = user_string($arg2);
    lineno = $arg3;
    frameptr = $arg4
}
```

If this file is installed in SystemTap's tapset directory (e.g. `/usr/share/systemtap/tapset`), then these additional probepoints become available:

python.function.entry(str filename, str funcname, int lineno, frameptr)

> This probe point indicates that execution of a Python function has begun. It is only triggered for pure-Python (bytecode) functions.

python.function.return(str filename, str funcname, int lineno, frameptr)

> This probe point is the converse of `python.function.return`, and indicates that execution of a Python function has ended (either via `return`, or via an exception). It is only triggered for pure-Python (bytecode) functions.

Examples

This SystemTap script uses the tapset above to more cleanly implement the example given above of tracing the Python function-call hierarchy, without needing to directly name the static markers:

```
probe python.function.entry
{
  printf("%s => %s in %s:%d\n",
         thread_indent(1), funcname, filename, lineno);
}

probe python.function.return
{
  printf("%s <= %s in %s:%d\n",
         thread_indent(-1), funcname, filename, lineno);
}
```

The following script uses the tapset above to provide a top-like view of all running CPython code, showing the top 20 most frequently entered bytecode frames, each second, across the whole system:

```
global fn_calls;

probe python.function.entry
{
    fn_calls[pid(), filename, funcname, lineno] += 1;
}

probe timer.ms(1000) {
    printf("\033[2J\033[1;1H") /* clear screen \*/
    printf("%6s %80s %6s %30s %6s\n",
           "PID", "FILENAME", "LINE", "FUNCTION", "CALLS")
    foreach ([pid, filename, funcname, lineno] in fn_calls-
limit 20) {
        printf("%6d %80s %6d %30s %6d\n",
            pid, filename, lineno, funcname,
            fn_calls[pid, filename, funcname, lineno]);
    }
    delete fn_calls;
}
```

Python support for the Linux `perf` profiler

author:: Pablo Galindo

The Linux perf profiler [https://perf.wiki.kernel.org] is a very powerful tool that allows you to profile and obtain information about the performance of your application. `perf` also has a very vibrant ecosystem of tools that aid with the analysis of the data that it produces.

The main problem with using the `perf` profiler with Python applications is that `perf` only gets information about native symbols, that is, the names of functions and procedures written in C. This means that the names and file names of Python functions in your code will not appear in the output of `perf`.

Since Python 3.12, the interpreter can run in a special mode that allows Python functions to appear in the output of the `perf` profiler. When this mode is enabled, the interpreter will interpose a small piece of code compiled on the fly before the execution of every Python function and it will teach `perf` the relationship between this piece of code and the associated Python function using perf map files.

Note

Support for the `perf` profiler is currently only available for Linux on select architectures. Check the output of the `configure` build step or check the output of `python -m` `sysconfig | grep HAVE_PERF_TRAMPOLINE` to see if your system is supported.

For example, consider the following script:

```
def foo(n):
    result = 0
    for _ in range(n):
        result += 1
    return result

def bar(n):
    foo(n)

def baz(n):
    bar(n)

if __name__ == "__main__":
    baz(1000000)
```

We can run `perf` to sample CPU stack traces at 9999 hertz:

```
$ perf record -F 9999 -g -o perf.data python my_script.py
```

Then we can use `perf report` to analyze the data:

```
$ perf report --stdio -n -g

# Children      Self       Samples  Command     Shared Object
Symbol
# ........  ........  ...........  ..........

|           |           |--2.97%--_PyObject_Malloc
...
```

As you can see, the Python functions are not shown in the output, only `_PyEval_EvalFrameDefault` (the function that evaluates the Python bytecode) shows up. Unfortunately that's not very useful because all Python functions use the same C function to evaluate bytecode so we cannot know which Python function corresponds to which bytecode-evaluating function.

Instead, if we run the same experiment with `perf` support enabled we get:

```
$ perf report --stdio -n -g

# Children      Self       Samples  Command     Shared Object
Symbol
# ........  ........  ............  ..........
..................
...............................................................
......

```

How to enable `perf` profiling support

`perf` profiling support can be enabled either from the start using the environment variable `PYTHONPERFSUPPORT` or the `-X perf` option, or dynamically using `sys.activate_stack_trampoline()` and `sys.deactivate_stack_trampoline()`.

The `sys` functions take precedence over the `-X` option, the `-X` option takes precedence over the environment variable.

Example, using the environment variable:

```
$ PYTHONPERFSUPPORT=1 perf record -F 9999 -g -o perf.data
python my_script.py
$ perf report -g -i perf.data
```

Example, using the `-X` option:

```
$ perf record -F 9999 -g -o perf.data python -X perf
my_script.py
$ perf report -g -i perf.data
```

Example, using the `sys` APIs in file `example.py`:

```
import sys

sys.activate_stack_trampoline("perf")
do_profiled_stuff()
sys.deactivate_stack_trampoline()

non_profiled_stuff()
```

…then:

```
$ perf record -F 9999 -g -o perf.data python ./example.py
$ perf report -g -i perf.data
```

How to obtain the best results

For best results, Python should be compiled with `CFLAGS="-fno-omit-frame-pointer -mno-omit-leaf-frame-pointer"` as this allows profilers to unwind using only the frame pointer and not on DWARF debug information. This is because as the code that is interposed to allow `perf` support is dynamically generated it doesn’t have any DWARF debugging information available.

You can check if your system has been compiled with this flag by running:

```
$ python -m sysconfig | grep 'no-omit-frame-pointer'
```

If you don’t see any output it means that your interpreter has not been compiled with frame pointers and therefore it may not be able to show Python functions in the output of `perf`.

How to work without frame pointers

If you are working with a Python interpreter that has been compiled without frame pointers, you can still use the `perf` profiler, but the overhead will be a bit higher because Python needs to generate unwinding information for every Python function call on the fly. Additionally, `perf` will take more time to process the data because it will need to use the DWARF debugging information to unwind the stack and this is a slow process.

To enable this mode, you can use the environment variable `PYTHON_PERF_JIT_SUPPORT` or the `-X perf_jit` option, which will enable the JIT mode for the `perf` profiler.

Note

Due to a bug in the `perf` tool, only `perf` versions higher than v6.8 will work with the JIT mode. The fix was also backported to the v6.7.2 version of the tool.

Note that when checking the version of the `perf` tool (which can be done by running `perf version`) you must take into account that some distros add some custom version numbers including a `-` character. This means that `perf 6.7-3` is not necessarily `perf 6.7.3`.

When using the perf JIT mode, you need an extra step before you can run `perf report`. You need to call the `perf inject` command to inject the JIT information into the `perf.data` file.:

```
$ perf record -F 9999 -g -k 1 --call-graph dwarf -o perf.data
python -Xperf_jit my_script.py
$ perf inject -i perf.data --jit --output perf.jit.data
$ perf report -g -i perf.jit.data
```

or using the environment variable:

```
$ PYTHON_PERF_JIT_SUPPORT=1 perf record -F 9999 -g --call-graph
dwarf -o perf.data python my_script.py
$ perf inject -i perf.data --jit --output perf.jit.data
$ perf report -g -i perf.jit.data
```

`perf inject --jit` command will read `perf.data`, automatically pick up the perf dump file that Python creates (in `/tmp/perf-$PID.dump`), and then create `perf.jit.data` which merges all the JIT information together. It should also create a lot of `jitted-XXXX-N.so` files in the current directory which are ELF images for all the JIT trampolines that were created by Python.

Warning

When using `--call-graph dwarf`, the `perf` tool will take snapshots of the stack of the process being profiled and save the information in the `perf.data` file. By default, the size of the stack dump is 8192 bytes, but you can change the size by passing it after a comma like `--call-graph dwarf,16384`.

The size of the stack dump is important because if the size is too small `perf` will not be able to unwind the stack and the output will be incomplete. On the other hand, if the size is too big, then `perf` won’t be able to sample the process as frequently as it would like as the overhead will be higher.

The stack size is particularly important when profiling Python code compiled with low optimization levels (like `-O0`), as these builds tend to have larger stack frames. If you are compiling Python with `-O0` and not seeing Python functions in your profiling output, try increasing the stack dump size to 65528 bytes (the maximum):

```
$ perf record -F 9999 -g -k 1 --call-graph dwarf,65528 -o
perf.data python -Xperf_jit my_script.py
```

Different compilation flags can significantly impact stack sizes:

- Builds with `-O0` typically have much larger stack frames than those with `-O1` or higher
- Adding optimizations (`-O1`, `-O2`, etc.) typically reduces stack size
- Frame pointers (`-fno-omit-frame-pointer`) generally provide more reliable stack unwinding

Annotations Best Practices

author:: Larry Hastings

Abstract

This document is designed to encapsulate the best practices for working with annotations dicts. If you write Python code that examines `__annotations__` on Python objects, we encourage you to follow the guidelines described below.

The document is organized into four sections: best practices for accessing the annotations of an object in Python versions 3.10 and newer, best practices for accessing the annotations of an object in Python versions 3.9 and older, other best practices for `__annotations__` that apply to any Python version, and quirks of `__annotations__`.

Note that this document is specifically about working with `__annotations__`, not uses *for* annotations. If you're looking for information on how to use "type hints" in your code, please see the `typing` module.

Accessing The Annotations Dict Of An Object In Python 3.10 And Newer

Python 3.10 adds a new function to the standard library: `inspect.get_annotations()`. In Python versions 3.10 through 3.13, calling this function is the best practice for accessing the annotations dict of any object that supports annotations.

This function can also “un-stringize” stringized annotations for you.

In Python 3.14, there is a new `annotationlib` module with functionality for working with annotations. This includes a `annotationlib.get_annotations()` function, which supersedes `inspect.get_annotations()`.

If for some reason `inspect.get_annotations()` isn’t viable for your use case, you may access the `__annotations__` data member manually. Best practice for this changed in Python 3.10 as well: as of Python 3.10, `o.__annotations__` is guaranteed to *always* work on Python functions, classes, and modules. If you’re certain the object you’re examining is one of these three *specific* objects, you may simply use `o.__annotations__` to get at the object’s annotations dict.

However, other types of callables–for example, callables created by `functools.partial()`–may not have an `__annotations__` attribute defined. When accessing the `__annotations__` of a possibly unknown object, best practice in Python versions 3.10 and newer is to call `getattr()` with three arguments, for example `getattr(o, '__annotations__', None)`.

Before Python 3.10, accessing `__annotations__` on a class that defines no annotations but that has a parent class with annotations would return the parent’s `__annotations__`. In Python 3.10 and newer, the child class’s annotations will be an empty dict instead.

Accessing The Annotations Dict Of An Object In Python 3.9 And Older

In Python 3.9 and older, accessing the annotations dict of an object is much more complicated than in newer versions. The problem is a design flaw in these older versions of Python, specifically to do with class annotations.

Best practice for accessing the annotations dict of other objects–functions, other callables, and modules–is the same as best practice for 3.10, assuming you aren't calling `inspect.get_annotations()`: you should use three-argument `getattr()` to access the object's `__annotations__` attribute.

Unfortunately, this isn't best practice for classes. The problem is that, since `__annotations__` is optional on classes, and because classes can inherit attributes from their base classes, accessing the `__annotations__` attribute of a class may inadvertently return the annotations dict of a *base class.* As an example:

```
class Base:
    a: int = 3
    b: str = 'abc'

class Derived(Base):
    pass

print(Derived.__annotations__)
```

This will print the annotations dict from `Base`, not `Derived`.

Your code will have to have a separate code path if the object you're examining is a class (`isinstance(o, type)`). In that case, best practice relies on an implementation detail of Python 3.9 and before: if a class has annotations defined, they are stored in the class's `__dict__` dictionary. Since the class may or may not have annotations defined, best practice is to call the `get()` method on the class dict.

To put it all together, here is some sample code that safely accesses the `__annotations__` attribute on an arbitrary object in Python 3.9 and before:

```
if isinstance(o, type):
    ann = o.__dict__.get('__annotations__', None)
else:
    ann = getattr(o, '__annotations__', None)
```

After running this code, `ann` should be either a dictionary or `None`. You’re encouraged to double-check the type of `ann` using **`isinstance()`** before further examination.

Note that some exotic or malformed type objects may not have a **`__dict__`** attribute, so for extra safety you may also wish to use **`getattr()`** to access **`__dict__`**.

Manually Un-Stringizing Stringized Annotations

In situations where some annotations may be “stringized”, and you wish to evaluate those strings to produce the Python values they represent, it really is best to call **`inspect.get_annotations()`** to do this work for you.

If you’re using Python 3.9 or older, or if for some reason you can’t use **`inspect.get_annotations()`**, you’ll need to duplicate its logic. You’re encouraged to examine the implementation of **`inspect.get_annotations()`** in the current Python version and follow a similar approach.

In a nutshell, if you wish to evaluate a stringized annotation on an arbitrary object `o`:

- If `o` is a module, use `o.__dict__` as the `globals` when calling **`eval()`**.

- If `o` is a class, use `sys.modules[o.__module__].__dict__` as the `globals`, and `dict(vars(o))` as the `locals`, when calling `eval()`.
- If `o` is a wrapped callable using `functools.update_wrapper()`, `functools.wraps()`, or `functools.partial()`, iteratively unwrap it by accessing either `o.__wrapped__` or `o.func` as appropriate, until you have found the root unwrapped function.
- If `o` is a callable (but not a class), use `o.__globals__` as the globals when calling `eval()`.

However, not all string values used as annotations can be successfully turned into Python values by `eval()`. String values could theoretically contain any valid string, and in practice there are valid use cases for type hints that require annotating with string values that specifically *can't* be evaluated. For example:

- **PEP 604** [https://peps.python.org/pep-0604/] union types using `|`, before support for this was added to Python 3.10.
- Definitions that aren't needed at runtime, only imported when `typing.TYPE_CHECKING` is true.

If `eval()` attempts to evaluate such values, it will fail and raise an exception. So, when designing a library API that works with annotations, it's recommended to only attempt to evaluate string values when explicitly requested to by the caller.

Best Practices For `__annotations__` In Any Python Version

- You should avoid assigning to the `__annotations__` member of objects directly. Let Python manage setting `__annotations__`.

- If you do assign directly to the `__annotations__` member of an object, you should always set it to a `dict` object.
- You should avoid accessing `__annotations__` directly on any object. Instead, use `annotationlib.get_annotations()` (Python 3.14+) or `inspect.get_annotations()` (Python 3.10+).
- If you do directly access the `__annotations__` member of an object, you should ensure that it's a dictionary before attempting to examine its contents.
- You should avoid modifying `__annotations__` dicts.
- You should avoid deleting the `__annotations__` attribute of an object.

`__annotations__` Quirks

In all versions of Python 3, function objects lazy-create an annotations dict if no annotations are defined on that object. You can delete the `__annotations__` attribute using `del fn.__annotations__`, but if you then access `fn.__annotations__` the object will create a new empty dict that it will store and return as its annotations. Deleting the annotations on a function before it has lazily created its annotations dict will throw an `AttributeError`; using `del fn.__annotations__` twice in a row is guaranteed to always throw an `AttributeError`.

Everything in the above paragraph also applies to class and module objects in Python 3.10 and newer.

In all versions of Python 3, you can set `__annotations__` on a function object to `None`. However, subsequently accessing the annotations on that object using `fn.__annotations__` will lazy-create an empty dictionary as per the first paragraph of this section. This is *not* true of modules and classes, in any Python version; those objects permit setting `__annotations__` to any Python value, and will retain whatever value is set.

If Python stringizes your annotations for you (using `from __future__ import annotations`), and you specify a string as an annotation, the string will itself be quoted. In effect the annotation is quoted *twice.* For example:

```
from __future__ import annotations
def foo(a: "str"): pass

print(foo.__annotations__)
```

This prints `{'a': "'str'"}`. This shouldn't really be considered a "quirk"; it's mentioned here simply because it might be surprising.

If you use a class with a custom metaclass and access `__annotations__` on the class, you may observe unexpected behavior; see **749** [https://peps.python.org/pep-0749/#pep749-metaclasses] for some examples. You can avoid these quirks by using **`annotationlib.get_annotations()`** on Python 3.14+ or **`inspect.get_annotations()`** on Python 3.10+. On earlier versions of Python, you can avoid these bugs by accessing the annotations from the class's **`__dict__`** (for example, `cls.__dict__.get('__annotations__', None)`).

In some versions of Python, instances of classes may have an `__annotations__` attribute. However, this is not supported functionality. If you need the annotations of an instance, you can use **`type()`** to access its class (for example, `annotationlib.get_annotations(type(myinstance))` on Python 3.14+).

Isolating Extension Modules

Abstract

Traditionally, state belonging to Python extension modules was kept in C `static` variables, which have process-wide scope. This document describes problems of such per-process state and shows a safer way: per-module state.

The document also describes how to switch to per-module state where possible. This transition involves allocating space for that state, potentially switching from static types to heap types, and—perhaps most importantly—accessing per-module state from code.

Who should read this

This guide is written for maintainers of C-API extensions who would like to make that extension safer to use in applications where Python itself is used as a library.

Background

An *interpreter* is the context in which Python code runs. It contains configuration (e.g. the import path) and runtime state (e.g. the set of imported modules).

Python supports running multiple interpreters in one process. There are two cases to think about—users may run interpreters:

- in sequence, with several `Py_InitializeEx()`/`Py_FinalizeEx()` cycles, and
- in parallel, managing “sub-interpreters” using `Py_NewInterpreter()`/`Py_EndInterpreter()`.

Both cases (and combinations of them) would be most useful when embedding Python within a library. Libraries generally shouldn’t make assumptions about the application that uses them, which include assuming a process-wide “main Python interpreter”.

Historically, Python extension modules don’t handle this use case well. Many extension modules (and even some stdlib modules) use *per-process* global state, because C `static` variables are extremely easy to use. Thus, data that should be specific to an interpreter ends up being shared between interpreters. Unless the extension developer is careful, it is very easy to introduce edge cases that lead to crashes when a module is loaded in more than one interpreter in the same process.

Unfortunately, *per-interpreter* state is not easy to achieve. Extension authors tend to not keep multiple interpreters in mind when developing, and it is currently cumbersome to test the behavior.

Enter Per-Module State

Instead of focusing on per-interpreter state, Python’s C API is evolving to better support the more granular *per-module* state. This means that C-level data should be attached to a *module object*. Each interpreter creates its own module object, keeping the data separate. For testing the isolation, multiple module objects corresponding to a single extension can even be loaded in a single interpreter.

Per-module state provides an easy way to think about lifetime and resource ownership: the extension module will initialize when a module object is created, and clean up when it’s freed. In this regard, a module is just like any other PyObject*; there are no “on interpreter shutdown” hooks to think—or forget—about.

Note that there are use cases for different kinds of “globals”: per-process, per-interpreter, per-thread or per-task state. With per-module state as the default, these are still possible, but you should treat them as exceptional cases: if you need them, you should give them additional care and testing. (Note that this guide does not cover them.)

Isolated Module Objects

The key point to keep in mind when developing an extension module is that several module objects can be created from a single shared library. For example:

```
>>> import sys
>>> import binascii
>>> old_binascii = binascii
>>> del sys.modules['binascii']
>>> import binascii  # create a new module object
>>> old_binascii == binascii
False
```

As a rule of thumb, the two modules should be completely independent. All objects and state specific to the module should be encapsulated within the module object, not shared with other module objects, and cleaned up when the module object is deallocated. Since this just is a rule of thumb, exceptions are possible (see Managing Global State), but they will need more thought and attention to edge cases.

While some modules could do with less stringent restrictions, isolated modules make it easier to set clear expectations and guidelines that work across a variety of use cases.

Surprising Edge Cases

Note that isolated modules do create some surprising edge cases. Most notably, each module object will typically not share its classes and exceptions with other similar modules. Continuing from the example above, note that `old_binascii.Error` and `binascii.Error` are separate objects. In the following code, the exception is *not* caught:

```
>>> old_binascii.Error == binascii.Error
False
>>> try:
...     old_binascii.unhexlify(b'qwertyuiop')
... except binascii.Error:
...     print('boo')
...
Traceback (most recent call last):
  File "<stdin>", line 2, in <module>
binascii.Error: Non-hexadecimal digit found
```

This is expected. Notice that pure-Python modules behave the same way: it is a part of how Python works.

The goal is to make extension modules safe at the C level, not to make hacks behave intuitively. Mutating `sys.modules` “manually” counts as a hack.

Making Modules Safe with Multiple Interpreters

Managing Global State

Sometimes, the state associated with a Python module is not specific to that module, but to the entire process (or something else “more global” than a module). For example:

- The `readline` module manages *the* terminal.
- A module running on a circuit board wants to control *the* on-board LED.

In these cases, the Python module should provide *access* to the global state, rather than *own* it. If possible, write the module so that multiple copies of it can access the state independently (along with other libraries, whether for Python or other languages). If that is not possible, consider explicit locking.

If it is necessary to use process-global state, the simplest way to avoid issues with multiple interpreters is to explicitly prevent a module from being loaded more than once per process—see Opt-Out: Limiting to One Module Object per Process.

Managing Per-Module State

To use per-module state, use multi-phase extension module initialization. This signals that your module supports multiple interpreters correctly.

Set `PyModuleDef.m_size` to a positive number to request that many bytes of storage local to the module. Usually, this will be set to the size of some module-specific `struct`, which can store all of the module’s C-level state. In particular, it is where you should put pointers to classes (including exceptions, but excluding static types) and settings (e.g. `csv`’s **`field_size_limit`**) which the C code needs to function.

Note

Another option is to store state in the module’s `__dict__`, but you must avoid crashing when users modify `__dict__` from Python code. This usually means error- and type-checking at the C level, which is easy to get wrong and hard to test sufficiently.

However, if module state is not needed in C code, storing it in `__dict__` only is a good idea.

If the module state includes `PyObject` pointers, the module object must hold references to those objects and implement the module-level hooks `m_traverse`, `m_clear` and `m_free`. These work like `tp_traverse`, `tp_clear` and `tp_free` of a class. Adding them will require some work and make the code longer; this is the price for modules which can be unloaded cleanly.

An example of a module with per-module state is currently available as xxlimited [https://github.com/python/cpython/blob/master/Modules/xxlimited.c]; example module initialization shown at the bottom of the file.

Opt-Out: Limiting to One Module Object per Process

A non-negative `PyModuleDef.m_size` signals that a module supports multiple interpreters correctly. If this is not yet the case for your module, you can explicitly make your module loadable only once per process. For example:

```
// A process-wide flag
static int loaded = 0;

// Mutex to provide thread safety (only needed for free-
threaded Python)
static PyMutex modinit_mutex = {0};

static int
exec_module(PyObject* module)
{
    PyMutex_Lock(&modinit_mutex);
    if (loaded) {
        PyMutex_Unlock(&modinit_mutex);
        PyErr_SetString(PyExc_ImportError,
                        "cannot load module more than once per
process");
        return -1;
    }
    loaded = 1;
    PyMutex_Unlock(&modinit_mutex);
    // ... rest of initialization
}
```

If your module's `PyModuleDef.m_clear` function is able to prepare for future re-initialization, it should clear the `loaded` flag. In this case, your module won't support multiple instances existing *concurrently*, but it will, for example, support being loaded after Python runtime shutdown (`Py_FinalizeEx()`) and re-initialization (`Py_Initialize()`).

Module State Access from Functions

Accessing the state from module-level functions is straightforward. Functions get the module object as their first argument; for extracting the state, you can use `PyModule_GetState`:

```
static PyObject *
func(PyObject *module, PyObject *args)
{
    my_struct *state = (my_struct*)PyModule_GetState(module);
    if (state == NULL) {
        return NULL;
    }
    // ... rest of logic
}
```

Note

`PyModule_GetState` may return `NULL` without setting an exception if there is no module state, i.e. `PyModuleDef.m_size` was zero. In your own module, you're in control of `m_size`, so this is easy to prevent.

Heap Types

Traditionally, types defined in C code are *static*; that is, `static PyTypeObject` structures defined directly in code and initialized using `PyType_Ready()`.

Such types are necessarily shared across the process. Sharing them between module objects requires paying attention to any state they own or access. To limit the possible issues, static types are immutable at the Python level: for example, you can't set `str.myattribute = 123`.

CPython implementation detail: Sharing truly immutable objects between interpreters is fine, as long as they don't provide access to mutable objects. However, in CPython, every Python object has a mutable implementation detail: the reference count. Changes to the refcount are guarded by the GIL. Thus, code that shares any Python objects across interpreters implicitly depends on CPython’s current, process-wide GIL.

Because they are immutable and process-global, static types cannot access “their” module state. If any method of such a type requires access to module state, the type must be converted to a *heap-allocated type*, or *heap type* for short. These correspond more closely to classes created by Python’s `class` statement.

For new modules, using heap types by default is a good rule of thumb.

Changing Static Types to Heap Types

Static types can be converted to heap types, but note that the heap type API was not designed for “lossless” conversion from static types—that is, creating a type that works exactly like a given static type. So, when rewriting the class definition in a new API, you are likely to unintentionally change a few details (e.g. pickleability or inherited slots). Always test the details that are important to you.

Watch out for the following two points in particular (but note that this is not a comprehensive list):

- Unlike static types, heap type objects are mutable by default. Use the `Py_TPFLAGS_IMMUTABLETYPE` flag to prevent mutability.
- Heap types inherit `tp_new` by default, so it may become possible to instantiate them from Python code. You can prevent this with the `Py_TPFLAGS_DISALLOW_INSTANTIATION` flag.

Defining Heap Types

Heap types can be created by filling a `PyType_Spec` structure, a description or “blueprint” of a class, and calling `PyType_FromModuleAndSpec()` to construct a new class object.

Note

Other functions, like `PyType_FromSpec()`, can also create heap types, but `PyType_FromModuleAndSpec()` associates the module with the class, allowing access to the module state from methods.

The class should generally be stored in *both* the module state (for safe access from C) and the module’s `__dict__` (for access from Python code).

Garbage-Collection Protocol

Instances of heap types hold a reference to their type. This ensures that the type isn’t destroyed before all its instances are, but may result in reference cycles that need to be broken by the garbage collector.

To avoid memory leaks, instances of heap types must implement the garbage collection protocol. That is, heap types should:

- Have the `Py_TPFLAGS_HAVE_GC` flag.
- Define a traverse function using `Py_tp_traverse`, which visits the type (e.g. using `Py_VISIT(Py_TYPE(self))`).

Please refer to the documentation of `Py_TPFLAGS_HAVE_GC` and `tp_traverse` for additional considerations.

The API for defining heap types grew organically, leaving it somewhat awkward to use in its current state. The following sections will guide you through common issues.

`tp_traverse` in Python 3.8 and lower

The requirement to visit the type from `tp_traverse` was added in Python 3.9. If you support Python 3.8 and lower, the traverse function must *not* visit the type, so it must be more complicated:

```
static int my_traverse(PyObject *self, visitproc visit, void
*arg)
{
    if (Py_Version >= 0x03090000) {
        Py_VISIT(Py_TYPE(self));
    }
    return 0;
}
```

Unfortunately, `Py_Version` was only added in Python 3.11. As a replacement, use:

- `PY_VERSION_HEX`, if not using the stable ABI, or
- `sys.version_info` (via `PySys_GetObject()` and `PyArg_ParseTuple()`).

Delegating `tp_traverse`

If your traverse function delegates to the `tp_traverse` of its base class (or another type), ensure that `Py_TYPE(self)` is visited only once. Note that only heap type are expected to visit the type in `tp_traverse`.

For example, if your traverse function includes:

```
base->tp_traverse(self, visit, arg)
```

…and `base` may be a static type, then it should also include:

```
if (base->tp_flags & Py_TPFLAGS_HEAPTYPE) {
    // a heap type's tp_traverse already visited Py_TYPE(self)
} else {
    if (Py_Version >= 0x03090000) {
        Py_VISIT(Py_TYPE(self));
    }
}
```

It is not necessary to handle the type’s reference count in **`tp_new`** and **`tp_clear`**.

Defining `tp_dealloc`

If your type has a custom **`tp_dealloc`** function, it needs to:

- call **`PyObject_GC_UnTrack()`** before any fields are invalidated, and
- decrement the reference count of the type.

To keep the type valid while `tp_free` is called, the type’s refcount needs to be decremented *after* the instance is deallocated. For example:

```
static void my_dealloc(PyObject *self)
{
    PyObject_GC_UnTrack(self);
    ...
    PyTypeObject *type = Py_TYPE(self);
    type->tp_free(self);
    Py_DECREF(type);
}
```

The default `tp_dealloc` function does this, so if your type does *not* override `tp_dealloc` you don’t need to add it.

Not overriding `tp_free`

The `tp_free` slot of a heap type must be set to `PyObject_GC_Del()`. This is the default; do not override it.

Avoiding `PyObject_New`

GC-tracked objects need to be allocated using GC-aware functions.

If you use `PyObject_New()` or `PyObject_NewVar()`:

- Get and call type's `tp_alloc` slot, if possible. That is, replace `TYPE *o = PyObject_New(TYPE, typeobj)` with:

  ```
  TYPE *o = typeobj->tp_alloc(typeobj, 0);
  ```

  Replace `o = PyObject_NewVar(TYPE, typeobj, size)` with the same, but use size instead of the 0.

- If the above is not possible (e.g. inside a custom `tp_alloc`), call `PyObject_GC_New()` or `PyObject_GC_NewVar()`:

  ```
  TYPE *o = PyObject_GC_New(TYPE, typeobj);
  ```

  ```
  TYPE *o = PyObject_GC_NewVar(TYPE, typeobj, size);
  ```

Module State Access from Classes

If you have a type object defined with `PyType_FromModuleAndSpec()`, you can call `PyType_GetModule()` to get the associated module, and then `PyModule_GetState()` to get the module's state.

To save a some tedious error-handling boilerplate code, you can combine these two steps with `PyType_GetModuleState()`, resulting in:

```
my_struct *state = (my_struct*)PyType_GetModuleState(type);
if (state == NULL) {
```

```
    return NULL;
}
```

Module State Access from Regular Methods

Accessing the module-level state from methods of a class is somewhat more complicated, but is possible thanks to API introduced in Python 3.9. To get the state, you need to first get the *defining class*, and then get the module state from it.

The largest roadblock is getting *the class a method was defined in*, or that method's "defining class" for short. The defining class can have a reference to the module it is part of.

Do not confuse the defining class with `Py_TYPE(self)`. If the method is called on a *subclass* of your type, `Py_TYPE(self)` will refer to that subclass, which may be defined in different module than yours.

Note

The following Python code can illustrate the concept. `Base.get_defining_class` returns `Base` even if `type(self) == Sub`:

```
class Base:
    def get_type_of_self(self):
        return type(self)

    def get_defining_class(self):
        return __class__

class Sub(Base):
    pass
```

For a method to get its “defining class”, it must use the METH_METHOD | METH_FASTCALL | METH_KEYWORDS `calling convention` and the corresponding `PyCMethod` signature:

```
PyObject *PyCMethod(
    PyObject *self,               // object the method was
called on
    PyTypeObject *defining_class, // defining class
    PyObject *const *args,        // C array of arguments
    Py_ssize_t nargs,             // length of "args"
    PyObject *kwnames)            // NULL, or dict of keyword
arguments
```

Once you have the defining class, call `PyType_GetModuleState()` to get the state of its associated module.

For example:

```
static PyObject *
example_method(PyObject *self,
        PyTypeObject *defining_class,
        PyObject *const *args,
        Py_ssize_t nargs,
        PyObject *kwnames)
{
    my_struct *state =
(my_struct*)PyType_GetModuleState(defining_class);
    if (state == NULL) {
        return NULL;
    }
    ... // rest of logic
}

PyDoc_STRVAR(example_method_doc, "...");

static PyMethodDef my_methods[] = {
    {"example_method",
      (PyCFunction)(void(*)(void))example_method,
      METH_METHOD|METH_FASTCALL|METH_KEYWORDS,
      example_method_doc}
    {NULL},
}
```

Module State Access from Slot Methods, Getters and Setters

Note

This is new in Python 3.11.

Slot methods—the fast C equivalents for special methods, such as `nb_add` for `__add__` or `tp_new` for initialization—have a very simple API that doesn't allow passing in the defining class, unlike with `PyCMethod`. The same goes for getters and setters defined with `PyGetSetDef`.

To access the module state in these cases, use the `PyType_GetModuleByDef()` function, and pass in the module definition. Once you have the module, call `PyModule_GetState()` to get the state:

```
PyObject *module = PyType_GetModuleByDef(Py_TYPE(self),
&module_def);
my_struct *state = (my_struct*)PyModule_GetState(module);
if (state == NULL) {
    return NULL;
}
```

`PyType_GetModuleByDef()` works by searching the method resolution order (i.e. all superclasses) for the first superclass that has a corresponding module.

Note

In very exotic cases (inheritance chains spanning multiple modules created from the same definition), **`PyType_GetModuleByDef()`** might not return the module of the true defining class. However, it will always return a module with the same definition, ensuring a compatible C memory layout.

Lifetime of the Module State

When a module object is garbage-collected, its module state is freed. For each pointer to (a part of) the module state, you must hold a reference to the module object.

Usually this is not an issue, because types created with `PyType_FromModuleAndSpec()`, and their instances, hold a reference to the module. However, you must be careful in reference counting when you reference module state from other places, such as callbacks for external libraries.

Open Issues

Several issues around per-module state and heap types are still open.

Discussions about improving the situation are best held on the discuss forum under c-api tag [https://discuss.python.org/c/core-dev/c-api/30].

Per-Class Scope

It is currently (as of Python 3.11) not possible to attach state to individual *types* without relying on CPython implementation details (which may change in the future—perhaps, ironically, to allow a proper solution for per-class scope).

Lossless Conversion to Heap Types

The heap type API was not designed for “lossless” conversion from static types; that is, creating a type that works exactly like a given static type.

timer file descriptor HOWTO

Release:: 1.13

This HOWTO discusses Python’s support for the linux timer file descriptor.

Examples

The following example shows how to use a timer file descriptor to execute a function twice a second:

```
# Practical scripts should use really use a non-blocking timer,
# we use a blocking timer here for simplicity.
import os, time

# Create the timer file descriptor
fd = os.timerfd_create(time.CLOCK_REALTIME)

# Start the timer in 1 second, with an interval of half a
second
os.timerfd_settime(fd, initial=1, interval=0.5)

try:
    # Process timer events four times.
    for _ in range(4):
        # read() will block until the timer expires
        _ = os.read(fd, 8)
        print("Timer expired")
finally:
    # Remember to close the timer file descriptor!
    os.close(fd)
```

To avoid the precision loss caused by the `float` type, timer file descriptors allow specifying initial expiration and interval in integer nanoseconds with `_ns` variants of the functions.

This example shows how `epoll()` can be used with timer file descriptors to wait until the file descriptor is ready for reading:

```
import os, time, select, socket, sys

# Create an epoll object
ep = select.epoll()

# In this example, use loopback address to send "stop" command
to the server.
#
# $ telnet 127.0.0.1 1234
# Trying 127.0.0.1...
# Connected to 127.0.0.1.
# Escape character is '^]'.
# stop
# Connection closed by foreign host.
#
sock = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
sock.bind(("127.0.0.1", 1234))
sock.setblocking(False)
sock.listen(1)
ep.register(sock, select.EPOLLIN)

# Create timer file descriptors in non-blocking mode.
num = 3
fds = []
for _ in range(num):
    fd = os.timerfd_create(time.CLOCK_REALTIME,
flags=os.TFD_NONBLOCK)
    fds.append(fd)
    # Register the timer file descriptor for read events
    ep.register(fd, select.EPOLLIN)

# Start the timer with os.timerfd_settime_ns() in nanoseconds.
# Timer 1 fires every 0.25 seconds; timer 2 every 0.5 seconds;
etc
for i, fd in enumerate(fds, start=1):
    one_sec_in_nsec = 10**9
    i = i * one_sec_in_nsec
    os.timerfd_settime_ns(fd, initial=i//4, interval=i//4)

timeout = 3
try:
    conn = None
    is_active = True
    while is_active:
        # Wait for the timer to expire for 3 seconds.
        # epoll.poll() returns a list of (fd, event) pairs.
        # fd is a file descriptor.
        # sock and conn[=returned value of socket.accept()] are
socket objects, not file descriptors.
        # So use sock.fileno() and conn.fileno() to get the
file descriptors.
        events = ep.poll(timeout)

        # If more than one timer file descriptors are ready for
reading at once,
        # epoll.poll() returns a list of (fd, event) pairs.
        #
        # In this example settings,
        #    1st timer fires every 0.25 seconds in 0.25
seconds. (0.25, 0.5, 0.75, 1.0, ...)
        #    2nd timer every 0.5 seconds in 0.5 seconds. (0.5,
1.0, 1.5, 2.0, ...)
        #    3rd timer every 0.75 seconds in 0.75 seconds.
(0.75, 1.5, 2.25, 3.0, ...)
        #
        #    In 0.25 seconds, only 1st timer fires.
        #    In 0.5 seconds, 1st timer and 2nd timer fires at
once.
        #    In 0.75 seconds, 1st timer and 3rd timer fires at
once.
        #    In 1.5 seconds, 1st timer, 2nd timer and 3rd timer
fires at once.
        #
        # If a timer file descriptor is signaled more than once
since
        # the last os.read() call, os.read() returns the number
of signaled
        # as host order of class bytes.
        print(f"Signaled events={events}")
        for fd, event in events:
            if event & select.EPOLLIN:
                if fd == sock.fileno():
                    # Check if there is a connection request.
                    print(f"Accepting connection {fd}")
                    conn, addr = sock.accept()
                    conn.setblocking(False)
                    print(f"Accepted connection {conn} from
{addr}")
                    ep.register(conn, select.EPOLLIN)
                elif conn and fd == conn.fileno():
                    # Check if there is data to read.
                    print(f"Reading data {fd}")
                    data = conn.recv(1024)
                    if data:
                        # You should catch UnicodeDecodeError
exception for safety.
                        cmd = data.decode()
                        if cmd.startswith("stop"):
                            print(f"Stopping server")
                            is_active = False
                        else:
                            print(f"Unknown command: {cmd}")
                    else:
                        # No more data, close connection
                        print(f"Closing connection {fd}")
                        ep.unregister(conn)
                        conn.close()
                        conn = None
                elif fd in fds:
                    print(f"Reading timer {fd}")
                    count = int.from_bytes(os.read(fd, 8),
byteorder=sys.byteorder)
                    print(f"Timer {fds.index(fd) + 1} expired
{count} times")
                else:
                    print(f"Unknown file descriptor {fd}")
finally:
    for fd in fds:
        ep.unregister(fd)
        os.close(fd)
    ep.close()
```

This example shows how `select()` can be used with timer file descriptors to wait until the file descriptor is ready for reading:

```
import os, time, select, socket, sys

# In this example, use loopback address to send "stop" command
to the server.
#
# $ telnet 127.0.0.1 1234
# Trying 127.0.0.1...
# Connected to 127.0.0.1.
# Escape character is '^]'.
# stop
# Connection closed by foreign host.
#
sock = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
sock.bind(("127.0.0.1", 1234))
sock.setblocking(False)
sock.listen(1)

# Create timer file descriptors in non-blocking mode.
num = 3
fds = [os.timerfd_create(time.CLOCK_REALTIME,
flags=os.TFD_NONBLOCK)
       for _ in range(num)]
select_fds = fds + [sock]

# Start the timers with os.timerfd_settime() in seconds.
# Timer 1 fires every 0.25 seconds; timer 2 every 0.5 seconds;
etc
for i, fd in enumerate(fds, start=1):
   os.timerfd_settime(fd, initial=i/4, interval=i/4)

timeout = 3
try:
    conn = None
    is_active = True
    while is_active:
       # Wait for the timer to expire for 3 seconds.
       # select.select() returns a list of file descriptors or
objects.
```

```
       rfd, wfd, xfd = select.select(select_fds, select_fds,
select_fds, timeout)
       for fd in rfd:
           if fd == sock:
               # Check if there is a connection request.
               print(f"Accepting connection {fd}")
               conn, addr = sock.accept()
               conn.setblocking(False)
               print(f"Accepted connection {conn} from {addr}")
               select_fds.append(conn)
           elif conn and fd == conn:
               # Check if there is data to read.
               print(f"Reading data {fd}")
               data = conn.recv(1024)
               if data:
                   # You should catch UnicodeDecodeError
exception for safety.
                   cmd = data.decode()
                   if cmd.startswith("stop"):
                       print(f"Stopping server")
                       is_active = False
                   else:
                       print(f"Unknown command: {cmd}")
               else:
                   # No more data, close connection
                   print(f"Closing connection {fd}")
                   select_fds.remove(conn)
                   conn.close()
                   conn = None
           elif fd in fds:
               print(f"Reading timer {fd}")
               count = int.from_bytes(os.read(fd, 8),
byteorder=sys.byteorder)
               print(f"Timer {fds.index(fd) + 1} expired
{count} times")
           else:
               print(f"Unknown file descriptor {fd}")
finally:
    for fd in fds:
       os.close(fd)
    sock.close()
    sock = None
```

The Python 2.3 Method Resolution Order

Note

This is a historical document, provided as an appendix to the official documentation. The Method Resolution Order discussed here was *introduced* in Python 2.3, but it is still used in later versions – including Python 3.

By Michele Simionato [https://www.phyast.pitt.edu/~micheles/].

Abstract:: *This document is intended for Python programmers who want to understand the C3 Method Resolution Order used in Python 2.3. Although it is not intended for newbies, it is quite pedagogical with many worked out examples. I am not aware of other publicly available documents with the same scope, therefore it should be useful.*

Disclaimer:

> *I donate this document to the Python Software Foundation, under the Python 2.3 license. As usual in these circumstances, I warn the reader that what follows* should *be correct, but I don't give any warranty. Use it at your own risk and peril!*

Acknowledgments:

> *All the people of the Python mailing list who sent me their support. Paul Foley who pointed out various imprecisions and made me to add the part on local precedence ordering. David Goodger for help with the formatting in reStructuredText. David Mertz for help with the editing. Finally, Guido van Rossum who enthusiastically added this document to the official Python 2.3 home-page.*

The beginning

> *Felix qui potuit rerum cognoscere causas* – Virgilius

Everything started with a post by Samuele Pedroni to the Python development mailing list [[1]]. In his post, Samuele showed that the Python 2.2 method resolution order is not monotonic and he proposed to replace it with the C3 method resolution order. Guido agreed with his arguments and therefore now Python 2.3 uses C3. The C3 method itself has nothing to do with Python, since it was invented by people working on Dylan and it is described in a paper intended for lispers [[2]]. The present paper gives a (hopefully) readable discussion of the C3 algorithm for Pythonistas who want to understand the reasons for the change.

First of all, let me point out that what I am going to say only applies to the *new style classes* introduced in Python 2.2: *classic classes* maintain their old method resolution order, depth first and then left to right. Therefore, there is no breaking of old code for classic classes; and even if in principle there could be breaking of code for Python 2.2 new style classes, in practice the cases in which the C3 resolution order differs from the Python 2.2 method resolution order are so rare that no real breaking of code is expected. Therefore:

> *Don’t be scared!*

Moreover, unless you make strong use of multiple inheritance and you have non-trivial hierarchies, you don’t need to understand the C3 algorithm, and you can easily skip this paper. On the other hand, if you really want to know how multiple inheritance works, then this paper is for you. The good news is that things are not as complicated as you might expect.

Let me begin with some basic definitions.

1. Given a class C in a complicated multiple inheritance hierarchy, it is a non-trivial task to specify the order in which methods are overridden, i.e. to specify the order of the ancestors of C.
2. The list of the ancestors of a class C, including the class itself, ordered from the nearest ancestor to the furthest, is called the class precedence list or the *linearization* of C.
3. The *Method Resolution Order* (MRO) is the set of rules that construct the linearization. In the Python literature, the idiom “the MRO of C” is also used as a synonymous for the linearization of the class C.
4. For instance, in the case of single inheritance hierarchy, if C is a subclass of C1, and C1 is a subclass of C2, then the linearization of C is simply the list [C, C1 , C2]. However, with multiple inheritance hierarchies, the construction of the linearization is more cumbersome, since it is more difficult to construct a linearization that respects *local precedence ordering* and *monotonicity*.
5. I will discuss the local precedence ordering later, but I can give the definition of monotonicity here. A MRO is

monotonic when the following is true: *if C1 precedes C2 in the linearization of C, then C1 precedes C2 in the linearization of any subclass of C*. Otherwise, the innocuous operation of deriving a new class could change the resolution order of methods, potentially introducing very subtle bugs. Examples where this happens will be shown later.

6. Not all classes admit a linearization. There are cases, in complicated hierarchies, where it is not possible to derive a class such that its linearization respects all the desired properties.

Here I give an example of this situation. Consider the hierarchy

```
>>> O = object
>>> class X(O): pass
>>> class Y(O): pass
>>> class A(X,Y): pass
>>> class B(Y,X): pass
```

which can be represented with the following inheritance graph, where I have denoted with O the `object` class, which is the beginning of any hierarchy for new style classes:

```
   -----------
  |           |
  |    O      |
  |  /   \    |
   - X    Y  /
     |  / | /
     | /  |/
     A    B
     \   /
       ?
```

In this case, it is not possible to derive a new class C from A and B, since X precedes Y in A, but Y precedes X in B, therefore the method resolution order would be ambiguous in C.

Python 2.3 raises an exception in this situation (TypeError: MRO conflict among bases Y, X) forbidding the naive programmer from creating ambiguous hierarchies. Python 2.2 instead does not raise an exception, but chooses an *ad hoc* ordering (CABXYO in this case).

The C3 Method Resolution Order

Let me introduce a few simple notations which will be useful for the following discussion. I will use the shortcut notation:

```
C1 C2 ... CN
```

to indicate the list of classes [C1, C2, … , CN].

The *head* of the list is its first element:

```
head = C1
```

whereas the *tail* is the rest of the list:

```
tail = C2 ... CN.
```

I shall also use the notation:

```
C + (C1 C2 ... CN) = C C1 C2 ... CN
```

to denote the sum of the lists [C] + [C1, C2, … ,CN].

Now I can explain how the MRO works in Python 2.3.

Consider a class C in a multiple inheritance hierarchy, with C inheriting from the base classes B1, B2, … , BN. We want to compute the linearization L[C] of the class C. The rule is the following:

> *the linearization of C is the sum of C plus the merge of the linearizations of the parents and the list of the parents.*

In symbolic notation:

```
L[C(B1 ... BN)] = C + merge(L[B1] ... L[BN], B1 ... BN)
```

In particular, if C is the `object` class, which has no parents, the linearization is trivial:

```
L[object] = object.
```

However, in general one has to compute the merge according to the following prescription:

> *take the head of the first list, i.e L[B1][0]; if this head is not in the tail of any of the other lists, then add it to the linearization of C and remove it from the lists in the merge, otherwise look at the head of the next list and take it, if it is a good head. Then repeat the operation until all the class are removed or it is impossible to find good heads. In this case, it is impossible to construct the merge, Python 2.3 will refuse to create the class C and will raise an exception.*

This prescription ensures that the merge operation *preserves* the ordering, if the ordering can be preserved. On the other hand, if the order cannot be preserved (as in the example of serious order disagreement discussed above) then the merge cannot be computed.

The computation of the merge is trivial if C has only one parent (single inheritance); in this case:

```
L[C(B)] = C + merge(L[B],B) = C + L[B]
```

However, in the case of multiple inheritance things are more cumbersome and I don’t expect you can understand the rule without a couple of examples ;-)

Examples

First example. Consider the following hierarchy:

```
>>> O = object
>>> class F(O): pass
>>> class E(O): pass
>>> class D(O): pass
>>> class C(D,F): pass
>>> class B(D,E): pass
>>> class A(B,C): pass
```

In this case the inheritance graph can be drawn as:

```
                            6
                           ---
  Level 3                 | O |                  (more
  general)
                        /  ---  \
                       /    |    \                      |
                      /     |     \                     |
                     /      |      \                    |
                    ---    ---    ---                   |
  Level 2        3 | D | 4| E |  | F | 5                |
                    ---    ---    ---                   |
                     \  \ _ /       |                   |
                      \    / \ _    |                   |
                       \  /      \  |                   |
                        ---      ---                    |
  Level 1            1 | B |    | C | 2                 |
                        ---      ---                    |
                          \      /                      |
                           \    /                      \ /
                             ---
  Level 0                 0 | A |                (more
  specialized)
                             ---
```

The linearizations of O,D,E and F are trivial:

```
L[O] = O
L[D] = D O
L[E] = E O
L[F] = F O
```

The linearization of B can be computed as:

```
L[B] = B + merge(DO, EO, DE)
```

We see that D is a good head, therefore we take it and we are reduced to compute `merge(O,EO,E)`. Now O is not a good head, since it is in the tail of the sequence EO. In this case the rule says that we have to skip to the next sequence. Then we see that E is a good head; we take it and we are reduced to compute `merge(O,O)` which gives O. Therefore:

```
L[B] =  B D E O
```

Using the same procedure one finds:

```
L[C] = C + merge(DO,FO,DF)
     = C + D + merge(O,FO,F)
     = C + D + F + merge(O,O)
     = C D F O
```

Now we can compute:

```
L[A] = A + merge(BDEO,CDFO,BC)
     = A + B + merge(DEO,CDFO,C)
     = A + B + C + merge(DEO,DFO)
     = A + B + C + D + merge(EO,FO)
     = A + B + C + D + E + merge(O,FO)
     = A + B + C + D + E + F + merge(O,O)
     = A B C D E F O
```

In this example, the linearization is ordered in a pretty nice way according to the inheritance level, in the sense that lower levels (i.e. more specialized classes) have higher precedence (see the inheritance graph). However, this is not the general case.

I leave as an exercise for the reader to compute the linearization for my second example:

```
>>> O = object
>>> class F(O): pass
>>> class E(O): pass
>>> class D(O): pass
>>> class C(D,F): pass
>>> class B(E,D): pass
>>> class A(B,C): pass
```

The only difference with the previous example is the change B(D,E) –> B(E,D); however even such a little modification completely changes the ordering of the hierarchy:

```
                             6
                            ---
  Level 3                  | O |
                         /  ---  \
                        /    |    \
                       /     |     \
                      /      |      \
                    ---     ---    ---
  Level 2        2 | E | 4 | D |  | F | 5
                    ---     ---    ---
                     \      / \     /
                      \    /   \   /
                       \  /     \ /
                        ---     ---
  Level 1            1 | B |   | C | 3
                        ---     ---
                         \       /
                          \     /
                            ---
  Level 0                0 | A |
                            ---
```

Notice that the class E, which is in the second level of the hierarchy, precedes the class C, which is in the first level of the hierarchy, i.e. E is more specialized than C, even if it is in a higher level.

A lazy programmer can obtain the MRO directly from Python 2.2, since in this case it coincides with the Python 2.3 linearization. It is enough to invoke the `mro()` method of class A:

```
>>> A.mro()
[<class 'A'>, <class 'B'>, <class 'E'>,
<class 'C'>, <class 'D'>, <class 'F'>,
<class 'object'>]
```

Finally, let me consider the example discussed in the first section, involving a serious order disagreement. In this case, it is straightforward to compute the linearizations of O, X, Y, A and B:

```
  L[O] = 0
  L[X] = X O
  L[Y] = Y O
  L[A] = A X Y O
  L[B] = B Y X O
```

However, it is impossible to compute the linearization for a class C that inherits from A and B:

```
L[C] = C + merge(AXYO, BYXO, AB)
     = C + A + merge(XYO, BYXO, B)
     = C + A + B + merge(XYO, YXO)
```

At this point we cannot merge the lists XYO and YXO, since X is in the tail of YXO whereas Y is in the tail of XYO: therefore there are no good heads and the C3 algorithm stops. Python 2.3 raises an error and refuses to create the class C.

Bad Method Resolution Orders

A MRO is *bad* when it breaks such fundamental properties as local precedence ordering and monotonicity. In this section, I will show that both the MRO for classic classes and the MRO for new style classes in Python 2.2 are bad.

It is easier to start with the local precedence ordering. Consider the following example:

```
>>> F=type('Food',(),{'remember2buy':'spam'})
>>> E=type('Eggs',(F,),{'remember2buy':'eggs'})
>>> G=type('GoodFood',(F,E),{}) # under Python 2.3 this is an
error!
```

with inheritance diagram

```
               O
               |
  (buy spam)   F
               | \
               | E   (buy eggs)
               | /
               G

        (buy eggs or spam ?)
```

We see that class G inherits from F and E, with F *before* E: therefore we would expect the attribute *G.remember2buy* to be inherited by *F.remember2buy* and not by *E.remember2buy*: nevertheless Python 2.2 gives

```
>>> G.remember2buy
'eggs'
```

This is a breaking of local precedence ordering since the order in the local precedence list, i.e. the list of the parents of G, is not preserved in the Python 2.2 linearization of G:

```
L[G,P22]= G E F object   # F *follows* E
```

One could argue that the reason why F follows E in the Python 2.2 linearization is that F is less specialized than E, since F is the superclass of E; nevertheless the breaking of local precedence ordering is quite non-intuitive and error prone. This is particularly true since it is a different from old style classes:

```
>>> class F: remember2buy='spam'
>>> class E(F): remember2buy='eggs'
>>> class G(F,E): pass
>>> G.remember2buy
'spam'
```

In this case the MRO is GFEF and the local precedence ordering is preserved.

As a general rule, hierarchies such as the previous one should be avoided, since it is unclear if F should override E or vice-versa. Python 2.3 solves the ambiguity by raising an exception in the creation of class G, effectively stopping the programmer from generating ambiguous hierarchies. The reason for that is that the C3 algorithm fails when the merge:

```
merge(FO,EFO,FE)
```

cannot be computed, because F is in the tail of EFO and E is in the tail of FE.

The real solution is to design a non-ambiguous hierarchy, i.e. to derive G from E and F (the more specific first) and not from F and E; in this case the MRO is GEF without any doubt.

```
             O
             |
             F (spam)
           / |
  (eggs)   E |
           \ |
             G
               (eggs, no doubt)
```

Python 2.3 forces the programmer to write good hierarchies (or, at least, less error-prone ones).

On a related note, let me point out that the Python 2.3 algorithm is smart enough to recognize obvious mistakes, as the duplication of classes in the list of parents:

```
>>> class A(object): pass
>>> class C(A,A): pass # error
Traceback (most recent call last):
  File "<stdin>", line 1, in ?
TypeError: duplicate base class A
```

Python 2.2 (both for classic classes and new style classes) in this situation, would not raise any exception.

Finally, I would like to point out two lessons we have learned from this example:

1. despite the name, the MRO determines the resolution order of attributes, not only of methods;
2. the default food for Pythonistas is spam ! (but you already knew that ;-)

Having discussed the issue of local precedence ordering, let me now consider the issue of monotonicity. My goal is to show that neither the MRO for classic classes nor that for Python 2.2 new style classes is monotonic.

To prove that the MRO for classic classes is non-monotonic is rather trivial, it is enough to look at the diamond diagram:

```
     C
    / \
   /   \
  A     B
   \   /
    \ /
     D
```

One easily discerns the inconsistency:

```
L[B,P21] = B C        # B precedes C : B's methods win
L[D,P21] = D A C B C  # B follows C  : C's methods win!
```

On the other hand, there are no problems with the Python 2.2 and 2.3 MROs, they give both:

```
L[D] = D A B C
```

Guido points out in his essay [[3]] that the classic MRO is not so bad in practice, since one can typically avoids diamonds for classic classes. But all new style classes inherit from `object`, therefore diamonds are unavoidable and inconsistencies shows up in every multiple inheritance graph.

The MRO of Python 2.2 makes breaking monotonicity difficult, but not impossible. The following example, originally provided by Samuele Pedroni, shows that the MRO of Python 2.2 is non-monotonic:

```
>>> class A(object): pass
>>> class B(object): pass
>>> class C(object): pass
>>> class D(object): pass
>>> class E(object): pass
>>> class K1(A,B,C): pass
>>> class K2(D,B,E): pass
>>> class K3(D,A):   pass
>>> class Z(K1,K2,K3): pass
```

Here are the linearizations according to the C3 MRO (the reader should verify these linearizations as an exercise and draw the inheritance diagram ;-)

```
L[A] = A O
L[B] = B O
L[C] = C O
L[D] = D O
L[E] = E O
L[K1]= K1 A B C O
L[K2]= K2 D B E O
L[K3]= K3 D A O
L[Z] = Z K1 K2 K3 D A B C E O
```

Python 2.2 gives exactly the same linearizations for A, B, C, D, E, K1, K2 and K3, but a different linearization for Z:

```
L[Z,P22] = Z K1 K3 A K2 D B C E O
```

It is clear that this linearization is *wrong*, since A comes before D whereas in the linearization of K3 A comes *after* D. In other words, in K3 methods derived by D override methods derived by A, but in Z, which still is a subclass of K3, methods derived by A override methods derived by D! This is a violation of monotonicity. Moreover, the Python 2.2 linearization of Z is also inconsistent with local precedence ordering, since the local precedence list of the class Z is [K1, K2, K3] (K2 precedes K3), whereas in the linearization of Z K2 *follows* K3. These problems explain why the 2.2 rule has been dismissed in favor of the C3 rule.

The end

This section is for the impatient reader, who skipped all the previous sections and jumped immediately to the end. This section is for the lazy programmer too, who didn’t want to exercise her/his brain. Finally, it is for the programmer with some hubris, otherwise s/he would not be reading a paper on the C3 method resolution order in multiple inheritance hierarchies ;-) These three virtues taken all together (and *not* separately) deserve a prize: the prize is a short Python 2.2 script that allows you to compute the 2.3 MRO without risk to your brain. Simply change the last line to play with the various examples I have discussed in this paper.:

```

Python support for free threading

Starting with the 3.13 release, CPython has support for a build of Python called free threading where the global interpreter lock (GIL) is disabled. Free-threaded execution allows for full utilization of the available processing power by running threads in parallel on available CPU cores. While not all software will benefit from this automatically, programs designed with threading in mind will run faster on multi-core hardware.

Some third-party packages, in particular ones with an extension module, may not be ready for use in a free-threaded build, and will re-enable the GIL.

This document describes the implications of free threading for Python code. See C API Extension Support for Free Threading for information on how to write C extensions that support the free-threaded build.

See also

PEP 703 [https://peps.python.org/pep-0703/] – Making the Global Interpreter Lock Optional in CPython for an overall description of free-threaded Python.

Installation

Starting with Python 3.13, the official macOS and Windows installers optionally support installing free-threaded Python binaries. The installers are available at https://www.python.org/downloads/.

For information on other platforms, see the Installing a Free-Threaded Python [https://py-free-threading.github.io/installing-cpython/], a community-maintained installation guide for installing free-threaded Python.

When building CPython from source, the `--disable-gil` configure option should be used to build a free-threaded Python interpreter.

Identifying free-threaded Python

To check if the current interpreter supports free-threading, `python -VV` and `sys.version` contain “free-threading build”. The new `sys._is_gil_enabled()` function can be used to check whether the GIL is actually disabled in the running process.

The `sysconfig.get_config_var("Py_GIL_DISABLED")` configuration variable can be used to determine whether the build supports free threading. If the variable is set to `1`, then the build supports free threading. This is the recommended mechanism for decisions related to the build configuration.

The global interpreter lock in free-threaded Python

Free-threaded builds of CPython support optionally running with the GIL enabled at runtime using the environment variable `PYTHON_GIL` or the command-line option `-X gil`.

The GIL may also automatically be enabled when importing a C-API extension module that is not explicitly marked as supporting free threading. A warning will be printed in this case.

In addition to individual package documentation, the following websites track the status of popular packages support for free threading:

- https://py-free-threading.github.io/tracking/
- https://hugovk.github.io/free-threaded-wheels/

Thread safety

The free-threaded build of CPython aims to provide similar thread-safety behavior at the Python level to the default GIL-enabled build. Built-in types like `dict`, `list`, and `set` use internal locks to protect against concurrent modifications in ways that behave similarly to the GIL. However, Python has not historically guaranteed specific behavior for concurrent modifications to these built-in types, so this should be treated as a description of the current implementation, not a guarantee of current or future behavior.

Note

It’s recommended to use the `threading.Lock` or other synchronization primitives instead of relying on the internal locks of built-in types, when possible.

Known limitations

This section describes known limitations of the free-threaded CPython build.

Immortalization

In the free-threaded build, some objects are immortal. Immortal objects are not deallocated and have reference counts that are never modified. This is done to avoid reference count contention that would prevent efficient multi-threaded scaling.

As of the 3.14 release, immortalization is limited to:

- Code constants: numeric literals, string literals, and tuple literals composed of other constants.
- Strings interned by `sys.intern()`.

Frame objects

It is not safe to access `frame.f_locals` from a frame object if that frame is currently executing in another thread, and doing so may crash the interpreter.

Iterators

It is generally not thread-safe to access the same iterator object from multiple threads concurrently, and threads may see duplicate or missing elements.

Single-threaded performance

The free-threaded build has additional overhead when executing Python code compared to the default GIL-enabled build. The amount of overhead depends on the workload and hardware. On the pyperformance benchmark suite, the average overhead ranges from about 1% on macOS aarch64 to 8% on x86-64 Linux systems.

Behavioral changes

This section describes CPython behavioural changes with the free-threaded build.

Context variables

In the free-threaded build, the flag `thread_inherit_context` is set to true by default which causes threads created with `threading.Thread` to start with a copy of the `Context()` of the caller of `start()`. In the default GIL-enabled build, the flag defaults to false so threads start with an empty `Context()`.

Warning filters

In the free-threaded build, the flag `context_aware_warnings` is set to true by default. In the default GIL-enabled build, the flag defaults to false. If the flag is true then the `warnings.catch_warnings` context manager uses a context variable for warning filters. If the flag is false then `catch_warnings` modifies the global filters list, which is not thread-safe. See the `warnings` module for more details.

C API Extension Support for Free Threading

Starting with the 3.13 release, CPython has support for running with the global interpreter lock (GIL) disabled in a configuration called free threading. This document describes how to adapt C API extensions to support free threading.

Identifying the Free-Threaded Build in C

The CPython C API exposes the `Py_GIL_DISABLED` macro: in the free-threaded build it's defined to `1`, and in the regular build it's not defined. You can use it to enable code that only runs under the free-threaded build:

```
#ifdef Py_GIL_DISABLED
/* code that only runs in the free-threaded build */
#endif
```

Note

On Windows, this macro is not defined automatically, but must be specified to the compiler when building. The `sysconfig.get_config_var()` function can be used to determine whether the current running interpreter had the macro defined.

Module Initialization

Extension modules need to explicitly indicate that they support running with the GIL disabled; otherwise importing the extension will raise a warning and enable the GIL at runtime.

There are two ways to indicate that an extension module supports running with the GIL disabled depending on whether the extension uses multi-phase or single-phase initialization.

Multi-Phase Initialization

Extensions that use multi-phase initialization (i.e., `PyModuleDef_Init()`) should add a `Py_mod_gil` slot in the module definition. If your extension supports older versions of CPython, you should guard the slot with a `PY_VERSION_HEX` check.

```
static struct PyModuleDef_Slot module_slots[] = {
    ...
#if PY_VERSION_HEX >= 0x030D0000
    {Py_mod_gil, Py_MOD_GIL_NOT_USED},
#endif
    {0, NULL}
};

static struct PyModuleDef moduledef = {
    PyModuleDef_HEAD_INIT,
    .m_slots = module_slots,
    ...
};
```

Single-Phase Initialization

Extensions that use single-phase initialization (i.e., `PyModule_Create()`) should call `PyUnstable_Module_SetGIL()` to indicate that they support running with the GIL disabled. The function is only defined in the free-threaded build, so you should guard the call with `#ifdef Py_GIL_DISABLED` to avoid compilation errors in the regular build.

```
static struct PyModuleDef moduledef = {
    PyModuleDef_HEAD_INIT,
    ...
};

PyMODINIT_FUNC
PyInit_mymodule(void)
{
    PyObject *m = PyModule_Create(&moduledef);
    if (m == NULL) {
        return NULL;
    }
#ifdef Py_GIL_DISABLED
    PyUnstable_Module_SetGIL(m, Py_MOD_GIL_NOT_USED);
#endif
    return m;
}
```

General API Guidelines

Most of the C API is thread-safe, but there are some exceptions.

- **Struct Fields**: Accessing fields in Python C API objects or structs directly is not thread-safe if the field may be concurrently modified.
- **Macros**: Accessor macros like `PyList_GET_ITEM`, `PyList_SET_ITEM`, and macros like `PySequence_Fast_GET_SIZE` that use the object returned by `PySequence_Fast()` do not perform any error checking or locking. These macros are not thread-safe if the container object may be modified concurrently.
- **Borrowed References**: C API functions that return borrowed references may not be thread-safe if the

containing object is modified concurrently. See the section on borrowed references for more information.

Container Thread Safety

Containers like `PyListObject`, `PyDictObject`, and `PySetObject` perform internal locking in the free-threaded build. For example, the `PyList_Append()` will lock the list before appending an item.

PyDict_Next

A notable exception is `PyDict_Next()`, which does not lock the dictionary. You should use `Py_BEGIN_CRITICAL_SECTION` to protect the dictionary while iterating over it if the dictionary may be concurrently modified:

```
Py_BEGIN_CRITICAL_SECTION(dict);
PyObject *key, *value;
Py_ssize_t pos = 0;
while (PyDict_Next(dict, &pos, &key, &value)) {
    ...
}
Py_END_CRITICAL_SECTION();
```

Borrowed References

Some C API functions return borrowed references. These APIs are not thread-safe if the containing object is modified concurrently. For example, it’s not safe to use `PyList_GetItem()` if the list may be modified concurrently.

The following table lists some borrowed reference APIs and their replacements that return strong references.

Borrowed reference API	Strong reference API
`PyList_GetItem()`	`PyList_GetItemRef()`
`PyList_GET_ITEM()`	`PyList_GetItemRef()`
`PyDict_GetItem()`	`PyDict_GetItemRef()`
`PyDict_GetItemWithError()`	`PyDict_GetItemRef()`
`PyDict_GetItemString()`	`PyDict_GetItemStringRef()`
`PyDict_SetDefault()`	`PyDict_SetDefaultRef()`
`PyDict_Next()`	none (see PyDict_Next)
`PyWeakref_GetObject()`	`PyWeakref_GetRef()`
`PyWeakref_GET_OBJECT()`	`PyWeakref_GetRef()`
`PyImport_AddModule()`	`PyImport_AddModuleRef()`
`PyCell_GET()`	`PyCell_Get()`

Not all APIs that return borrowed references are problematic. For example, `PyTuple_GetItem()` is safe because tuples are immutable. Similarly, not all uses of the above APIs are problematic. For example, `PyDict_GetItem()` is often used for parsing keyword argument dictionaries in function calls; those keyword argument dictionaries are effectively private (not accessible by other threads), so using borrowed references in that context is safe.

Some of these functions were added in Python 3.13. You can use the pythoncapi-compat [https://github.com/python/pythoncapi-compat] package to provide implementations of these functions for older Python versions.

Memory Allocation APIs

Python’s memory management C API provides functions in three different allocation domains: “raw”, “mem”, and “object”. For thread-safety, the free-threaded build requires that only Python objects are allocated using the object domain, and that all Python objects are allocated using that domain. This differs from the prior Python versions, where this was only a best practice and not a hard requirement.

Note

Search for uses of `PyObject_Malloc()` in your extension and check that the allocated memory is used for Python objects. Use `PyMem_Malloc()` to allocate buffers instead of `PyObject_Malloc()`.

Thread State and GIL APIs

Python provides a set of functions and macros to manage thread state and the GIL, such as:

- `PyGILState_Ensure()` and `PyGILState_Release()`
- `PyEval_SaveThread()` and `PyEval_RestoreThread()`
- `Py_BEGIN_ALLOW_THREADS` and `Py_END_ALLOW_THREADS`

These functions should still be used in the free-threaded build to manage thread state even when the GIL is disabled. For example, if you create a thread outside of Python, you must call `PyGILState_Ensure()` before calling into the Python API to ensure that the thread has a valid Python thread state.

You should continue to call `PyEval_SaveThread()` or `Py_BEGIN_ALLOW_THREADS` around blocking operations, such as I/O or lock acquisitions, to allow other threads to run the cyclic garbage collector.

Protecting Internal Extension State

Your extension may have internal state that was previously protected by the GIL. You may need to add locking to protect this state. The approach will depend on your extension, but some common patterns include:

- **Caches**: global caches are a common source of shared state. Consider using a lock to protect the cache or disabling it in the free-threaded build if the cache is not critical for performance.
- **Global State**: global state may need to be protected by a lock or moved to thread local storage. C11 and C++11 provide the `thread_local` or `_Thread_local` for thread-local storage [https://en.cppreference.com/w/c/language/storage_duration].

Critical Sections

In the free-threaded build, CPython provides a mechanism called “critical sections” to protect data that would otherwise be protected by the GIL. While extension authors may not interact with the internal critical section implementation directly, understanding their behavior is crucial when using certain C API functions or managing shared state in the free-threaded build.

What Are Critical Sections?

Conceptually, critical sections act as a deadlock avoidance layer built on top of simple mutexes. Each thread maintains a stack of active critical sections. When a thread needs to acquire a lock associated with a critical section (e.g., implicitly when calling a thread-safe C API function like `PyDict_SetItem()`, or explicitly using macros), it attempts to acquire the underlying mutex.

Using Critical Sections

The primary APIs for using critical sections are:

- `Py_BEGIN_CRITICAL_SECTION` and `Py_END_CRITICAL_SECTION` - For locking a single object
- `Py_BEGIN_CRITICAL_SECTION2` and `Py_END_CRITICAL_SECTION2` - For locking two objects simultaneously

These macros must be used in matching pairs and must appear in the same C scope, since they establish a new local scope. These macros are no-ops in non-free-threaded builds, so they can be safely added to code that needs to support both build types.

A common use of a critical section would be to lock an object while accessing an internal attribute of it. For example, if an extension type has an internal count field, you could use a critical section while reading or writing that field:

```
// read the count, returns new reference to internal count
value
PyObject *result;
Py_BEGIN_CRITICAL_SECTION(obj);
result = Py_NewRef(obj->count);
Py_END_CRITICAL_SECTION();
return result;

// write the count, consumes reference from new_count
Py_BEGIN_CRITICAL_SECTION(obj);
obj->count = new_count;
Py_END_CRITICAL_SECTION();
```

How Critical Sections Work

Unlike traditional locks, critical sections do not guarantee exclusive access throughout their entire duration. If a thread would block while holding a critical section (e.g., by acquiring another lock or performing I/O), the critical section is temporarily suspended—all locks are released—and then resumed when the blocking operation completes.

This behavior is similar to what happens with the GIL when a thread makes a blocking call. The key differences are:

- Critical sections operate on a per-object basis rather than globally
- Critical sections follow a stack discipline within each thread (the “begin” and “end” macros enforce this since they must be paired and within the same scope)
- Critical sections automatically release and reacquire locks around potential blocking operations

Deadlock Avoidance

Critical sections help avoid deadlocks in two ways:

1. If a thread tries to acquire a lock that's already held by another thread, it first suspends all of its active critical sections, temporarily releasing their locks
2. When the blocking operation completes, only the top-most critical section is reacquired first

This means you cannot rely on nested critical sections to lock multiple objects at once, as the inner critical section may suspend the outer ones. Instead, use `Py_BEGIN_CRITICAL_SECTION2` to lock two objects simultaneously.

Note that the locks described above are only `PyMutex` based locks. The critical section implementation does not know about or affect other locking mechanisms that might be in use, like POSIX mutexes. Also note that while blocking on any `PyMutex` causes the critical sections to be suspended, only the mutexes that are part of the critical sections are released. If `PyMutex` is used without a critical section, it will not be released and therefore does not get the same deadlock avoidance.

Important Considerations

- Critical sections may temporarily release their locks, allowing other threads to modify the protected data. Be careful about making assumptions about the state of the data after operations that might block.
- Because locks can be temporarily released (suspended), entering a critical section does not guarantee exclusive access to the protected resource throughout the section's duration. If code within a critical section calls another function that blocks (e.g., acquires another lock,

performs blocking I/O), all locks held by the thread via critical sections will be released. This is similar to how the GIL can be released during blocking calls.
- Only the lock(s) associated with the most recently entered (top-most) critical section are guaranteed to be held at any given time. Locks for outer, nested critical sections might have been suspended.
- You can lock at most two objects simultaneously with these APIs. If you need to lock more objects, you'll need to restructure your code.
- While critical sections will not deadlock if you attempt to lock the same object twice, they are less efficient than purpose-built reentrant locks for this use case.
- When using **`Py_BEGIN_CRITICAL_SECTION2`**, the order of the objects doesn't affect correctness (the implementation handles deadlock avoidance), but it's good practice to always lock objects in a consistent order.
- Remember that the critical section macros are primarily for protecting access to *Python objects* that might be involved in internal CPython operations susceptible to the deadlock scenarios described above. For protecting purely internal extension state, standard mutexes or other synchronization primitives might be more appropriate.

Building Extensions for the Free-Threaded Build

C API extensions need to be built specifically for the free-threaded build. The wheels, shared libraries, and binaries are indicated by a `t` suffix.

- pypa/manylinux [https://github.com/pypa/manylinux] supports the free-threaded build, with the `t` suffix, such as `python3.13t`.

- pypa/cibuildwheel [https://github.com/pypa/cibuildwheel] supports the free-threaded build on Python 3.13 and 3.14. On Python 3.14, free-threaded wheels will be built by default. On Python 3.13, you will need to set CIBW_ENABLE to cpython-freethreading [https://cibuildwheel.pypa.io/en/stable/options/#enable].

Limited C API and Stable ABI

The free-threaded build does not currently support the Limited C API or the stable ABI. If you use setuptools [https://setuptools.pypa.io/en/latest/setuptools.html] to build your extension and currently set `py_limited_api=True` you can use `py_limited_api=not sysconfig.get_config_var("Py_GIL_DISABLED")` to opt out of the limited API when building with the free-threaded build.

Note

You will need to build separate wheels specifically for the free-threaded build. If you currently use the stable ABI, you can continue to build a single wheel for multiple non-free-threaded Python versions.

Windows

Due to a limitation of the official Windows installer, you will need to manually define `Py_GIL_DISABLED=1` when building extensions from source.

Porting Extension Modules to Support Free-Threading [https://py-free-threading.github.io/porting/]: A community-maintained porting guide for extension authors.

Remote debugging attachment protocol

This protocol enables external tools to attach to a running CPython process and execute Python code remotely.

Most platforms require elevated privileges to attach to another Python process.

Permission requirements

Attaching to a running Python process for remote debugging requires elevated privileges on most platforms. The specific requirements and troubleshooting steps depend on your operating system:

Linux

The tracer process must have the `CAP_SYS_PTRACE` capability or equivalent privileges. You can only trace processes you own and can signal. Tracing may fail if the process is already being traced, or if it is running with set-user-ID or set-group-ID. Security modules like Yama may further restrict tracing.

To temporarily relax ptrace restrictions (until reboot), run:

```
echo 0 | sudo tee /proc/sys/kernel/yama/ptrace_scope
```

Note

Disabling `ptrace_scope` reduces system hardening and should only be done in trusted environments.

If running inside a container, use `--cap-add=SYS_PTRACE` or `--privileged`, and run as root if needed.

Try re-running the command with elevated privileges:

```
sudo -E !!
```

macOS

To attach to another process, you typically need to run your debugging tool with elevated privileges. This can be done by using `sudo` or running as root.

Even when attaching to processes you own, macOS may block debugging unless the debugger is run with root privileges due to system security restrictions.

Windows

To attach to another process, you usually need to run your debugging tool with administrative privileges. Start the command prompt or terminal as Administrator.

Some processes may still be inaccessible even with Administrator rights, unless you have the `SeDebugPrivilege` privilege enabled.

To resolve file or folder access issues, adjust the security permissions:

1. Right-click the file or folder and select **Properties**.

2. Go to the **Security** tab to view users and groups with access.
3. Click **Edit** to modify permissions.
4. Select your user account.
5. In **Permissions**, check **Read** or **Full control** as needed.
6. Click **Apply**, then **OK** to confirm.

Note

Ensure you’ve satisfied all Permission requirements before proceeding.

This section describes the low-level protocol that enables external tools to inject and execute a Python script within a running CPython process.

This mechanism forms the basis of the `sys.remote_exec()` function, which instructs a remote Python process to execute a `.py` file. However, this section does not document the usage of that function. Instead, it provides a detailed explanation of the underlying protocol, which takes as input the `pid` of a target Python process and the path to a Python source file to be executed. This information supports independent reimplementation of the protocol, regardless of programming language.

Warning

The execution of the injected script depends on the interpreter reaching a safe evaluation point. As a result, execution may be delayed depending on the runtime state of the target process.

Once injected, the script is executed by the interpreter within the target process the next time a safe evaluation point is reached. This approach enables remote execution capabilities without modifying the behavior or structure of the running Python application.

Subsequent sections provide a step-by-step description of the protocol, including techniques for locating interpreter structures in memory, safely accessing internal fields, and triggering code execution. Platform-specific variations are noted where applicable, and example implementations are included to clarify each operation.

Locating the PyRuntime structure

CPython places the `PyRuntime` structure in a dedicated binary section to help external tools find it at runtime. The name and format of this section vary by platform. For example, `.PyRuntime` is used on ELF systems, and `__DATA,__PyRuntime` is used on macOS. Tools can find the offset of this structure by examining the binary on disk.

The `PyRuntime` structure contains CPython’s global interpreter state and provides access to other internal data, including the list of interpreters, thread states, and debugger support fields.

To work with a remote Python process, a debugger must first find the memory address of the `PyRuntime` structure in the target process. This address can’t be hardcoded or calculated from a symbol name, because it depends on where the operating system loaded the binary.

The method for finding `PyRuntime` depends on the platform, but the steps are the same in general:

1. Find the base address where the Python binary or shared library was loaded in the target process.
2. Use the on-disk binary to locate the offset of the `.PyRuntime` section.
3. Add the section offset to the base address to compute the address in memory.

The sections below explain how to do this on each supported platform and include example code.

Linux (ELF)

To find the `PyRuntime` structure on Linux:

1. Read the process's memory map (for example, `/proc/<pid>/maps`) to find the address where the Python executable or `libpython` was loaded.
2. Parse the ELF section headers in the binary to get the offset of the `.PyRuntime` section.
3. Add that offset to the base address from step 1 to get the memory address of `PyRuntime`.

The following is an example implementation:

```
def find_py_runtime_linux(pid: int) -> int:
    # Step 1: Try to find the Python executable in memory
    binary_path, base_address = find_mapped_binary(
        pid, name_contains="python"
    )

    # Step 2: Fallback to shared library if executable is not
found
    if binary_path is None:
        binary_path, base_address = find_mapped_binary(
            pid, name_contains="libpython"
        )

    # Step 3: Parse ELF headers to get .PyRuntime section
offset
    section_offset = parse_elf_section_offset(
        binary_path, ".PyRuntime"
    )

    # Step 4: Compute PyRuntime address in memory
    return base_address + section_offset
```

On Linux systems, there are two main approaches to read memory from another process. The first is through the `/proc` filesystem, specifically by reading from `/proc/[pid]/mem` which provides direct access to the process's memory. This requires appropriate permissions - either being the same user as the target process or having root access. The second approach is using the `process_vm_readv()` system call which provides a more efficient way to copy memory between processes. While ptrace's `PTRACE_PEEKTEXT` operation can also be used to read memory, it is significantly slower as it only reads one word at a time and requires multiple context switches between the tracer and tracee processes.

For parsing ELF sections, the process involves reading and interpreting the ELF file format structures from the binary file on disk. The ELF header contains a pointer to the section header table. Each section header contains metadata about a section including its name (stored in a separate string table), offset, and size. To find a specific section like .PyRuntime, you need to walk through these headers and match the section name. The section header then provides the offset where that section exists in the file, which can be used to calculate its runtime address when the binary is loaded into memory.

You can read more about the ELF file format in the ELF specification [https://en.wikipedia.org/wiki/Executable_and_Linkable_Format].

macOS (Mach-O)

To find the `PyRuntime` structure on macOS:

1. Call `task_for_pid()` to get the `mach_port_t` task port for the target process. This handle is needed to read memory using APIs like `mach_vm_read_overwrite` and `mach_vm_region`.
2. Scan the memory regions to find the one containing the Python executable or `libpython`.
3. Load the binary file from disk and parse the Mach-O headers to find the section named `PyRuntime` in the `__DATA` segment. On macOS, symbol names are automatically prefixed with an underscore, so the `PyRuntime` symbol appears as `_PyRuntime` in the symbol table, but the section name is not affected.

The following is an example implementation:

```
def find_py_runtime_macos(pid: int) -> int:
    # Step 1: Get access to the process's memory
    handle = get_memory_access_handle(pid)

    # Step 2: Try to find the Python executable in memory
    binary_path, base_address = find_mapped_binary(
        handle, name_contains="python"
    )

    # Step 3: Fallback to libpython if the executable is not
found
    if binary_path is None:
        binary_path, base_address = find_mapped_binary(
            handle, name_contains="libpython"
        )

    # Step 4: Parse Mach-O headers to get __DATA,__PyRuntime
section offset
    section_offset = parse_macho_section_offset(
        binary_path, "__DATA", "__PyRuntime"
    )

    # Step 5: Compute the PyRuntime address in memory
    return base_address + section_offset
```

On macOS, accessing another process’s memory requires using Mach-O specific APIs and file formats. The first step is obtaining a `task_port` handle via `task_for_pid()`, which provides access to the target process’s memory space. This handle enables memory operations through APIs like `mach_vm_read_overwrite()`.

The process memory can be examined using `mach_vm_region()` to scan through the virtual memory space, while `proc_regionfilename()` helps identify which binary files are loaded at each memory region. When the Python binary or library is found, its Mach-O headers need to be parsed to locate the `PyRuntime` structure.

The Mach-O format organizes code and data into segments and sections. The `PyRuntime` structure lives in a section named `__PyRuntime` within the `__DATA` segment. The actual runtime address calculation involves finding the `__TEXT` segment which serves as the binary’s base address, then locating the `__DATA` segment containing our target section. The final address is computed by combining the base address with the appropriate section offsets from the Mach-O headers.

Note that accessing another process’s memory on macOS typically requires elevated privileges - either root access or special security entitlements granted to the debugging process.

Windows (PE)

To find the `PyRuntime` structure on Windows:

1. Use the ToolHelp API to enumerate all modules loaded in the target process. This is done using functions such as CreateToolhelp32Snapshot [https://learn.microsoft.com/en-us/windows/win32/api/tlhelp32/nf-tlhelp32-createtoolhelp32snapshot], Module32First [https://learn.microsoft.com/en-us/windows/win32/api/tlhelp32/nf-tlhelp32-module32first], and Module32Next [https://learn.microsoft.com/en-us/windows/win32/api/tlhelp32/nf-tlhelp32-module32next].
2. Identify the module corresponding to `python.exe` or `python`*`XY`*`.dll`, where `X` and `Y` are the major and minor version numbers of the Python version, and record its base address.
3. Locate the `PyRuntim` section. Due to the PE format's 8-character limit on section names (defined as `IMAGE_SIZEOF_SHORT_NAME`), the original name `PyRuntime` is truncated. This section contains the `PyRuntime` structure.
4. Retrieve the section's relative virtual address (RVA) and add it to the base address of the module.

The following is an example implementation:

```
def find_py_runtime_windows(pid: int) -> int:
    # Step 1: Try to find the Python executable in memory
    binary_path, base_address = find_loaded_module(
        pid, name_contains="python"
    )

    # Step 2: Fallback to shared pythonXY.dll if the executable
is not
    # found
    if binary_path is None:
        binary_path, base_address = find_loaded_module(
            pid, name_contains="python3"
        )

    # Step 3: Parse PE section headers to get the RVA of the
PyRuntime
```

```
    # section. The section name appears as "PyRuntim" due to
the
    # 8-character limit defined by the PE format
(IMAGE_SIZEOF_SHORT_NAME).
    section_rva = parse_pe_section_offset(binary_path,
"PyRuntim")

    # Step 4: Compute PyRuntime address in memory
    return base_address + section_rva
```

On Windows, accessing another process’s memory requires using the Windows API functions like `CreateToolhelp32Snapshot()` and `Module32First()/Module32Next()` to enumerate loaded modules. The `OpenProcess()` function provides a handle to access the target process’s memory space, enabling memory operations through `ReadProcessMemory()`.

The process memory can be examined by enumerating loaded modules to find the Python binary or DLL. When found, its PE headers need to be parsed to locate the `PyRuntime` structure.

The PE format organizes code and data into sections. The `PyRuntime` structure lives in a section named “PyRuntim” (truncated from “PyRuntime” due to PE’s 8-character name limit). The actual runtime address calculation involves finding the module’s base address from the module entry, then locating our target section in the PE headers. The final address is computed by combining the base address with the section’s virtual address from the PE section headers.

Note that accessing another process’s memory on Windows typically requires appropriate privileges - either administrative access or the `SeDebugPrivilege` privilege granted to the debugging process.

Reading _Py_DebugOffsets

Once the address of the `PyRuntime` structure has been determined, the next step is to read the `_Py_DebugOffsets` structure located at the beginning of the `PyRuntime` block.

This structure provides version-specific field offsets that are needed to safely read interpreter and thread state memory. These offsets vary between CPython versions and must be checked before use to ensure they are compatible.

To read and check the debug offsets, follow these steps:

1. Read memory from the target process starting at the `PyRuntime` address, covering the same number of bytes as the `_Py_DebugOffsets` structure. This structure is located at the very start of the `PyRuntime` memory block. Its layout is defined in CPython’s internal headers and stays the same within a given minor version, but may change in major versions.
2. Check that the structure contains valid data:
    - The `cookie` field must match the expected debug marker.
    - The `version` field must match the version of the Python interpreter used by the debugger.
    - If either the debugger or the target process is using a pre-release version (for example, an alpha, beta, or release candidate), the versions must match exactly.
    - The `free_threaded` field must have the same value in both the debugger and the target process.
3. If the structure is valid, the offsets it contains can be used to locate fields in memory. If any check fails, the debugger should stop the operation to avoid reading memory in the wrong format.

The following is an example implementation that reads and checks `_Py_DebugOffsets`:

```
def read_debug_offsets(pid: int, py_runtime_addr: int) -> DebugOffsets:
    # Step 1: Read memory from the target process at the PyRuntime address
    data = read_process_memory(
        pid, address=py_runtime_addr, size=DEBUG_OFFSETS_SIZE
    )

    # Step 2: Deserialize the raw bytes into a _Py_DebugOffsets structure
    debug_offsets = parse_debug_offsets(data)

    # Step 3: Validate the contents of the structure
    if debug_offsets.cookie != EXPECTED_COOKIE:
        raise RuntimeError("Invalid or missing debug cookie")
    if debug_offsets.version != LOCAL_PYTHON_VERSION:
        raise RuntimeError(
            "Mismatch between caller and target Python versions"
        )
    if debug_offsets.free_threaded != LOCAL_FREE_THREADED:
        raise RuntimeError("Mismatch in free-threaded configuration")

    return debug_offsets
```

Warning

Process suspension recommended

To avoid race conditions and ensure memory consistency, it is strongly recommended that the target process be suspended before performing any operations that read or write internal interpreter state. The Python runtime may concurrently mutate interpreter data structures—such as creating or destroying threads—during normal execution. This can result in invalid memory reads or writes.

A debugger may suspend execution by attaching to the process with `ptrace` or by sending a `SIGSTOP` signal. Execution should only be resumed after debugger-side memory operations are complete.

Note

Some tools, such as profilers or sampling-based debuggers, may operate on a running process without suspension. In such cases, tools must be explicitly designed to handle partially updated or inconsistent memory. For most debugger implementations, suspending the process remains the safest and most robust approach.

Locating the interpreter and thread state

Before code can be injected and executed in a remote Python process, the debugger must choose a thread in which to schedule execution. This is necessary because the control fields used to perform remote code injection are located in the `_PyRemoteDebuggerSupport` structure, which is embedded in a `PyThreadState` object. These fields are modified by the debugger to request execution of injected scripts.

The `PyThreadState` structure represents a thread running inside a Python interpreter. It maintains the thread's evaluation context and contains the fields required for debugger coordination. Locating a valid `PyThreadState` is therefore a key prerequisite for triggering execution remotely.

A thread is typically selected based on its role or ID. In most cases, the main thread is used, but some tools may target a specific thread by its native thread ID. Once the target thread is chosen, the debugger must locate both the interpreter and the associated thread state structures in memory.

The relevant internal structures are defined as follows:

- `PyInterpreterState` represents an isolated Python interpreter instance. Each interpreter maintains its own set of imported modules, built-in state, and thread state list. Although most Python applications use a single interpreter, CPython supports multiple interpreters in the same process.
- `PyThreadState` represents a thread running within an interpreter. It contains execution state and the control fields used by the debugger.

To locate a thread:

1. Use the offset `runtime_state.interpreters_head` to obtain the address of the first interpreter in the `PyRuntime` structure. This is the entry point to the linked list of active interpreters.
2. Use the offset `interpreter_state.threads_main` to access the main thread state associated with the selected interpreter. This is typically the most reliable thread to target.
3. Optionally, use the offset `interpreter_state.threads_head` to iterate through the linked list of all thread states. Each `PyThreadState` structure contains a `native_thread_id`

field, which may be compared to a target thread ID to find a specific thread.
4. Once a valid `PyThreadState` has been found, its address can be used in later steps of the protocol, such as writing debugger control fields and scheduling execution.

The following is an example implementation that locates the main thread state:

```
def find_main_thread_state(
    pid: int, py_runtime_addr: int, debug_offsets:
DebugOffsets,
) -> int:
    # Step 1: Read interpreters_head from PyRuntime
    interp_head_ptr = (
        py_runtime_addr +
debug_offsets.runtime_state.interpreters_head
    )
    interp_addr = read_pointer(pid, interp_head_ptr)
    if interp_addr == 0:
        raise RuntimeError("No interpreter found in the target
process")

    # Step 2: Read the threads_main pointer from the
interpreter
    threads_main_ptr = (
        interp_addr +
debug_offsets.interpreter_state.threads_main
    )
    thread_state_addr = read_pointer(pid, threads_main_ptr)
    if thread_state_addr == 0:
        raise RuntimeError("Main thread state is not
available")

    return thread_state_addr
```

The following example demonstrates how to locate a thread by its native thread ID:

```
def find_thread_by_id(
    pid: int,
    interp_addr: int,
    debug_offsets: DebugOffsets,
    target_tid: int,
) -> int:
    # Start at threads_head and walk the linked list
    thread_ptr = read_pointer(
        pid,
        interp_addr +
debug_offsets.interpreter_state.threads_head
    )

    while thread_ptr:
        native_tid_ptr = (
            thread_ptr +
debug_offsets.thread_state.native_thread_id
        )
        native_tid = read_int(pid, native_tid_ptr)
        if native_tid == target_tid:
            return thread_ptr
        thread_ptr = read_pointer(
            pid,
            thread_ptr + debug_offsets.thread_state.next
        )

    raise RuntimeError("Thread with the given ID was not
found")
```

Once a valid thread state has been located, the debugger can proceed with modifying its control fields and scheduling execution, as described in the next section.

Writing control information

Once a valid `PyThreadState` structure has been identified, the debugger may modify control fields within it to schedule the execution of a specified Python script. These control fields are checked periodically by the interpreter, and when set correctly, they trigger the execution of remote code at a safe point in the evaluation loop.

Each `PyThreadState` contains a `_PyRemoteDebuggerSupport` structure used for communication between the debugger and the interpreter. The locations of its fields are defined by the `_Py_DebugOffsets` structure and include the following:

- `debugger_script_path`: A fixed-size buffer that holds the full path to a Python source file (`.py`). This file must be accessible and readable by the target process when execution is triggered.
- `debugger_pending_call`: An integer flag. Setting this to `1` tells the interpreter that a script is ready to be executed.
- `eval_breaker`: A field checked by the interpreter during execution. Setting bit 5 (`_PY_EVAL_PLEASE_STOP_BIT`, value `1U << 5`) in this field causes the interpreter to pause and check for debugger activity.

To complete the injection, the debugger must perform the following steps:

1. Write the full script path into the `debugger_script_path` buffer.
2. Set `debugger_pending_call` to `1`.
3. Read the current value of `eval_breaker`, set bit 5 (`_PY_EVAL_PLEASE_STOP_BIT`), and write the updated value back. This signals the interpreter to check for debugger activity.

The following is an example implementation:

```
def inject_script(
    pid: int,
    thread_state_addr: int,
    debug_offsets: DebugOffsets,
    script_path: str
) -> None:
    # Compute the base offset of _PyRemoteDebuggerSupport
    support_base = (
        thread_state_addr +
        debug_offsets.debugger_support.remote_debugger_support
    )

    # Step 1: Write the script path into debugger_script_path
    script_path_ptr = (
        support_base +
        debug_offsets.debugger_support.debugger_script_path
    )
    write_string(pid, script_path_ptr, script_path)

    # Step 2: Set debugger_pending_call to 1
    pending_ptr = (
        support_base +
        debug_offsets.debugger_support.debugger_pending_call
    )
    write_int(pid, pending_ptr, 1)

    # Step 3: Set _PY_EVAL_PLEASE_STOP_BIT (bit 5, value 1 <<
5) in
    # eval_breaker
    eval_breaker_ptr = (
        thread_state_addr +
        debug_offsets.debugger_support.eval_breaker
    )
    breaker = read_int(pid, eval_breaker_ptr)
    breaker |= (1 << 5)
    write_int(pid, eval_breaker_ptr, breaker)
```

Once these fields are set, the debugger may resume the process (if it was suspended). The interpreter will process the request at the next safe evaluation point, load the script from disk, and execute it.

It is the responsibility of the debugger to ensure that the script file remains present and accessible to the target process during execution.

Note

Script execution is asynchronous. The script file cannot be deleted immediately after injection. The debugger should wait until the injected script has produced an observable effect before removing the file. This effect depends on what the script is designed to do. For example, a debugger might wait until the remote process connects back to a socket before removing the script. Once such an effect is observed, it is safe to assume the file is no longer needed.

Summary

To inject and execute a Python script in a remote process:

1. Locate the `PyRuntime` structure in the target process's memory.
2. Read and validate the `_Py_DebugOffsets` structure at the beginning of `PyRuntime`.
3. Use the offsets to locate a valid `PyThreadState`.
4. Write the path to a Python script into `debugger_script_path`.
5. Set the `debugger_pending_call` flag to `1`.
6. Set `_PY_EVAL_PLEASE_STOP_BIT` in the `eval_breaker` field.
7. Resume the process (if suspended). The script will execute at the next safe evaluation point.

General Information

What is Python?

Python is an interpreted, interactive, object-oriented programming language. It incorporates modules, exceptions, dynamic typing, very high level dynamic data types, and classes. It supports multiple programming paradigms beyond object-oriented programming, such as procedural and functional programming. Python combines remarkable power with very clear syntax. It has interfaces to many system calls and libraries, as well as to various window systems, and is extensible in C or C++. It is also usable as an extension language for applications that need a programmable interface. Finally, Python is portable: it runs on many Unix variants including Linux and macOS, and on Windows.

To find out more, start with The Python Tutorial. The Beginner’s Guide to Python [https://wiki.python.org/moin/BeginnersGuide] links to other introductory tutorials and resources for learning Python.

What is the Python Software Foundation?

The Python Software Foundation is an independent non-profit organization that holds the copyright on Python versions 2.1 and newer. The PSF's mission is to advance open source technology related to the Python programming language and to publicize the use of Python. The PSF's home page is at https://www.python.org/psf/.

Donations to the PSF are tax-exempt in the US. If you use Python and find it helpful, please contribute via the PSF donation page [https://www.python.org/psf/donations/].

Are there copyright restrictions on the use of Python?

You can do anything you want with the source, as long as you leave the copyrights in and display those copyrights in any documentation about Python that you produce. If you honor the copyright rules, it's OK to use Python for commercial use, to sell copies of Python in source or binary form (modified or unmodified), or to sell products that incorporate Python in some form. We would still like to know about all commercial use of Python, of course.

See the license page [https://docs.python.org/3/license.html] to find further explanations and the full text of the PSF License.

The Python logo is trademarked, and in certain cases permission is required to use it. Consult the Trademark Usage Policy [https://www.python.org/psf/trademarks/] for more information.

Why was Python created in the first place?

Here's a *very* brief summary of what started it all, written by Guido van Rossum:

I had extensive experience with implementing an interpreted language in the ABC group at CWI, and from working with this group I had learned a lot about language design. This is the origin of many Python features, including the use of indentation for statement grouping and the inclusion of very-high-level data types (although the details are all different in Python).

I had a number of gripes about the ABC language, but also liked many of its features. It was impossible to extend the ABC language (or its implementation) to remedy my complaints – in fact its lack of extensibility was one of its biggest problems. I had some experience with using Modula-2+ and talked with the designers of Modula-3 and read the Modula-3 report. Modula-3 is the origin of the syntax and semantics used for exceptions, and some other Python features.

I was working in the Amoeba distributed operating system group at CWI. We needed a better way to do system administration than by writing either C programs or Bourne shell scripts, since Amoeba had its own system call interface which wasn't easily accessible from the Bourne shell. My experience with error handling in Amoeba made me acutely aware of the importance of exceptions as a programming language feature.

It occurred to me that a scripting language with a syntax like ABC but with access to the Amoeba system calls would fill the need. I realized that it would be foolish to write an Amoeba-specific language, so I decided that I needed a language that was generally extensible.

> During the 1989 Christmas holidays, I had a lot of time on my hand, so I decided to give it a try. During the next year, while still mostly working on it in my own time, Python was used in the Amoeba project with increasing success, and the feedback from colleagues made me add many early improvements.
>
> In February 1991, after just over a year of development, I decided to post to USENET. The rest is in the `Misc/HISTORY` file.

What is Python good for?

Python is a high-level general-purpose programming language that can be applied to many different classes of problems.

The language comes with a large standard library that covers areas such as string processing (regular expressions, Unicode, calculating differences between files), internet protocols (HTTP, FTP, SMTP, XML-RPC, POP, IMAP), software engineering (unit testing, logging, profiling, parsing Python code), and operating system interfaces (system calls, filesystems, TCP/IP sockets). Look at the table of contents for The Python Standard Library to get an idea of what's available. A wide variety of third-party extensions are also available. Consult the Python Package Index [https://pypi.org] to find packages of interest to you.

How does the Python version numbering scheme work?

Python versions are numbered "A.B.C" or "A.B":

- *A* is the major version number – it is only incremented for really major changes in the language.

- *B* is the minor version number – it is incremented for less earth-shattering changes.
- *C* is the micro version number – it is incremented for each bugfix release.

Not all releases are bugfix releases. In the run-up to a new feature release, a series of development releases are made, denoted as alpha, beta, or release candidate. Alphas are early releases in which interfaces aren't yet finalized; it's not unexpected to see an interface change between two alpha releases. Betas are more stable, preserving existing interfaces but possibly adding new modules, and release candidates are frozen, making no changes except as needed to fix critical bugs.

Alpha, beta and release candidate versions have an additional suffix:

- The suffix for an alpha version is “aN” for some small number *N*.
- The suffix for a beta version is “bN” for some small number *N*.
- The suffix for a release candidate version is “rcN” for some small number *N*.

In other words, all versions labeled *2.0aN* precede the versions labeled *2.0bN*, which precede versions labeled *2.0rcN*, and *those* precede 2.0.

You may also find version numbers with a “+” suffix, e.g. “2.2+”. These are unreleased versions, built directly from the CPython development repository. In practice, after a final minor release is made, the version is incremented to the next minor version, which becomes the “a0” version, e.g. “2.4a0”.

See the Developer’s Guide [https://devguide.python.org/developer-workflow/development-cycle/] for more information about the development cycle, and **PEP 387** [https://peps.python.org/pep-0387/] to learn more about Python’s backward compatibility policy. See also the documentation for `sys.version`, `sys.hexversion`, and `sys.version_info`.

How do I obtain a copy of the Python source?

The latest Python source distribution is always available from python.org, at https://www.python.org/downloads/. The latest development sources can be obtained at https://github.com/python/cpython/.

The source distribution is a gzipped tar file containing the complete C source, Sphinx-formatted documentation, Python library modules, example programs, and several useful pieces of freely distributable software. The source will compile and run out of the box on most UNIX platforms.

Consult the Getting Started section of the Python Developer’s Guide [https://devguide.python.org/setup/] for more information on getting the source code and compiling it.

How do I get documentation on Python?

The standard documentation for the current stable version of Python is available at https://docs.python.org/3/. EPUB, plain text, and downloadable HTML versions are also available at https://docs.python.org/3/download.html.

The documentation is written in reStructuredText and processed by the Sphinx documentation tool [https://www.sphinx-doc.org/]. The reStructuredText source for the documentation is part of the Python source distribution.

I’ve never programmed before. Is there a Python tutorial?

There are numerous tutorials and books available. The standard documentation includes The Python Tutorial.

Consult the Beginner’s Guide [https://wiki.python.org/moin/BeginnersGuide] to find information for beginning Python programmers, including lists of tutorials.

Is there a newsgroup or mailing list devoted to Python?

There is a newsgroup, *comp.lang.python*, and a mailing list, python-list [https://mail.python.org/mailman/listinfo/python-list]. The newsgroup and mailing list are gatewayed into each other – if you can read news it’s unnecessary to subscribe to the mailing list. *comp.lang.python* is high-traffic, receiving hundreds of postings every day, and Usenet readers are often more able to cope with this volume.

Announcements of new software releases and events can be found in comp.lang.python.announce, a low-traffic moderated list that receives about five postings per day. It’s available as the python-announce mailing list [https://mail.python.org/mailman3/lists/python-announce-list.python.org/].

More info about other mailing lists and newsgroups can be found at https://www.python.org/community/lists/.

How do I get a beta test version of Python?

Alpha and beta releases are available from https://www.python.org/downloads/. All releases are announced on the comp.lang.python and comp.lang.python.announce newsgroups and on the Python home page at https://www.python.org/; an RSS feed of news is available.

You can also access the development version of Python through Git. See The Python Developer's Guide [https://devguide.python.org/] for details.

How do I submit bug reports and patches for Python?

To report a bug or submit a patch, use the issue tracker at https://github.com/python/cpython/issues.

For more information on how Python is developed, consult the Python Developer's Guide [https://devguide.python.org/].

Are there any published articles about Python that I can reference?

It's probably best to cite your favorite book about Python.

The very first article [https://ir.cwi.nl/pub/18204] about Python was written in 1991 and is now quite outdated.

> Guido van Rossum and Jelke de Boer, "Interactively Testing Remote Servers Using the Python Programming Language", CWI Quarterly, Volume 4, Issue 4 (December 1991), Amsterdam, pp 283–303.

Are there any books on Python?

Yes, there are many, and more are being published. See the python.org wiki at https://wiki.python.org/moin/PythonBooks for a list.

You can also search online bookstores for “Python” and filter out the Monty Python references; or perhaps search for “Python” and “language”.

Where in the world is www.python.org located?

The Python project’s infrastructure is located all over the world and is managed by the Python Infrastructure Team. Details here [https://infra.psf.io].

Why is it called Python?

When he began implementing Python, Guido van Rossum was also reading the published scripts from “Monty Python’s Flying Circus” [https://en.wikipedia.org/wiki/Monty_Python], a BBC comedy series from the 1970s. Van Rossum thought he needed a name that was short, unique, and slightly mysterious, so he decided to call the language Python.

Do I have to like “Monty Python’s Flying Circus”?

No, but it helps. :)

Python in the real world

How stable is Python?

Very stable. New, stable releases have been coming out roughly every 6 to 18 months since 1991, and this seems likely to continue. As of version 3.9, Python will have a new feature release every 12 months (**PEP 602** [https://peps.python.org/pep-0602/]).

The developers issue bugfix releases of older versions, so the stability of existing releases gradually improves. Bugfix releases, indicated by a third component of the version number (e.g. 3.5.3, 3.6.2), are managed for stability; only fixes for known problems are included in a bugfix release, and it's guaranteed that interfaces will remain the same throughout a series of bugfix releases.

The latest stable releases can always be found on the Python download page [https://www.python.org/downloads/]. Python 3.x is the recommended version and supported by most widely used libraries. Python 2.x **is not maintained anymore** [https://peps.python.org/pep-0373/].

How many people are using Python?

There are probably millions of users, though it's difficult to obtain an exact count.

Python is available for free download, so there are no sales figures, and it's available from many different sites and packaged with many Linux distributions, so download statistics don't tell the whole story either.

The comp.lang.python newsgroup is very active, but not all Python users post to the group or even read it.

Have any significant projects been done in Python?

See https://www.python.org/about/success for a list of projects that use Python. Consulting the proceedings for past Python conferences [https://www.python.org/community/workshops/] will reveal contributions from many different companies and organizations.

High-profile Python projects include the Mailman mailing list manager [https://www.list.org] and the Zope application server [https://www.zope.dev]. Several Linux distributions, most notably Red Hat [https://www.redhat.com], have written part or all of their installer and system administration software in Python. Companies that use Python internally include Google, Yahoo, and Lucasfilm Ltd.

What new developments are expected for Python in the future?

See https://peps.python.org/ for the Python Enhancement Proposals (PEPs). PEPs are design documents describing a suggested new feature for Python, providing a concise technical specification and a rationale. Look for a PEP titled “Python X.Y Release Schedule”, where X.Y is a version that hasn’t been publicly released yet.

New development is discussed on the python-dev mailing list [https://mail.python.org/mailman3/lists/python-dev.python.org/].

Is it reasonable to propose incompatible changes to Python?

In general, no. There are already millions of lines of Python code around the world, so any change in the language that invalidates more than a very small fraction of existing programs has to be frowned upon. Even if you can provide a conversion program, there’s still the problem of updating all documentation; many books have been written about Python, and we don’t want to invalidate them all at a single stroke.

Providing a gradual upgrade path is necessary if a feature has to be changed. **PEP 5** [https://peps.python.org/pep-0005/]

describes the procedure followed for introducing backward-incompatible changes while minimizing disruption for users.

Is Python a good language for beginning programmers?

Yes.

It is still common to start students with a procedural and statically typed language such as Pascal, C, or a subset of C++ or Java. Students may be better served by learning Python as their first language. Python has a very simple and consistent syntax and a large standard library and, most importantly, using Python in a beginning programming course lets students concentrate on important programming skills such as problem decomposition and data type design. With Python, students can be quickly introduced to basic concepts such as loops and procedures. They can probably even work with user-defined objects in their very first course.

For a student who has never programmed before, using a statically typed language seems unnatural. It presents additional complexity that the student must master and slows the pace of the course. The students are trying to learn to think like a computer, decompose problems, design consistent interfaces, and encapsulate data. While learning to use a statically typed language is important in the long term, it is not necessarily the best topic to address in the students’ first programming course.

Many other aspects of Python make it a good first language. Like Java, Python has a large standard library so that students can be assigned programming projects very early in the course that *do* something. Assignments aren’t restricted to the standard four-function calculator and check balancing programs. By using the standard library, students can gain the satisfaction of working on realistic applications as they learn the fundamentals of programming. Using the standard library also teaches students about code reuse. Third-party modules such as PyGame are also helpful in extending the students’ reach.

Python’s interactive interpreter enables students to test language features while they’re programming. They can keep a window with the interpreter running while they enter their program’s source in another window. If they can’t remember the methods for a list, they can do something like this:

```
>>> L = []
>>> dir(L)
['__add__', '__class__', '__contains__', '__delattr__',
'__delitem__',
'__dir__', '__doc__', '__eq__', '__format__', '__ge__',
'__getattribute__', '__getitem__', '__gt__', '__hash__',
'__iadd__',
'__imul__', '__init__', '__iter__', '__le__', '__len__',
'__lt__',
'__mul__', '__ne__', '__new__', '__reduce__', '__reduce_ex__',
'__repr__', '__reversed__', '__rmul__', '__setattr__',
'__setitem__',
'__sizeof__', '__str__', '__subclasshook__', 'append', 'clear',
'copy', 'count', 'extend', 'index', 'insert', 'pop', 'remove',
'reverse', 'sort']
>>> [d for d in dir(L) if '__' not in d]
['append', 'clear', 'copy', 'count', 'extend', 'index',
'insert', 'pop', 'remove', 'reverse', 'sort']

>>> help(L.append)
Help on built-in function append:

append(...)
    L.append(object) -> None -- append object to end

>>> L.append(1)
>>> L
[1]
```

With the interpreter, documentation is never far from the student as they are programming.

There are also good IDEs for Python. IDLE is a cross-platform IDE for Python that is written in Python using Tkinter. Emacs users will be happy to know that there is a very good Python mode for Emacs. All of these programming environments provide syntax highlighting, auto-indenting, and access to the interactive interpreter while coding. Consult the Python wiki [https://wiki.python.org/moin/PythonEditors] for a full list of Python editing environments.

If you want to discuss Python’s use in education, you may be interested in joining the edu-sig mailing list [https://www.python.org/community/sigs/current/edu-sig].

General Questions

Is there a source code level debugger with breakpoints, single-stepping, etc.?

Yes.

Several debuggers for Python are described below, and the built-in function `breakpoint()` allows you to drop into any of them.

The pdb module is a simple but adequate console-mode debugger for Python. It is part of the standard Python library, and is **`documented in the Library Reference Manual`**. You can also write your own debugger by using the code for pdb as an example.

The IDLE interactive development environment, which is part of the standard Python distribution (normally available as Tools/scripts/idle3 [https://github.com/python/cpython/blob/main/Tools/scripts/idle3]), includes a graphical debugger.

PythonWin is a Python IDE that includes a GUI debugger based on pdb. The PythonWin debugger colors breakpoints and has quite a few cool features such as debugging non-PythonWin programs. PythonWin is available as part of pywin32 [https://github.com/mhammond/pywin32] project and as a part of the ActivePython [https://www.activestate.com/products/python/] distribution.

Eric [https://eric-ide.python-projects.org/] is an IDE built on PyQt and the Scintilla editing component.

trepan3k [https://github.com/rocky/python3-trepan/] is a gdb-like debugger.

Visual Studio Code [https://code.visualstudio.com/] is an IDE with debugging tools that integrates with version-control software.

There are a number of commercial Python IDEs that include graphical debuggers. They include:

- Wing IDE [https://wingware.com/]
- Komodo IDE [https://www.activestate.com/products/komodo-ide/]
- PyCharm [https://www.jetbrains.com/pycharm/]

Are there tools to help find bugs or perform static analysis?

Yes.

Pylint [https://pylint.pycqa.org/en/latest/index.html] and Pyflakes [https://github.com/PyCQA/pyflakes] do basic checking that will help you catch bugs sooner.

Static type checkers such as Mypy [https://mypy-lang.org/], Pyre [https://pyre-check.org/], and Pytype [https://github.com/google/pytype] can check type hints in Python source code.

How can I create a stand-alone binary from a Python script?

You don’t need the ability to compile Python to C code if all you want is a stand-alone program that users can download and run without having to install the Python distribution first. There are a number of tools that determine the set of modules required by a program and bind these modules together with a Python binary to produce a single executable.

One is to use the freeze tool, which is included in the Python source tree as Tools/freeze [https://github.com/python/cpython/tree/main/Tools/freeze]. It converts Python byte code to C arrays; with a C compiler you can embed all your modules into a new program, which is then linked with the standard Python modules.

It works by scanning your source recursively for import statements (in both forms) and looking for the modules in the standard Python path as well as in the source directory (for built-in modules). It then turns the bytecode for modules written in Python into C code (array initializers that can be turned into code objects using the marshal module) and creates a custom-made config file that only contains those built-in modules which are actually used in the program. It then compiles the generated C code and links it with the rest of the Python interpreter to form a self-contained binary which acts exactly like your script.

The following packages can help with the creation of console and GUI executables:

- Nuitka [https://nuitka.net/] (Cross-platform)
- PyInstaller [https://pyinstaller.org/] (Cross-platform)
- PyOxidizer [https://pyoxidizer.readthedocs.io/en/stable/] (Cross-platform)
- cx_Freeze [https://marcelotduarte.github.io/cx_Freeze/] (Cross-platform)
- py2app [https://github.com/ronaldoussoren/py2app] (macOS only)
- py2exe [https://www.py2exe.org/] (Windows only)

Are there coding standards or a style guide for Python programs?

Yes. The coding style required for standard library modules is documented as **PEP 8** [https://peps.python.org/pep-0008/].

Core Language

Why am I getting an UnboundLocalError when the variable has a value?

It can be a surprise to get the `UnboundLocalError` in previously working code when it is modified by adding an assignment statement somewhere in the body of a function.

This code:

```
>>> x = 10
>>> def bar():
...     print(x)
...
>>> bar()
10
```

works, but this code:

```
>>> x = 10
>>> def foo():
...     print(x)
...     x += 1
```

results in an **`UnboundLocalError`**:

```
>>> foo()
Traceback (most recent call last):
  ...
UnboundLocalError: local variable 'x' referenced before
assignment
```

This is because when you make an assignment to a variable in a scope, that variable becomes local to that scope and shadows any similarly named variable in the outer scope. Since the last statement in foo assigns a new value to `x`, the compiler recognizes it as a local variable. Consequently when the earlier `print(x)` attempts to print the uninitialized local variable and an error results.

In the example above you can access the outer scope variable by declaring it global:

```
>>> x = 10
>>> def foobar():
...     global x
...     print(x)
...     x += 1
...
>>> foobar()
10
```

This explicit declaration is required in order to remind you that (unlike the superficially analogous situation with class and instance variables) you are actually modifying the value of the variable in the outer scope:

```
>>> print(x)
11
```

You can do a similar thing in a nested scope using the `nonlocal` keyword:

```
>>> def foo():
...    x = 10
...    def bar():
...        nonlocal x
...        print(x)
...        x += 1
...    bar()
...    print(x)
...
>>> foo()
10
11
```

What are the rules for local and global variables in Python?

In Python, variables that are only referenced inside a function are implicitly global. If a variable is assigned a value anywhere within the function's body, it's assumed to be a local unless explicitly declared as global.

Though a bit surprising at first, a moment's consideration explains this. On one hand, requiring `global` for assigned variables provides a bar against unintended side-effects. On the other hand, if `global` was required for all global references, you'd be using `global` all the time. You'd have to declare as global every reference to a built-in function or to a component of an imported module. This clutter would defeat the usefulness of the `global` declaration for identifying side-effects.

Why do lambdas defined in a loop with different values all return the same result?

Assume you use a for loop to define a few different lambdas (or even plain functions), e.g.:

```
>>> squares = []
>>> for x in range(5):
...     squares.append(lambda: x**2)
```

This gives you a list that contains 5 lambdas that calculate `x**2`. You might expect that, when called, they would return, respectively, `0`, `1`, `4`, `9`, and `16`. However, when you actually try you will see that they all return `16`:

```
>>> squares[2]()
16
>>> squares[4]()
16
```

This happens because `x` is not local to the lambdas, but is defined in the outer scope, and it is accessed when the lambda is called — not when it is defined. At the end of the loop, the value of `x` is `4`, so all the functions now return `4**2`, i.e. `16`. You can also verify this by changing the value of `x` and see how the results of the lambdas change:

```
>>> x = 8
>>> squares[2]()
64
```

In order to avoid this, you need to save the values in variables local to the lambdas, so that they don't rely on the value of the global `x`:

```
>>> squares = []
>>> for x in range(5):
...     squares.append(lambda n=x: n**2)
```

Here, `n=x` creates a new variable `n` local to the lambda and computed when the lambda is defined so that it has the same value that `x` had at that point in the loop. This means that the value of `n` will be `0` in the first lambda, `1` in the second, `2` in the third, and so on. Therefore each lambda will now return the correct result:

```
>>> squares[2]()
4
>>> squares[4]()
16
```

Note that this behaviour is not peculiar to lambdas, but applies to regular functions too.

How do I share global variables across modules?

The canonical way to share information across modules within a single program is to create a special module (often called config or cfg). Just import the config module in all modules of your application; the module then becomes available as a global name. Because there is only one instance of each module, any changes made to the module object get reflected everywhere. For example:

config.py:

```
x = 0   # Default value of the 'x' configuration setting
```

mod.py:

```
import config
config.x = 1
```

main.py:

```
import config
import mod
print(config.x)
```

Note that using a module is also the basis for implementing the singleton design pattern, for the same reason.

What are the “best practices” for using import in a module?

In general, don’t use `from modulename import *`. Doing so clutters the importer’s namespace, and makes it much harder for linters to detect undefined names.

Import modules at the top of a file. Doing so makes it clear what other modules your code requires and avoids questions of whether the module name is in scope. Using one import per line makes it easy to add and delete module imports, but using multiple imports per line uses less screen space.

It’s good practice if you import modules in the following order:

1. standard library modules – e.g. `sys`, `os`, `argparse`, `re`
2. third-party library modules (anything installed in Python’s site-packages directory) – e.g. **`dateutil`**, **`requests`**, **`PIL.Image`**
3. locally developed modules

It is sometimes necessary to move imports to a function or class to avoid problems with circular imports. Gordon McMillan says:

> Circular imports are fine where both modules use the “import <module>” form of import. They fail when the 2nd module wants to grab a name out of the first (“from module import name”) and the import is at the top level. That’s because names in the 1st are not yet available, because the first module is busy importing the 2nd.

In this case, if the second module is only used in one function, then the import can easily be moved into that function. By the time the import is called, the first module will have finished initializing, and the second module can do its import.

It may also be necessary to move imports out of the top level of code if some of the modules are platform-specific. In that case, it may not even be possible to import all of the modules at the top of the file. In this case, importing the correct modules in the corresponding platform-specific code is a good option.

Only move imports into a local scope, such as inside a function definition, if it’s necessary to solve a problem such as avoiding a circular import or are trying to reduce the initialization time of a module. This technique is especially helpful if many of the imports are unnecessary depending on how the program executes. You may also want to move imports into a function if the modules are only ever used in that function. Note that loading a module the first time may be expensive because of the one time initialization of the module, but loading a module multiple times is virtually free, costing only a couple of dictionary lookups. Even if the module name has gone out of scope, the module is probably available in `sys.modules`.

Why are default values shared between objects?

This type of bug commonly bites neophyte programmers. Consider this function:

```
def foo(mydict={}):  # Danger: shared reference to one dict for
all calls
    ... compute something ...
    mydict[key] = value
    return mydict
```

The first time you call this function, `mydict` contains a single item. The second time, `mydict` contains two items because when `foo()` begins executing, `mydict` starts out with an item already in it.

It is often expected that a function call creates new objects for default values. This is not what happens. Default values are created exactly once, when the function is defined. If that object is changed, like the dictionary in this example, subsequent calls to the function will refer to this changed object.

By definition, immutable objects such as numbers, strings, tuples, and `None`, are safe from change. Changes to mutable objects such as dictionaries, lists, and class instances can lead to confusion.

Because of this feature, it is good programming practice to not use mutable objects as default values. Instead, use `None` as the default value and inside the function, check if the parameter is `None` and create a new list/dictionary/whatever if it is. For example, don’t write:

```
def foo(mydict={}):
    ...
```

but:

```
def foo(mydict=None):
    if mydict is None:
        mydict = {}  # create a new dict for local namespace
```

This feature can be useful. When you have a function that's time-consuming to compute, a common technique is to cache the parameters and the resulting value of each call to the function, and return the cached value if the same value is requested again. This is called "memoizing", and can be implemented like this:

```
# Callers can only provide two parameters and optionally pass
_cache by keyword
def expensive(arg1, arg2, *, _cache={}):
    if (arg1, arg2) in _cache:
        return _cache[(arg1, arg2)]

    # Calculate the value
    result = ... expensive computation ...
    _cache[(arg1, arg2)] = result           # Store result in
the cache
    return result
```

You could use a global variable containing a dictionary instead of the default value; it's a matter of taste.

How can I pass optional or keyword parameters from one function to another?

Collect the arguments using the `*` and `**` specifiers in the function's parameter list; this gives you the positional arguments as a tuple and the keyword arguments as a dictionary. You can then pass these arguments when calling another function by using `*` and `**`:

```
def f(x, *args, **kwargs):
    ...
    kwargs['width'] = '14.3c'
    ...
    g(x, *args, **kwargs)
```

What is the difference between arguments and parameters?

Parameters are defined by the names that appear in a function definition, whereas arguments are the values actually passed to a function when calling it. Parameters define what kind of arguments a function can accept. For example, given the function definition:

```
def func(foo, bar=None, **kwargs):
    pass
```

foo, *bar* and *kwargs* are parameters of `func`. However, when calling `func`, for example:

```
func(42, bar=314, extra=somevar)
```

the values `42`, `314`, and `somevar` are arguments.

Why did changing list ‘y’ also change list ‘x’?

If you wrote code like:

```
>>> x = []
>>> y = x
>>> y.append(10)
>>> y
[10]
>>> x
[10]
```

you might be wondering why appending an element to `y` changed `x` too.

There are two factors that produce this result:

1. Variables are simply names that refer to objects. Doing `y = x` doesn’t create a copy of the list – it creates a new variable `y` that refers to the same object `x` refers to. This means that there is only one object (the list), and both `x` and `y` refer to it.
2. Lists are mutable, which means that you can change their content.

After the call to **`append()`**, the content of the mutable object has changed from `[]` to `[10]`. Since both the variables refer to the same object, using either name accesses the modified value `[10]`.

If we instead assign an immutable object to `x`:

```
>>> x = 5  # ints are immutable
>>> y = x
>>> x = x + 1  # 5 can't be mutated, we are creating a new
object here
>>> x
6
>>> y
5
```

we can see that in this case `x` and `y` are not equal anymore. This is because integers are immutable, and when we do `x = x + 1` we are not mutating the int `5` by incrementing its value; instead, we are creating a new object (the int `6`) and assigning it to `x` (that is, changing which object `x` refers to). After this assignment we have two objects (the ints `6` and `5`) and two variables that refer to them (`x` now refers to `6` but `y` still refers to `5`).

Some operations (for example `y.append(10)` and `y.sort()`) mutate the object, whereas superficially similar operations (for example `y = y + [10]` and **`sorted(y)`**) create a new object. In general in Python (and in all cases in the standard library) a method that mutates an object will return `None` to help avoid getting the two types of operations confused. So if you mistakenly write `y.sort()` thinking it will give you a sorted copy of `y`, you'll instead end up with `None`, which will likely cause your program to generate an easily diagnosed error.

However, there is one class of operations where the same operation sometimes has different behaviors with different types: the augmented assignment operators. For example, `+=` mutates lists but not tuples or ints (`a_list += [1, 2, 3]` is equivalent to `a_list.extend([1, 2, 3])` and mutates `a_list`, whereas `some_tuple += (1, 2, 3)` and `some_int += 1` create new objects).

In other words:

- If we have a mutable object (**`list`**, **`dict`**, **`set`**, etc.), we can use some specific operations to mutate it and all the variables that refer to it will see the change.
- If we have an immutable object (**`str`**, **`int`**, **`tuple`**, etc.), all the variables that refer to it will always see the same value, but operations that transform that value into a new value always return a new object.

If you want to know if two variables refer to the same object or not, you can use the **`is`** operator, or the built-in function **`id()`**.

How do I write a function with output parameters (call by reference)?

Remember that arguments are passed by assignment in Python. Since assignment just creates references to objects, there's no alias between an argument name in the caller and callee, and so no call-by-reference per se. You can achieve the desired effect in a number of ways.

1. By returning a tuple of the results:

   ```
   >>> def func1(a, b):
   ...     a = 'new-value'        # a and b are local names
   ...     b = b + 1              # assigned to new objects
   ...     return a, b            # return new values
   ...
   >>> x, y = 'old-value', 99
   >>> func1(x, y)
   ('new-value', 100)
   ```

   This is almost always the clearest solution.

2. By using global variables. This isn’t thread-safe, and is not recommended.

3. By passing a mutable (changeable in-place) object:

   ```
   >>> def func2(a):
   ...     a[0] = 'new-value'     # 'a' references a mutable
   list
   ...     a[1] = a[1] + 1        # changes a shared object
   ...
   >>> args = ['old-value', 99]
   >>> func2(args)
   >>> args
   ['new-value', 100]
   ```

4. By passing in a dictionary that gets mutated:

   ```
   >>> def func3(args):
   ...     args['a'] = 'new-value'     # args is a mutable
   dictionary
   ...     args['b'] = args['b'] + 1   # change it in-place
   ...
   >>> args = {'a': 'old-value', 'b': 99}
   >>> func3(args)
   >>> args
   {'a': 'new-value', 'b': 100}
   ```

5. Or bundle up values in a class instance:

```
>>> class Namespace:
...     def __init__(self, /, **args):
...         for key, value in args.items():
...             setattr(self, key, value)
...
>>> def func4(args):
...     args.a = 'new-value'        # args is a mutable
Namespace
...     args.b = args.b + 1         # change object in-
place
...
>>> args = Namespace(a='old-value', b=99)
>>> func4(args)
>>> vars(args)
{'a': 'new-value', 'b': 100}
```

There's almost never a good reason to get this complicated.

Your best choice is to return a tuple containing the multiple results.

How do you make a higher order function in Python?

You have two choices: you can use nested scopes or you can use callable objects. For example, suppose you wanted to define `linear(a,b)` which returns a function `f(x)` that computes the value `a*x+b`. Using nested scopes:

```
def linear(a, b):
    def result(x):
        return a * x + b
    return result
```

Or using a callable object:

```
class linear:

    def __init__(self, a, b):
        self.a, self.b = a, b

    def __call__(self, x):
        return self.a * x + self.b
```

In both cases,

```
taxes = linear(0.3, 2)
```

gives a callable object where `taxes(10e6) == 0.3 * 10e6 + 2`.

The callable object approach has the disadvantage that it is a bit slower and results in slightly longer code. However, note that a collection of callables can share their signature via inheritance:

```
class exponential(linear):
    # __init__ inherited
    def __call__(self, x):
        return self.a * (x ** self.b)
```

Object can encapsulate state for several methods:

```
class counter:

    value = 0

    def set(self, x):
        self.value = x

    def up(self):
        self.value = self.value + 1

    def down(self):
        self.value = self.value - 1

count = counter()
inc, dec, reset = count.up, count.down, count.set
```

Here `inc()`, `dec()` and `reset()` act like functions which share the same counting variable.

How do I copy an object in Python?

In general, try `copy.copy()` or `copy.deepcopy()` for the general case. Not all objects can be copied, but most can.

Some objects can be copied more easily. Dictionaries have a `copy()` method:

```
newdict = olddict.copy()
```

Sequences can be copied by slicing:

```
new_l = l[:]
```

How can I find the methods or attributes of an object?

For an instance `x` of a user-defined class, `dir(x)` returns an alphabetized list of the names containing the instance attributes and methods and attributes defined by its class.

How can my code discover the name of an object?

Generally speaking, it can’t, because objects don’t really have names. Essentially, assignment always binds a name to a value; the same is true of `def` and `class` statements, but in that case the value is a callable. Consider the following code:

```
>>> class A:
...     pass
...
>>> B = A
>>> a = B()
>>> b = a
>>> print(b)
<__main__.A object at 0x16D07CC>
```

```
>>> print(a)
<__main__.A object at 0x16D07CC>
```

Arguably the class has a name: even though it is bound to two names and invoked through the name `B` the created instance is still reported as an instance of class `A`. However, it is impossible to say whether the instance's name is `a` or `b`, since both names are bound to the same value.

Generally speaking it should not be necessary for your code to "know the names" of particular values. Unless you are deliberately writing introspective programs, this is usually an indication that a change of approach might be beneficial.

In comp.lang.python, Fredrik Lundh once gave an excellent analogy in answer to this question:

> The same way as you get the name of that cat you found on your porch: the cat (object) itself cannot tell you its name, and it doesn't really care – so the only way to find out what it's called is to ask all your neighbours (namespaces) if it's their cat (object)…
>
> ….and don't be surprised if you'll find that it's known by many names, or no name at all!

What's up with the comma operator's precedence?

Comma is not an operator in Python. Consider this session:

```
>>> "a" in "b", "a"
(False, 'a')
```

Since the comma is not an operator, but a separator between expressions the above is evaluated as if you had entered:

```
("a" in "b"), "a"
```

not:

```
"a" in ("b", "a")
```

The same is true of the various assignment operators (`=`, `+=` etc). They are not truly operators but syntactic delimiters in assignment statements.

Is there an equivalent of C’s “?:” ternary operator?

Yes, there is. The syntax is as follows:

```
[on_true] if [expression] else [on_false]

x, y = 50, 25
small = x if x < y else y
```

Before this syntax was introduced in Python 2.5, a common idiom was to use logical operators:

```
[expression] and [on_true] or [on_false]
```

However, this idiom is unsafe, as it can give wrong results when *on_true* has a false boolean value. Therefore, it is always better to use the `... if ... else ...` form.

Is it possible to write obfuscated one-liners in Python?

Yes. Usually this is done by nesting `lambda` within **`lambda`**. See the following three examples, slightly adapted from Ulf Bartelt:

```
from functools import reduce
```

```
# Primes < 1000
print(list(filter(None,map(lambda y:y*reduce(lambda x,y:x*y!=0,
map(lambda
x,y=y:y%x,range(2,int(pow(y,0.5)+1))),1),range(2,1000)))))

# First 10 Fibonacci numbers
print(list(map(lambda x,f=lambda x,f:(f(x-1,f)+f(x-2,f)) if x>1
else 1:
f(x,f), range(10))))

# Mandelbrot set
print((lambda Ru,Ro,Iu,Io,IM,Sx,Sy:reduce(lambda
x,y:x+'\n'+y,map(lambda y,
Iu=Iu,Io=Io,Ru=Ru,Ro=Ro,Sy=Sy,L=lambda
yc,Iu=Iu,Io=Io,Ru=Ru,Ro=Ro,i=IM,
Sx=Sx,Sy=Sy:reduce(lambda x,y:x+y,map(lambda
x,xc=Ru,yc=yc,Ru=Ru,Ro=Ro,
i=i,Sx=Sx,F=lambda xc,yc,x,y,k,f=lambda xc,yc,x,y,k,f:(k<=0)or
(x*x+y*y
>=4.0) or 1+f(xc,yc,x*x-y*y+xc,2.0*x*y+yc,k-
1,f):f(xc,yc,x,y,k,f):chr(
64+F(Ru+x*(Ro-Ru)/Sx,yc,0,0,i)),range(Sx))):L(Iu+y*(Io-
Iu)/Sy),range(Sy
))))(-2.1, 0.7, -1.2, 1.2, 30, 80, 24))
#    \___ ___/  \___ ___/  |   |   |__ lines on screen
#        V          V      |   |______ columns on screen
#        |          |      |__________ maximum of "iterations"
#        |          |_________________ range on y axis
#        |____________________________ range on x axis
```

Don’t try this at home, kids!

What does the slash(/) in the parameter list of a function mean?

A slash in the argument list of a function denotes that the parameters prior to it are positional-only. Positional-only parameters are the ones without an externally usable name. Upon calling a function that accepts positional-only parameters, arguments are mapped to parameters based solely on their position. For example, `divmod()` is a function that accepts positional-only parameters. Its documentation looks like this:

```
>>> help(divmod)
Help on built-in function divmod in module builtins:

divmod(x, y, /)
    Return the tuple (x//y, x%y).  Invariant: div*y + mod == x.
```

The slash at the end of the parameter list means that both parameters are positional-only. Thus, calling `divmod()` with keyword arguments would lead to an error:

```
>>> divmod(x=3, y=4)
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
TypeError: divmod() takes no keyword arguments
```

Numbers and strings

How do I specify hexadecimal and octal integers?

To specify an octal digit, precede the octal value with a zero, and then a lower or uppercase “o”. For example, to set the variable “a” to the octal value “10” (8 in decimal), type:

```
>>> a = 0o10
>>> a
8
```

Hexadecimal is just as easy. Simply precede the hexadecimal number with a zero, and then a lower or uppercase “x”. Hexadecimal digits can be specified in lower or uppercase. For example, in the Python interpreter:

```
>>> a = 0xa5
>>> a
165
>>> b = 0XB2
>>> b
178
```

Why does -22 // 10 return -3?

It’s primarily driven by the desire that `i % j` have the same sign as `j`. If you want that, and also want:

```
i == (i // j) * j + (i % j)
```

then integer division has to return the floor. C also requires that identity to hold, and then compilers that truncate `i // j` need to make `i % j` have the same sign as `i`.

There are few real use cases for `i % j` when `j` is negative. When `j` is positive, there are many, and in virtually all of them it’s more useful for `i % j` to be `>= 0`. If the clock says 10 now, what did it say 200 hours ago? `-190 % 12 == 2` is useful; `-190 % 12 == -10` is a bug waiting to bite.

How do I get int literal attribute instead of SyntaxError?

Trying to lookup an `int` literal attribute in the normal manner gives a `SyntaxError` because the period is seen as a decimal point:

```
>>> 1.__class__
  File "<stdin>", line 1
  1.__class__
   ^
SyntaxError: invalid decimal literal
```

The solution is to separate the literal from the period with either a space or parentheses.

```
>>> 1 .__class__
<class 'int'>
>>> (1).__class__
<class 'int'>
```

How do I convert a string to a number?

For integers, use the built-in `int()` type constructor, e.g. `int('144') == 144`. Similarly, `float()` converts to a floating-point number, e.g. `float('144') == 144.0`.

By default, these interpret the number as decimal, so that `int('0144') == 144` holds true, and `int('0x144')` raises `ValueError`. `int(string, base)` takes the base to convert from as a second optional argument, so `int( '0x144', 16) == 324`. If the base is specified as 0, the number is interpreted using Python’s rules: a leading ‘0o’ indicates octal, and ‘0x’ indicates a hex number.

Do not use the built-in function `eval()` if all you need is to convert strings to numbers. `eval()` will be significantly slower and it presents a security risk: someone could pass you a Python expression that might have unwanted side effects. For example, someone could pass `__import__('os').system("rm -rf $HOME")` which would erase your home directory.

`eval()` also has the effect of interpreting numbers as Python expressions, so that e.g. `eval('09')` gives a syntax error because Python does not allow leading ‘0’ in a decimal number (except ‘0’).

How do I convert a number to a string?

To convert, e.g., the number `144` to the string `'144'`, use the built-in type constructor **`str()`**. If you want a hexadecimal or octal representation, use the built-in functions **`hex()`** or **`oct()`**. For fancy formatting, see the f-strings and Format String Syntax sections, e.g. `"{:04d}".format(144)` yields `'0144'` and `"{:.3f}".format(1.0/3.0)` yields `'0.333'`.

How do I modify a string in place?

You can’t, because strings are immutable. In most situations, you should simply construct a new string from the various parts you want to assemble it from. However, if you need an object with the ability to modify in-place unicode data, try using an **`io.StringIO`** object or the **`array`** module:

```
>>> import io
>>> s = "Hello, world"
>>> sio = io.StringIO(s)
>>> sio.getvalue()
'Hello, world'
>>> sio.seek(7)
7
>>> sio.write("there!")
6
>>> sio.getvalue()
'Hello, there!'

>>> import array
>>> a = array.array('w', s)
>>> print(a)
array('w', 'Hello, world')
>>> a[0] = 'y'
>>> print(a)
array('w', 'yello, world')
>>> a.tounicode()
'yello, world'
```

How do I use strings to call functions/methods?

There are various techniques.

- The best is to use a dictionary that maps strings to functions. The primary advantage of this technique is that the strings do not need to match the names of the functions. This is also the primary technique used to emulate a case construct:

  ```
  def a():
      pass

  def b():
      pass

  dispatch = {'go': a, 'stop': b}  # Note lack of parens for
  funcs

  dispatch[get_input()]()  # Note trailing parens to call
  function
  ```

- Use the built-in function `getattr()`:

  ```
  import foo
  getattr(foo, 'bar')()
  ```

  Note that `getattr()` works on any object, including classes, class instances, modules, and so on.

  This is used in several places in the standard library, like this:

  ```
  class Foo:
      def do_foo(self):
          ...

      def do_bar(self):
          ...

  f = getattr(foo_instance, 'do_' + opname)
  f()
  ```

- Use `locals()` to resolve the function name:

  ```
  def myFunc():
      print("hello")

  fname = "myFunc"

  f = locals()[fname]
  f()
  ```

Is there an equivalent to Perl's `chomp()` for removing trailing newlines from strings?

You can use `S.rstrip("\r\n")` to remove all occurrences of any line terminator from the end of the string `S` without removing other trailing whitespace. If the string `S` represents more than one line, with several empty lines at the end, the line terminators for all the blank lines will be removed:

```
>>> lines = ("line 1 \r\n"
...          "\r\n"
...          "\r\n")
>>> lines.rstrip("\n\r")
'line 1 '
```

Since this is typically only desired when reading text one line at a time, using `S.rstrip()` this way works well.

Is there a `scanf()` or `sscanf()` equivalent?

Not as such.

For simple input parsing, the easiest approach is usually to split the line into whitespace-delimited words using the `split()` method of string objects and then convert decimal strings to numeric values using `int()` or `float()`. **`split()`** supports an optional "sep" parameter which is useful if the line uses something other than whitespace as a separator.

For more complicated input parsing, regular expressions are more powerful than C’s `sscanf` and better suited for the task.

What does `UnicodeDecodeError` or `UnicodeEncodeError` error mean?

See the Unicode HOWTO.

Can I end a raw string with an odd number of backslashes?

A raw string ending with an odd number of backslashes will escape the string’s quote:

```
>>> r'C:\this\will\not\work\'
  File "<stdin>", line 1
    r'C:\this\will\not\work\'
    ^
SyntaxError: unterminated string literal (detected at line 1)
```

There are several workarounds for this. One is to use regular strings and double the backslashes:

```
>>> 'C:\\this\\will\\work\\'
'C:\\this\\will\\work\\'
```

Another is to concatenate a regular string containing an escaped backslash to the raw string:

```
>>> r'C:\this\will\work' '\\'
'C:\\this\\will\\work\\'
```

It is also possible to use `os.path.join()` to append a backslash on Windows:

```
>>> os.path.join(r'C:\this\will\work', '')
'C:\\this\\will\\work\\'
```

Note that while a backslash will “escape” a quote for the purposes of determining where the raw string ends, no escaping occurs when interpreting the value of the raw string. That is, the backslash remains present in the value of the raw string:

```
>>> r'backslash\'preserved'
"backslash\\'preserved"
```

Also see the specification in the language reference.

Performance

My program is too slow. How do I speed it up?

That’s a tough one, in general. First, here are a list of things to remember before diving further:

- Performance characteristics vary across Python implementations. This FAQ focuses on CPython.
- Behaviour can vary across operating systems, especially when talking about I/O or multi-threading.
- You should always find the hot spots in your program *before* attempting to optimize any code (see the **`profile`** module).
- Writing benchmark scripts will allow you to iterate quickly when searching for improvements (see the **`timeit`** module).
- It is highly recommended to have good code coverage (through unit testing or any other technique) before potentially introducing regressions hidden in sophisticated optimizations.

That being said, there are many tricks to speed up Python code. Here are some general principles which go a long way towards reaching acceptable performance levels:

- Making your algorithms faster (or changing to faster ones) can yield much larger benefits than trying to sprinkle micro-optimization tricks all over your code.
- Use the right data structures. Study documentation for the Built-in Types and the `collections` module.
- When the standard library provides a primitive for doing something, it is likely (although not guaranteed) to be faster than any alternative you may come up with. This is doubly true for primitives written in C, such as builtins and some extension types. For example, be sure to use either the `list.sort()` built-in method or the related `sorted()` function to do sorting (and see the Sorting Techniques for examples of moderately advanced usage).
- Abstractions tend to create indirections and force the interpreter to work more. If the levels of indirection outweigh the amount of useful work done, your program will be slower. You should avoid excessive abstraction, especially under the form of tiny functions or methods (which are also often detrimental to readability).

If you have reached the limit of what pure Python can allow, there are tools to take you further away. For example, Cython [https://cython.org] can compile a slightly modified version of Python code into a C extension, and can be used on many different platforms. Cython can take advantage of compilation (and optional type annotations) to make your code significantly faster than when interpreted. If you are confident in your C programming skills, you can also write a C extension module yourself.

The wiki page devoted to performance tips [https://wiki.python.org/moin/PythonSpeed/PerformanceTips].

What is the most efficient way to concatenate many strings together?

`str` and `bytes` objects are immutable, therefore concatenating many strings together is inefficient as each concatenation creates a new object. In the general case, the total runtime cost is quadratic in the total string length.

To accumulate many `str` objects, the recommended idiom is to place them into a list and call `str.join()` at the end:

```
chunks = []
for s in my_strings:
    chunks.append(s)
result = ''.join(chunks)
```

(another reasonably efficient idiom is to use `io.StringIO`)

To accumulate many `bytes` objects, the recommended idiom is to extend a `bytearray` object using in-place concatenation (the `+=` operator):

```
result = bytearray()
for b in my_bytes_objects:
    result += b
```

Sequences (Tuples/Lists)

How do I convert between tuples and lists?

The type constructor `tuple(seq)` converts any sequence (actually, any iterable) into a tuple with the same items in the same order.

For example, `tuple([1, 2, 3])` yields `(1, 2, 3)` and `tuple('abc')` yields `('a', 'b', 'c')`. If the argument is a tuple, it does not make a copy but returns the same object, so it is cheap to call `tuple()` when you aren't sure that an object is already a tuple.

The type constructor `list(seq)` converts any sequence or iterable into a list with the same items in the same order. For example, `list((1, 2, 3))` yields `[1, 2, 3]` and `list('abc')` yields `['a', 'b', 'c']`. If the argument is a list, it makes a copy just like `seq[:]` would.

What's a negative index?

Python sequences are indexed with positive numbers and negative numbers. For positive numbers 0 is the first index 1 is the second index and so forth. For negative indices -1 is the last index and -2 is the penultimate (next to last) index and so forth. Think of `seq[-n]` as the same as `seq[len(seq)-n]`.

Using negative indices can be very convenient. For example `S[:-1]` is all of the string except for its last character, which is useful for removing the trailing newline from a string.

How do I iterate over a sequence in reverse order?

Use the `reversed()` built-in function:

```
for x in reversed(sequence):
    ...  # do something with x ...
```

This won't touch your original sequence, but build a new copy with reversed order to iterate over.

How do you remove duplicates from a list?

See the Python Cookbook for a long discussion of many ways to do this:

https://code.activestate.com/recipes/52560/

If you don’t mind reordering the list, sort it and then scan from the end of the list, deleting duplicates as you go:

```
if mylist:
    mylist.sort()
    last = mylist[-1]
    for i in range(len(mylist)-2, -1, -1):
        if last == mylist[i]:
            del mylist[i]
        else:
            last = mylist[i]
```

If all elements of the list may be used as set keys (i.e. they are all hashable) this is often faster

```
mylist = list(set(mylist))
```

This converts the list into a set, thereby removing duplicates, and then back into a list.

How do you remove multiple items from a list

As with removing duplicates, explicitly iterating in reverse with a delete condition is one possibility. However, it is easier and faster to use slice replacement with an implicit or explicit forward iteration. Here are three variations.:

```
mylist[:] = filter(keep_function, mylist)
mylist[:] = (x for x in mylist if keep_condition)
mylist[:] = [x for x in mylist if keep_condition]
```

The list comprehension may be fastest.

How do you make an array in Python?

Use a list:

```
["this", 1, "is", "an", "array"]
```

Lists are equivalent to C or Pascal arrays in their time complexity; the primary difference is that a Python list can contain objects of many different types.

The `array` module also provides methods for creating arrays of fixed types with compact representations, but they are slower to index than lists. Also note that NumPy [https://numpy.org/] and other third party packages define array-like structures with various characteristics as well.

To get Lisp-style linked lists, you can emulate *cons cells* using tuples:

```
lisp_list = ("like",  ("this",  ("example", None) ) )
```

If mutability is desired, you could use lists instead of tuples. Here the analogue of a Lisp *car* is `lisp_list[0]` and the analogue of *cdr* is `lisp_list[1]`. Only do this if you’re sure you really need to, because it’s usually a lot slower than using Python lists.

How do I create a multidimensional list?

You probably tried to make a multidimensional array like this:

```
>>> A = [[None] * 2] * 3
```

This looks correct if you print it:

```
>>> A
[[None, None], [None, None], [None, None]]
```

But when you assign a value, it shows up in multiple places:

```
>>> A[0][0] = 5
>>> A
[[5, None], [5, None], [5, None]]
```

The reason is that replicating a list with `*` doesn't create copies, it only creates references to the existing objects. The `*3` creates a list containing 3 references to the same list of length two. Changes to one row will show in all rows, which is almost certainly not what you want.

The suggested approach is to create a list of the desired length first and then fill in each element with a newly created list:

```
A = [None] * 3
for i in range(3):
    A[i] = [None] * 2
```

This generates a list containing 3 different lists of length two. You can also use a list comprehension:

```
w, h = 2, 3
A = [[None] * w for i in range(h)]
```

Or, you can use an extension that provides a matrix datatype; NumPy [https://numpy.org/] is the best known.

How do I apply a method or function to a sequence of objects?

To call a method or function and accumulate the return values is a list, a list comprehension is an elegant solution:

```
result = [obj.method() for obj in mylist]

result = [function(obj) for obj in mylist]
```

To just run the method or function without saving the return values, a plain `for` loop will suffice:

```
for obj in mylist:
    obj.method()

for obj in mylist:
    function(obj)
```

Why does a_tuple[i] += [‘item’] raise an exception when the addition works?

This is because of a combination of the fact that augmented assignment operators are *assignment* operators, and the difference between mutable and immutable objects in Python.

This discussion applies in general when augmented assignment operators are applied to elements of a tuple that point to mutable objects, but we’ll use a `list` and `+=` as our exemplar.

If you wrote:

```
>>> a_tuple = (1, 2)
>>> a_tuple[0] += 1
Traceback (most recent call last):
   ...
TypeError: 'tuple' object does not support item assignment
```

The reason for the exception should be immediately clear: `1` is added to the object `a_tuple[0]` points to (`1`), producing the result object, `2`, but when we attempt to assign the result of the computation, `2`, to element `0` of the tuple, we get an error because we can’t change what an element of a tuple points to.

Under the covers, what this augmented assignment statement is doing is approximately this:

```
>>> result = a_tuple[0] + 1
>>> a_tuple[0] = result
Traceback (most recent call last):
  ...
TypeError: 'tuple' object does not support item assignment
```

It is the assignment part of the operation that produces the error, since a tuple is immutable.

When you write something like:

```
>>> a_tuple = (['foo'], 'bar')
>>> a_tuple[0] += ['item']
Traceback (most recent call last):
  ...
TypeError: 'tuple' object does not support item assignment
```

The exception is a bit more surprising, and even more surprising is the fact that even though there was an error, the append worked:

```
>>> a_tuple[0]
['foo', 'item']
```

To see why this happens, you need to know that (a) if an object implements an `__iadd__()` magic method, it gets called when the `+=` augmented assignment is executed, and its return value is what gets used in the assignment statement; and (b) for lists, **`__iadd__()`** is equivalent to calling `extend()` on the list and returning the list. That’s why we say that for lists, `+=` is a “shorthand” for `list.extend()`:

```
>>> a_list = []
>>> a_list += [1]
>>> a_list
[1]
```

This is equivalent to:

```
>>> result = a_list.__iadd__([1])
>>> a_list = result
```

The object pointed to by a_list has been mutated, and the pointer to the mutated object is assigned back to `a_list`. The end result of the assignment is a no-op, since it is a pointer to the same object that `a_list` was previously pointing to, but the assignment still happens.

Thus, in our tuple example what is happening is equivalent to:

```
>>> result = a_tuple[0].__iadd__(['item'])
>>> a_tuple[0] = result
Traceback (most recent call last):
  ...
TypeError: 'tuple' object does not support item assignment
```

The **`__iadd__()`** succeeds, and thus the list is extended, but even though `result` points to the same object that `a_tuple[0]` already points to, that final assignment still results in an error, because tuples are immutable.

I want to do a complicated sort: can you do a Schwartzian Transform in Python?

The technique, attributed to Randal Schwartz of the Perl community, sorts the elements of a list by a metric which maps each element to its “sort value”. In Python, use the `key` argument for the `list.sort()` method:

```
Isorted = L[:]
Isorted.sort(key=lambda s: int(s[10:15]))
```

How can I sort one list by values from another list?

Merge them into an iterator of tuples, sort the resulting list, and then pick out the element you want.

```
>>> list1 = ["what", "I'm", "sorting", "by"]
>>> list2 = ["something", "else", "to", "sort"]
>>> pairs = zip(list1, list2)
>>> pairs = sorted(pairs)
>>> pairs
[("I'm", 'else'), ('by', 'sort'), ('sorting', 'to'), ('what',
'something')]
>>> result = [x[1] for x in pairs]
>>> result
['else', 'sort', 'to', 'something']
```

Objects

What is a class?

A class is the particular object type created by executing a class statement. Class objects are used as templates to create instance objects, which embody both the data (attributes) and code (methods) specific to a datatype.

A class can be based on one or more other classes, called its base class(es). It then inherits the attributes and methods of its base classes. This allows an object model to be successively refined by inheritance. You might have a generic `Mailbox` class that provides basic accessor methods for a mailbox, and subclasses such as `MboxMailbox`, `MaildirMailbox`, `OutlookMailbox` that handle various specific mailbox formats.

What is a method?

A method is a function on some object `x` that you normally call as `x.name(arguments...)`. Methods are defined as functions inside the class definition:

```
class C:
    def meth(self, arg):
        return arg * 2 + self.attribute
```

What is self?

Self is merely a conventional name for the first argument of a method. A method defined as `meth(self, a, b, c)` should be called as `x.meth(a, b, c)` for some instance `x` of the class in which the definition occurs; the called method will think it is called as `meth(x, a, b, c)`.

See also Why must 'self' be used explicitly in method definitions and calls?.

How do I check if an object is an instance of a given class or of a subclass of it?

Use the built-in function **`isinstance(obj, cls)`**. You can check if an object is an instance of any of a number of classes by providing a tuple instead of a single class, e.g. `isinstance(obj, (class1, class2, ...))`, and can also check whether an object is one of Python's built-in types, e.g. `isinstance(obj, str)` or `isinstance(obj, (int, float, complex))`.

Note that **`isinstance()`** also checks for virtual inheritance from an abstract base class. So, the test will return `True` for a registered class even if hasn't directly or indirectly inherited from it. To test for "true inheritance", scan the MRO of the class:

```
from collections.abc import Mapping

class P:
     pass

class C(P):
    pass
```

```
Mapping.register(P)

>>> c = C()
>>> isinstance(c, C)        # direct
True
>>> isinstance(c, P)        # indirect
True
>>> isinstance(c, Mapping)  # virtual
True

# Actual inheritance chain
>>> type(c).__mro__
(<class 'C'>, <class 'P'>, <class 'object'>)

# Test for "true inheritance"
>>> Mapping in type(c).__mro__
False
```

Note that most programs do not use [`isinstance()`] on user-defined classes very often. If you are developing the classes yourself, a more proper object-oriented style is to define methods on the classes that encapsulate a particular behaviour, instead of checking the object's class and doing a different thing based on what class it is. For example, if you have a function that does something:

```
def search(obj):
    if isinstance(obj, Mailbox):
        ...  # code to search a mailbox
    elif isinstance(obj, Document):
        ...  # code to search a document
    elif ...
```

A better approach is to define a `search()` method on all the classes and just call it:

```
class Mailbox:
    def search(self):
        ...  # code to search a mailbox
```

```
class Document:
    def search(self):
        ...  # code to search a document

obj.search()
```

What is delegation?

Delegation is an object oriented technique (also called a design pattern). Let’s say you have an object `x` and want to change the behaviour of just one of its methods. You can create a new class that provides a new implementation of the method you’re interested in changing and delegates all other methods to the corresponding method of `x`.

Python programmers can easily implement delegation. For example, the following class implements a class that behaves like a file but converts all written data to uppercase:

```
class UpperOut:

    def __init__(self, outfile):
        self._outfile = outfile

    def write(self, s):
        self._outfile.write(s.upper())

    def __getattr__(self, name):
        return getattr(self._outfile, name)
```

Here the `UpperOut` class redefines the `write()` method to convert the argument string to uppercase before calling the underlying `self._outfile.write()` method. All other methods are delegated to the underlying `self._outfile` object. The delegation is accomplished via the `__getattr__()` method; consult the language reference for more information about controlling attribute access.

Note that for more general cases delegation can get trickier. When attributes must be set as well as retrieved, the class must define a `__setattr__()` method too, and it must do so carefully. The basic implementation of `__setattr__()` is roughly equivalent to the following:

```
class X:
    ...
    def __setattr__(self, name, value):
        self.__dict__[name] = value
    ...
```

Many `__setattr__()` implementations call `object.__setattr__()` to set an attribute on self without causing infinite recursion:

```
class X:
    def __setattr__(self, name, value):
        # Custom logic here...
        object.__setattr__(self, name, value)
```

Alternatively, it is possible to set attributes by inserting entries into `self.__dict__` directly.

How do I call a method defined in a base class from a derived class that extends it?

Use the built-in `super()` function:

```
class Derived(Base):
    def meth(self):
        super().meth()  # calls Base.meth
```

In the example, `super()` will automatically determine the instance from which it was called (the `self` value), look up the method resolution order (MRO) with `type(self).__mro__`, and return the next in line after `Derived` in the MRO: `Base`.

How can I organize my code to make it easier to change the base class?

You could assign the base class to an alias and derive from the alias. Then all you have to change is the value assigned to the alias. Incidentally, this trick is also handy if you want to decide dynamically (e.g. depending on availability of resources) which base class to use. Example:

```
class Base:
    ...

BaseAlias = Base

class Derived(BaseAlias):
    ...
```

How do I create static class data and static class methods?

Both static data and static methods (in the sense of C++ or Java) are supported in Python.

For static data, simply define a class attribute. To assign a new value to the attribute, you have to explicitly use the class name in the assignment:

```
class C:
    count = 0   # number of times C.__init__ called

    def __init__(self):
        C.count = C.count + 1

    def getcount(self):
        return C.count  # or return self.count
```

`c.count` also refers to `C.count` for any `c` such that `isinstance(c, C)` holds, unless overridden by `c` itself or by some class on the base-class search path from `c.__class__` back to `C`.

Caution: within a method of C, an assignment like `self.count = 42` creates a new and unrelated instance named “count” in `self`’s own dict. Rebinding of a class-static data name must always specify the class whether inside a method or not:

```
C.count = 314
```

Static methods are possible:

```
class C:
    @staticmethod
    def static(arg1, arg2, arg3):
        # No 'self' parameter!
        ...
```

However, a far more straightforward way to get the effect of a static method is via a simple module-level function:

```
def getcount():
    return C.count
```

If your code is structured so as to define one class (or tightly related class hierarchy) per module, this supplies the desired encapsulation.

How can I overload constructors (or methods) in Python?

This answer actually applies to all methods, but the question usually comes up first in the context of constructors.

In C++ you’d write

```
class C {
    C() { cout << "No arguments\n"; }
    C(int i) { cout << "Argument is " << i << "\n"; }
}
```

In Python you have to write a single constructor that catches all cases using default arguments. For example:

```
class C:
    def __init__(self, i=None):
        if i is None:
            print("No arguments")
        else:
            print("Argument is", i)
```

This is not entirely equivalent, but close enough in practice.

You could also try a variable-length argument list, e.g.

```
def __init__(self, *args):
    ...
```

The same approach works for all method definitions.

I try to use __spam and I get an error about _SomeClassName__spam.

Variable names with double leading underscores are “mangled” to provide a simple but effective way to define class private variables. Any identifier of the form `__spam` (at least two leading underscores, at most one trailing underscore) is textually replaced with `_classname__spam`, where `classname` is the current class name with any leading underscores stripped.

The identifier can be used unchanged within the class, but to access it outside the class, the mangled name must be used:

```
class A:
    def __one(self):
        return 1
    def two(self):
        return 2 * self.__one()
```

```
class B(A):
    def three(self):
        return 3 * self._A__one()

four = 4 * A()._A__one()
```

In particular, this does not guarantee privacy since an outside user can still deliberately access the private attribute; many Python programmers never bother to use private variable names at all.

See also

The private name mangling specifications for details and special cases.

My class defines __del__ but it is not called when I delete the object.

There are several possible reasons for this.

The `del` statement does not necessarily call `__del__()` – it simply decrements the object's reference count, and if this reaches zero `__del__()` is called.

If your data structures contain circular links (e.g. a tree where each child has a parent reference and each parent has a list of children) the reference counts will never go back to zero. Once in a while Python runs an algorithm to detect such cycles, but the garbage collector might run some time after the last reference to your data structure vanishes, so your `__del__()` method may be called at an inconvenient and random time. This is inconvenient if you're trying to reproduce a problem. Worse, the order in which object's `__del__()` methods are executed is arbitrary. You can run `gc.collect()` to force a collection, but there *are* pathological cases where objects will never be collected.

Despite the cycle collector, it’s still a good idea to define an explicit `close()` method on objects to be called whenever you’re done with them. The `close()` method can then remove attributes that refer to subobjects. Don’t call **`__del__()`** directly – **`__del__()`** should call `close()` and `close()` should make sure that it can be called more than once for the same object.

Another way to avoid cyclical references is to use the `weakref` module, which allows you to point to objects without incrementing their reference count. Tree data structures, for instance, should use weak references for their parent and sibling references (if they need them!).

Finally, if your **`__del__()`** method raises an exception, a warning message is printed to `sys.stderr`.

How do I get a list of all instances of a given class?

Python does not keep track of all instances of a class (or of a built-in type). You can program the class’s constructor to keep track of all instances by keeping a list of weak references to each instance.

Why does the result of `id()` appear to be not unique?

The `id()` builtin returns an integer that is guaranteed to be unique during the lifetime of the object. Since in CPython, this is the object’s memory address, it happens frequently that after an object is deleted from memory, the next freshly created object is allocated at the same position in memory. This is illustrated by this example:

```
>>> id(1000)
13901272
>>> id(2000)
13901272
```

The two ids belong to different integer objects that are created before, and deleted immediately after execution of the `id()` call. To be sure that objects whose id you want to examine are still alive, create another reference to the object:

```
>>> a = 1000; b = 2000
>>> id(a)
13901272
>>> id(b)
13891296
```

When can I rely on identity tests with the *is* operator?

The `is` operator tests for object identity. The test `a is b` is equivalent to `id(a) == id(b)`.

The most important property of an identity test is that an object is always identical to itself, `a is a` always returns `True`. Identity tests are usually faster than equality tests. And unlike equality tests, identity tests are guaranteed to return a boolean `True` or `False`.

However, identity tests can *only* be substituted for equality tests when object identity is assured. Generally, there are three circumstances where identity is guaranteed:

1. Assignments create new names but do not change object identity. After the assignment `new = old`, it is

guaranteed that `new is old`.
2. Putting an object in a container that stores object references does not change object identity. After the list assignment `s[0] = x`, it is guaranteed that `s[0] is x`.
3. If an object is a singleton, it means that only one instance of that object can exist. After the assignments `a = None` and `b = None`, it is guaranteed that `a is b` because `None` is a singleton.

In most other circumstances, identity tests are inadvisable and equality tests are preferred. In particular, identity tests should not be used to check constants such as **`int`** and **`str`** which aren't guaranteed to be singletons:

```
>>> a = 1000
>>> b = 500
>>> c = b + 500
>>> a is c
False

>>> a = 'Python'
>>> b = 'Py'
>>> c = b + 'thon'
>>> a is c
False
```

Likewise, new instances of mutable containers are never identical:

```
>>> a = []
>>> b = []
>>> a is b
False
```

In the standard library code, you will see several common patterns for correctly using identity tests:

1. As recommended by **PEP 8** [https://peps.python.org/pep-0008/], an identity test is the preferred way to check for `None`.

This reads like plain English in code and avoids confusion with other objects that may have boolean values that evaluate to false.

2. Detecting optional arguments can be tricky when `None` is a valid input value. In those situations, you can create a singleton sentinel object guaranteed to be distinct from other objects. For example, here is how to implement a method that behaves like **`dict.pop()`**:

   ```
   _sentinel = object()

   def pop(self, key, default=_sentinel):
       if key in self:
           value = self[key]
           del self[key]
           return value
       if default is _sentinel:
           raise KeyError(key)
       return default
   ```

3. Container implementations sometimes need to augment equality tests with identity tests. This prevents the code from being confused by objects such as `float('NaN')` that are not equal to themselves.

For example, here is the implementation of **`collections.abc.Sequence.__contains__()`**:

```
def __contains__(self, value):
    for v in self:
        if v is value or v == value:
            return True
    return False
```

How can a subclass control what data is stored in an immutable instance?

When subclassing an immutable type, override the `__new__()` method instead of the `__init__()` method. The latter only runs *after* an instance is created, which is too late to alter data in an immutable instance.

All of these immutable classes have a different signature than their parent class:

```
from datetime import date

class FirstOfMonthDate(date):
    "Always choose the first day of the month"
    def __new__(cls, year, month, day):
        return super().__new__(cls, year, month, 1)

class NamedInt(int):
    "Allow text names for some numbers"
    xlat = {'zero': 0, 'one': 1, 'ten': 10}
    def __new__(cls, value):
        value = cls.xlat.get(value, value)
        return super().__new__(cls, value)

class TitleStr(str):
    "Convert str to name suitable for a URL path"
    def __new__(cls, s):
        s = s.lower().replace(' ', '-')
        s = ''.join([c for c in s if c.isalnum() or c == '-'])
        return super().__new__(cls, s)
```

The classes can be used like this:

```
>>> FirstOfMonthDate(2012, 2, 14)
FirstOfMonthDate(2012, 2, 1)
>>> NamedInt('ten')
10
>>> NamedInt(20)
20
>>> TitleStr('Blog: Why Python Rocks')
'blog-why-python-rocks'
```

How do I cache method calls?

The two principal tools for caching methods are `functools.cached_property()` and `functools.lru_cache()`. The former stores results at the instance level and the latter at the class level.

The *cached_property* approach only works with methods that do not take any arguments. It does not create a reference to the instance. The cached method result will be kept only as long as the instance is alive.

The advantage is that when an instance is no longer used, the cached method result will be released right away. The disadvantage is that if instances accumulate, so too will the accumulated method results. They can grow without bound.

The *lru_cache* approach works with methods that have hashable arguments. It creates a reference to the instance unless special efforts are made to pass in weak references.

The advantage of the least recently used algorithm is that the cache is bounded by the specified *maxsize*. The disadvantage is that instances are kept alive until they age out of the cache or until the cache is cleared.

This example shows the various techniques:

```
class Weather:
    "Lookup weather information on a government website"

    def __init__(self, station_id):
        self._station_id = station_id
        # The _station_id is private and immutable

    def current_temperature(self):
        "Latest hourly observation"
        # Do not cache this because old results
        # can be out of date.

    @cached_property
    def location(self):
        "Return the longitude/latitude coordinates of the
station"
        # Result only depends on the station_id

    @lru_cache(maxsize=20)
    def historic_rainfall(self, date, units='mm'):
        "Rainfall on a given date"
        # Depends on the station_id, date, and units.
```

The above example assumes that the *station_id* never changes. If the relevant instance attributes are mutable, the *cached_property* approach can’t be made to work because it cannot detect changes to the attributes.

To make the *lru_cache* approach work when the *station_id* is mutable, the class needs to define the `__eq__()` and `__hash__()` methods so that the cache can detect relevant attribute updates:

```
class Weather:
    "Example with a mutable station identifier"

    def __init__(self, station_id):
        self.station_id = station_id

    def change_station(self, station_id):
        self.station_id = station_id

    def __eq__(self, other):
        return self.station_id == other.station_id

    def __hash__(self):
        return hash(self.station_id)

    @lru_cache(maxsize=20)
    def historic_rainfall(self, date, units='cm'):
        'Rainfall on a given date'
        # Depends on the station_id, date, and units.
```

Modules

How do I create a .pyc file?

When a module is imported for the first time (or when the source file has changed since the current compiled file was created) a `.pyc` file containing the compiled code should be created in a `__pycache__` subdirectory of the directory containing the `.py` file. The `.pyc` file will have a filename that starts with the same name as the `.py` file, and ends with `.pyc`, with a middle component that depends on the particular `python` binary that created it. (See **PEP 3147** [https://peps.python.org/pep-3147/] for details.)

One reason that a `.pyc` file may not be created is a permissions problem with the directory containing the source file, meaning that the `__pycache__` subdirectory cannot be created. This can happen, for example, if you develop as one user but run as another, such as if you are testing with a web server.

Unless the `PYTHONDONTWRITEBYTECODE` environment variable is set, creation of a .pyc file is automatic if you're importing a module and Python has the ability (permissions, free space, etc…) to create a `__pycache__` subdirectory and write the compiled module to that subdirectory.

Running Python on a top level script is not considered an import and no `.pyc` will be created. For example, if you have a top-level module `foo.py` that imports another module `xyz.py`, when you run `foo` (by typing `python foo.py` as a shell command), a `.pyc` will be created for `xyz` because `xyz` is imported, but no `.pyc` file will be created for `foo` since `foo.py` isn't being imported.

If you need to create a `.pyc` file for `foo` – that is, to create a `.pyc` file for a module that is not imported – you can, using the **`py_compile`** and **`compileall`** modules.

The **`py_compile`** module can manually compile any module. One way is to use the `compile()` function in that module interactively:

```
>>> import py_compile
>>> py_compile.compile('foo.py')
```

This will write the `.pyc` to a `__pycache__` subdirectory in the same location as `foo.py` (or you can override that with the optional parameter `cfile`).

You can also automatically compile all files in a directory or directories using the **`compileall`** module. You can do it from the shell prompt by running `compileall.py` and providing the path of a directory containing Python files to compile:

```
python -m compileall .
```

How do I find the current module name?

A module can find out its own module name by looking at the predefined global variable `__name__`. If this has the value `'__main__'`, the program is running as a script. Many modules that are usually used by importing them also provide a command-line interface or a self-test, and only execute this code after checking `__name__`:

```
def main():
    print('Running test...')
    ...

if __name__ == '__main__':
    main()
```

How can I have modules that mutually import each other?

Suppose you have the following modules:

`foo.py`:

```
from bar import bar_var
foo_var = 1
```

`bar.py`:

```
from foo import foo_var
bar_var = 2
```

The problem is that the interpreter will perform the following steps:

- main imports `foo`
- Empty globals for `foo` are created
- `foo` is compiled and starts executing
- `foo` imports `bar`
- Empty globals for `bar` are created
- `bar` is compiled and starts executing
- `bar` imports `foo` (which is a no-op since there already is a module named `foo`)
- The import mechanism tries to read `foo_var` from `foo` globals, to set `bar.foo_var = foo.foo_var`

The last step fails, because Python isn’t done with interpreting `foo` yet and the global symbol dictionary for `foo` is still empty.

The same thing happens when you use `import foo`, and then try to access `foo.foo_var` in global code.

There are (at least) three possible workarounds for this problem.

Guido van Rossum recommends avoiding all uses of `from <module> import ...`, and placing all code inside functions. Initializations of global variables and class variables should use constants or built-in functions only. This means everything from an imported module is referenced as `<module>.<name>`.

Jim Roskind suggests performing steps in the following order in each module:

- exports (globals, functions, and classes that don't need imported base classes)
- `import` statements
- active code (including globals that are initialized from imported values).

Van Rossum doesn't like this approach much because the imports appear in a strange place, but it does work.

Matthias Urlichs recommends restructuring your code so that the recursive import is not necessary in the first place.

These solutions are not mutually exclusive.

__import__('x.y.z') returns <module 'x'>; how do I get z?

Consider using the convenience function `import_module()` from `importlib` instead:

```
z = importlib.import_module('x.y.z')
```

When I edit an imported module and reimport it, the changes don't show up. Why does this

happen?

For reasons of efficiency as well as consistency, Python only reads the module file on the first time a module is imported. If it didn't, in a program consisting of many modules where each one imports the same basic module, the basic module would be parsed and re-parsed many times. To force re-reading of a changed module, do this:

```
import importlib
import modname
importlib.reload(modname)
```

Warning: this technique is not 100% fool-proof. In particular, modules containing statements like

```
from modname import some_objects
```

will continue to work with the old version of the imported objects. If the module contains class definitions, existing class instances will *not* be updated to use the new class definition. This can result in the following paradoxical behaviour:

```
>>> import importlib
>>> import cls
>>> c = cls.C()                # Create an instance of C
>>> importlib.reload(cls)
<module 'cls' from 'cls.py'>
>>> isinstance(c, cls.C)       # isinstance is false?!?
False
```

The nature of the problem is made clear if you print out the "identity" of the class objects:

```
>>> hex(id(c.__class__))
'0x7352a0'
>>> hex(id(cls.C))
'0x4198d0'
```

- Why does Python allow commas at the end of lists and tuples?

Why does Python use indentation for grouping of statements?

Guido van Rossum believes that using indentation for grouping is extremely elegant and contributes a lot to the clarity of the average Python program. Most people learn to love this feature after a while.

Since there are no begin/end brackets there cannot be a disagreement between grouping perceived by the parser and the human reader. Occasionally C programmers will encounter a fragment of code like this:

```
if (x <= y)
        x++;
        y--;
z++;
```

Only the `x++` statement is executed if the condition is true, but the indentation leads many to believe otherwise. Even experienced C programmers will sometimes stare at it a long time wondering as to why `y` is being decremented even for `x > y`.

Because there are no begin/end brackets, Python is much less prone to coding-style conflicts. In C there are many different ways to place the braces. After becoming used to reading and writing code using a particular style, it is normal to feel somewhat uneasy when reading (or being required to write) in a different one.

Many coding styles place begin/end brackets on a line by themselves. This makes programs considerably longer and wastes valuable screen space, making it harder to get a good overview of a program. Ideally, a function should fit on one screen (say, 20–30 lines). 20 lines of Python can do a lot more work than 20 lines of C. This is not solely due to the lack of begin/end brackets – the lack of declarations and the high-level data types are also responsible – but the indentation-based syntax certainly helps.

Why am I getting strange results with simple arithmetic operations?

See the next question.

Why are floating-point calculations so inaccurate?

Users are often surprised by results like this:

```
>>> 1.2 - 1.0
0.19999999999999996
```

and think it is a bug in Python. It’s not. This has little to do with Python, and much more to do with how the underlying platform handles floating-point numbers.

The **`float`** type in CPython uses a C `double` for storage. A **`float`** object’s value is stored in binary floating-point with a fixed precision (typically 53 bits) and Python uses C operations, which in turn rely on the hardware implementation in the processor, to perform floating-point operations. This means that as far as floating-point operations are concerned, Python behaves like many popular languages including C and Java.

Many numbers that can be written easily in decimal notation cannot be expressed exactly in binary floating point. For example, after:

```
>>> x = 1.2
```

the value stored for `x` is a (very good) approximation to the decimal value `1.2`, but is not exactly equal to it. On a typical machine, the actual stored value is:

```
1.0011001100110011001100110011001100110011001100110011 (binary)
```

which is exactly:

```
1.1999999999999999555910790149937383830547332763671875
(decimal)
```

The typical precision of 53 bits provides Python floats with 15–16 decimal digits of accuracy.

For a fuller explanation, please see the floating-point arithmetic chapter in the Python tutorial.

Why are Python strings immutable?

There are several advantages.

One is performance: knowing that a string is immutable means we can allocate space for it at creation time, and the storage requirements are fixed and unchanging. This is also one of the reasons for the distinction between tuples and lists.

Another advantage is that strings in Python are considered as “elemental” as numbers. No amount of activity will change the value 8 to anything else, and in Python, no amount of activity will change the string “eight” to anything else.

Why must ‘self’ be used explicitly in method definitions and calls?

The idea was borrowed from Modula-3. It turns out to be very useful, for a variety of reasons.

First, it’s more obvious that you are using a method or instance attribute instead of a local variable. Reading `self.x` or `self.meth()` makes it absolutely clear that an instance variable or method is used even if you don’t know the class definition by heart. In C++, you can sort of tell by the lack of a local variable declaration (assuming globals are rare or easily recognizable) – but in Python, there are no local variable declarations, so you’d have to look up the class definition to be sure. Some C++ and Java coding standards call for instance attributes to have an `m_` prefix, so this explicitness is still useful in those languages, too.

Second, it means that no special syntax is necessary if you want to explicitly reference or call the method from a particular class. In C++, if you want to use a method from a base class which is overridden in a derived class, you have to use the `::` operator – in Python you can write `baseclass.methodname(self, <argument list>)`. This is particularly useful for `__init__()` methods, and in general in cases where a derived class method wants to extend the base class method of the same name and thus has to call the base class method somehow.

Finally, for instance variables it solves a syntactic problem with assignment: since local variables in Python are (by definition!) those variables to which a value is assigned in a function body (and that aren't explicitly declared global), there has to be some way to tell the interpreter that an assignment was meant to assign to an instance variable instead of to a local variable, and it should preferably be syntactic (for efficiency reasons). C++ does this through declarations, but Python doesn't have declarations and it would be a pity having to introduce them just for this purpose. Using the explicit `self.var` solves this nicely. Similarly, for using instance variables, having to write `self.var` means that references to unqualified names inside a method don't have to search the instance's directories. To put it another way, local variables and instance variables live in two different namespaces, and you need to tell Python which namespace to use.

Why can't I use an assignment in an expression?

Starting in Python 3.8, you can!

Assignment expressions using the walrus operator `:=` assign a variable in an expression:

```
while chunk := fp.read(200):
   print(chunk)
```

See **PEP 572** [https://peps.python.org/pep-0572/] for more information.

Why does Python use methods for some functionality (e.g. list.index()) but functions for other (e.g. len(list))?

As Guido said:

> (a) For some operations, prefix notation just reads better than postfix – prefix (and infix!) operations have a long tradition in mathematics which likes notations where the visuals help the mathematician thinking about a problem. Compare the easy with which we rewrite a formula like x*(a+b) into x*a + x*b to the clumsiness of doing the same thing using a raw OO notation.
>
> (b) When I read code that says len(x) I *know* that it is asking for the length of something. This tells me two things: the result is an integer, and the argument is some kind of container. To the contrary, when I read x.len(), I have to already know that x is some kind of container implementing an interface or inheriting from a class that has a standard len(). Witness the confusion we occasionally have when a class that is not implementing a mapping has a get() or keys() method, or something that isn't a file has a write() method.

Why is join() a string method instead of a list or tuple method?

Strings became much more like other standard types starting in Python 1.6, when methods were added which give the same functionality that has always been available using the functions of the string module. Most of these new methods have been widely accepted, but the one which appears to make some programmers feel uncomfortable is:

```
", ".join(['1', '2', '4', '8', '16'])
```

which gives the result:

```
"1, 2, 4, 8, 16"
```

There are two common arguments against this usage.

The first runs along the lines of: “It looks really ugly using a method of a string literal (string constant)”, to which the answer is that it might, but a string literal is just a fixed value. If the methods are to be allowed on names bound to strings there is no logical reason to make them unavailable on literals.

The second objection is typically cast as: “I am really telling a sequence to join its members together with a string constant”. Sadly, you aren’t. For some reason there seems to be much less difficulty with having `split()` as a string method, since in that case it is easy to see that

```
"1, 2, 4, 8, 16".split(", ")
```

is an instruction to a string literal to return the substrings delimited by the given separator (or, by default, arbitrary runs of white space).

`join()` is a string method because in using it you are telling the separator string to iterate over a sequence of strings and insert itself between adjacent elements. This method can be used with any argument which obeys the rules for sequence objects, including any new classes you might define yourself. Similar methods exist for bytes and bytearray objects.

How fast are exceptions?

A `try`/`except` block is extremely efficient if no exceptions are raised. Actually catching an exception is expensive. In versions of Python prior to 2.0 it was common to use this idiom:

```
try:
    value = mydict[key]
except KeyError:
    mydict[key] = getvalue(key)
    value = mydict[key]
```

This only made sense when you expected the dict to have the key almost all the time. If that wasn't the case, you coded it like this:

```
if key in mydict:
    value = mydict[key]
else:
    value = mydict[key] = getvalue(key)
```

For this specific case, you could also use `value = dict.setdefault(key, getvalue(key))`, but only if the `getvalue()` call is cheap enough because it is evaluated in all cases.

Why isn’t there a switch or case statement in Python?

In general, structured switch statements execute one block of code when an expression has a particular value or set of values. Since Python 3.10 one can easily match literal values, or constants within a namespace, with a `match ... case` statement. An older alternative is a sequence of `if... elif... elif... else`.

For cases where you need to choose from a very large number of possibilities, you can create a dictionary mapping case values to functions to call. For example:

```
functions = {'a': function_1,
             'b': function_2,
             'c': self.method_1}

func = functions[value]
func()
```

For calling methods on objects, you can simplify yet further by using the `getattr()` built-in to retrieve methods with a particular name:

```
class MyVisitor:
    def visit_a(self):
        ...

    def dispatch(self, value):
        method_name = 'visit_' + str(value)
        method = getattr(self, method_name)
        method()
```

It’s suggested that you use a prefix for the method names, such as `visit_` in this example. Without such a prefix, if values are coming from an untrusted source, an attacker would be able to call any method on your object.

Imitating switch with fallthrough, as with C's switch-case-default, is possible, much harder, and less needed.

Can't you emulate threads in the interpreter instead of relying on an OS-specific thread implementation?

Answer 1: Unfortunately, the interpreter pushes at least one C stack frame for each Python stack frame. Also, extensions can call back into Python at almost random moments. Therefore, a complete threads implementation requires thread support for C.

Answer 2: Fortunately, there is Stackless Python [https://github.com/stackless-dev/stackless/wiki], which has a completely redesigned interpreter loop that avoids the C stack.

Why can't lambda expressions contain statements?

Python lambda expressions cannot contain statements because Python's syntactic framework can't handle statements nested inside expressions. However, in Python, this is not a serious problem. Unlike lambda forms in other languages, where they add functionality, Python lambdas are only a shorthand notation if you're too lazy to define a function.

Functions are already first class objects in Python, and can be declared in a local scope. Therefore the only advantage of using a lambda instead of a locally defined function is that you don't need to invent a name for the function – but that's just a local variable to which the function object (which is exactly the same type of object that a lambda expression yields) is assigned!

Can Python be compiled to machine code, C or some other language?

Cython [https://cython.org/] compiles a modified version of Python with optional annotations into C extensions. Nuitka [https://nuitka.net/] is an up-and-coming compiler of Python into C++ code, aiming to support the full Python language.

How does Python manage memory?

The details of Python memory management depend on the implementation. The standard implementation of Python, CPython, uses reference counting to detect inaccessible objects, and another mechanism to collect reference cycles, periodically executing a cycle detection algorithm which looks for inaccessible cycles and deletes the objects involved. The **`gc`** module provides functions to perform a garbage collection, obtain debugging statistics, and tune the collector's parameters.

Other implementations (such as Jython [https://www.jython.org] or PyPy [https://pypy.org]), however, can rely on a different mechanism such as a full-blown garbage collector. This difference can cause some subtle porting problems if your Python code depends on the behavior of the reference counting implementation.

In some Python implementations, the following code (which is fine in CPython) will probably run out of file descriptors:

```
for file in very_long_list_of_files:
    f = open(file)
    c = f.read(1)
```

Indeed, using CPython's reference counting and destructor scheme, each new assignment to `f` closes the previous file. With a traditional GC, however, those file objects will only get collected (and closed) at varying and possibly long intervals.

If you want to write code that will work with any Python implementation, you should explicitly close the file or use the **`with`** statement; this will work regardless of memory management scheme:

```
for file in very_long_list_of_files:
    with open(file) as f:
        c = f.read(1)
```

Why doesn't CPython use a more traditional garbage collection scheme?

For one thing, this is not a C standard feature and hence it's not portable. (Yes, we know about the Boehm GC library. It has bits of assembler code for *most* common platforms, not for all of them, and although it is mostly transparent, it isn't completely transparent; patches are required to get Python to work with it.)

Traditional GC also becomes a problem when Python is embedded into other applications. While in a standalone Python it's fine to replace the standard `malloc()` and `free()` with versions provided by the GC library, an application embedding Python may want to have its *own* substitute for `malloc()` and `free()`, and may not want Python's. Right now, CPython works with anything that implements `malloc()` and `free()` properly.

Why isn’t all memory freed when CPython exits?

Objects referenced from the global namespaces of Python modules are not always deallocated when Python exits. This may happen if there are circular references. There are also certain bits of memory that are allocated by the C library that are impossible to free (e.g. a tool like Purify will complain about these). Python is, however, aggressive about cleaning up memory on exit and does try to destroy every single object.

If you want to force Python to delete certain things on deallocation use the `atexit` module to run a function that will force those deletions.

Why are there separate tuple and list data types?

Lists and tuples, while similar in many respects, are generally used in fundamentally different ways. Tuples can be thought of as being similar to Pascal `records` or C `structs`; they’re small collections of related data which may be of different types which are operated on as a group. For example, a Cartesian coordinate is appropriately represented as a tuple of two or three numbers.

Lists, on the other hand, are more like arrays in other languages. They tend to hold a varying number of objects all of which have the same type and which are operated on one-by-one. For example, `os.listdir('.')` returns a list of strings representing the files in the current directory. Functions which operate on this output would generally not break if you added another file or two to the directory.

Tuples are immutable, meaning that once a tuple has been created, you can’t replace any of its elements with a new value. Lists are mutable, meaning that you can always change a list’s elements. Only immutable elements can be used as dictionary keys, and hence only tuples and not lists can be used as keys.

How are lists implemented in CPython?

CPython’s lists are really variable-length arrays, not Lisp-style linked lists. The implementation uses a contiguous array of references to other objects, and keeps a pointer to this array and the array’s length in a list head structure.

This makes indexing a list `a[i]` an operation whose cost is independent of the size of the list or the value of the index.

When items are appended or inserted, the array of references is resized. Some cleverness is applied to improve the performance of appending items repeatedly; when the array must be grown, some extra space is allocated so the next few times don’t require an actual resize.

How are dictionaries implemented in CPython?

CPython’s dictionaries are implemented as resizable hash tables. Compared to B-trees, this gives better performance for lookup (the most common operation by far) under most circumstances, and the implementation is simpler.

Dictionaries work by computing a hash code for each key stored in the dictionary using the `hash()` built-in function.

The hash code varies widely depending on the key and a per-process seed; for example, `'Python'` could hash to `-539294296` while `'python'`, a string that differs by a single bit, could hash to `1142331976`. The hash code is then used to calculate a location in an internal array where the value will be stored. Assuming that you're storing keys that all have different hash values, this means that dictionaries take constant time – *O*(1), in Big-O notation – to retrieve a key.

Why must dictionary keys be immutable?

The hash table implementation of dictionaries uses a hash value calculated from the key value to find the key. If the key were a mutable object, its value could change, and thus its hash could also change. But since whoever changes the key object can't tell that it was being used as a dictionary key, it can't move the entry around in the dictionary. Then, when you try to look up the same object in the dictionary it won't be found because its hash value is different. If you tried to look up the old value it wouldn't be found either, because the value of the object found in that hash bin would be different.

If you want a dictionary indexed with a list, simply convert the list to a tuple first; the function `tuple(L)` creates a tuple with the same entries as the list `L`. Tuples are immutable and can therefore be used as dictionary keys.

Some unacceptable solutions that have been proposed:

- Hash lists by their address (object ID). This doesn't work because if you construct a new list with the same value it won't be found; e.g.:

```
mydict = {[1, 2]: '12'}
print(mydict[[1, 2]])
```

would raise a `KeyError` exception because the id of the `[1, 2]` used in the second line differs from that in the first line. In other words, dictionary keys should be compared using `==`, not using `is`.

- Make a copy when using a list as a key. This doesn’t work because the list, being a mutable object, could contain a reference to itself, and then the copying code would run into an infinite loop.

- Allow lists as keys but tell the user not to modify them. This would allow a class of hard-to-track bugs in programs when you forgot or modified a list by accident. It also invalidates an important invariant of dictionaries: every value in `d.keys()` is usable as a key of the dictionary.

- Mark lists as read-only once they are used as a dictionary key. The problem is that it’s not just the top-level object that could change its value; you could use a tuple containing a list as a key. Entering anything as a key into a dictionary would require marking all objects reachable from there as read-only – and again, self-referential objects could cause an infinite loop.

There is a trick to get around this if you need to, but use it at your own risk: You can wrap a mutable structure inside a class instance which has both a `__eq__()` and a `__hash__()` method. You must then make sure that the hash value for all such wrapper objects that reside in a dictionary (or other hash based structure), remain fixed while the object is in the dictionary (or other structure).

```
class ListWrapper:
    def __init__(self, the_list):
        self.the_list = the_list

    def __eq__(self, other):
        return self.the_list == other.the_list

    def __hash__(self):
        l = self.the_list
        result = 98767 - len(l)*555
        for i, el in enumerate(l):
            try:
                result = result + (hash(el) % 9999999) * 1001 +
i
            except Exception:
                result = (result % 7777777) + i * 333
        return result
```

Note that the hash computation is complicated by the possibility that some members of the list may be unhashable and also by the possibility of arithmetic overflow.

Furthermore it must always be the case that if `o1 == o2` (ie `o1.__eq__(o2) is True`) then `hash(o1) == hash(o2)` (ie, `o1.__hash__() == o2.__hash__()`), regardless of whether the object is in a dictionary or not. If you fail to meet these restrictions dictionaries and other hash based structures will misbehave.

In the case of **`ListWrapper`**, whenever the wrapper object is in a dictionary the wrapped list must not change to avoid anomalies. Don’t do this unless you are prepared to think hard about the requirements and the consequences of not meeting them correctly. Consider yourself warned.

Why doesn’t list.sort() return the sorted list?

In situations where performance matters, making a copy of the list just to sort it would be wasteful. Therefore, `list.sort()` sorts the list in place. In order to remind you of that fact, it does not return the sorted list. This way, you won't be fooled into accidentally overwriting a list when you need a sorted copy but also need to keep the unsorted version around.

If you want to return a new list, use the built-in `sorted()` function instead. This function creates a new list from a provided iterable, sorts it and returns it. For example, here's how to iterate over the keys of a dictionary in sorted order:

```
for key in sorted(mydict):
    ...  # do whatever with mydict[key]...
```

How do you specify and enforce an interface spec in Python?

An interface specification for a module as provided by languages such as C++ and Java describes the prototypes for the methods and functions of the module. Many feel that compile-time enforcement of interface specifications helps in the construction of large programs.

Python 2.6 adds an `abc` module that lets you define Abstract Base Classes (ABCs). You can then use `isinstance()` and `issubclass()` to check whether an instance or a class implements a particular ABC. The `collections.abc` module defines a set of useful ABCs such as `Iterable`, `Container`, and `MutableMapping`.

For Python, many of the advantages of interface specifications can be obtained by an appropriate test discipline for components.

A good test suite for a module can both provide a regression test and serve as a module interface specification and a set of examples. Many Python modules can be run as a script to provide a simple “self test.” Even modules which use complex external interfaces can often be tested in isolation using trivial “stub” emulations of the external interface. The `doctest` and `unittest` modules or third-party test frameworks can be used to construct exhaustive test suites that exercise every line of code in a module.

An appropriate testing discipline can help build large complex applications in Python as well as having interface specifications would. In fact, it can be better because an interface specification cannot test certain properties of a program. For example, the `list.append()` method is expected to add new elements to the end of some internal list; an interface specification cannot test that your `list.append()` implementation will actually do this correctly, but it’s trivial to check this property in a test suite.

Writing test suites is very helpful, and you might want to design your code to make it easily tested. One increasingly popular technique, test-driven development, calls for writing parts of the test suite first, before you write any of the actual code. Of course Python allows you to be sloppy and not write test cases at all.

Why is there no goto?

In the 1970s people realized that unrestricted goto could lead to messy “spaghetti” code that was hard to understand and revise. In a high-level language, it is also unneeded as long as there are ways to branch (in Python, with `if` statements and `or`, `and`, and `if`/`else` expressions) and loop (with `while` and `for` statements, possibly containing `continue` and `break`).

One can also use exceptions to provide a “structured goto” that works even across function calls. Many feel that exceptions can conveniently emulate all reasonable uses of the `go` or `goto` constructs of C, Fortran, and other languages. For example:

```
class label(Exception): pass  # declare a label

try:
    ...
    if condition: raise label()  # goto label
    ...
except label:  # where to goto
    pass
...
```

This doesn’t allow you to jump into the middle of a loop, but that’s usually considered an abuse of `goto` anyway. Use sparingly.

Why can’t raw strings (r-strings) end with a backslash?

More precisely, they can’t end with an odd number of backslashes: the unpaired backslash at the end escapes the closing quote character, leaving an unterminated string.

Raw strings were designed to ease creating input for processors (chiefly regular expression engines) that want to do their own backslash escape processing. Such processors consider an unmatched trailing backslash to be an error anyway, so raw strings disallow that. In return, they allow you to pass on the string quote character by escaping it with a backslash. These rules work well when r-strings are used for their intended purpose.

If you’re trying to build Windows pathnames, note that all Windows system calls accept forward slashes too:

```
f = open("/mydir/file.txt")  # works fine!
```

If you’re trying to build a pathname for a DOS command, try e.g. one of

```
dir = r"\this\is\my\dos\dir" "\\"
dir = r"\this\is\my\dos\dir\ "[:-1]
dir = "\\this\\is\\my\\dos\\dir\\"
```

Why doesn’t Python have a “with” statement for attribute assignments?

Python has a `with` statement that wraps the execution of a block, calling code on the entrance and exit from the block. Some languages have a construct that looks like this:

```
with obj:
    a = 1               # equivalent to obj.a = 1
    total = total + 1   # obj.total = obj.total + 1
```

In Python, such a construct would be ambiguous.

Other languages, such as Object Pascal, Delphi, and C++, use static types, so it’s possible to know, in an unambiguous way, what member is being assigned to. This is the main point of static typing – the compiler *always* knows the scope of every variable at compile time.

Python uses dynamic types. It is impossible to know in advance which attribute will be referenced at runtime. Member attributes may be added or removed from objects on the fly. This makes it impossible to know, from a simple reading, what attribute is being referenced: a local one, a global one, or a member attribute?

For instance, take the following incomplete snippet:

```
def foo(a):
    with a:
        print(x)
```

The snippet assumes that `a` must have a member attribute called `x`. However, there is nothing in Python that tells the interpreter this. What should happen if `a` is, let us say, an integer? If there is a global variable named `x`, will it be used inside the **`with`** block? As you see, the dynamic nature of Python makes such choices much harder.

The primary benefit of **`with`** and similar language features (reduction of code volume) can, however, easily be achieved in Python by assignment. Instead of:

```
function(args).mydict[index][index].a = 21
function(args).mydict[index][index].b = 42
function(args).mydict[index][index].c = 63
```

write this:

```
ref = function(args).mydict[index][index]
ref.a = 21
ref.b = 42
ref.c = 63
```

This also has the side-effect of increasing execution speed because name bindings are resolved at run-time in Python, and the second version only needs to perform the resolution once.

Similar proposals that would introduce syntax to further reduce code volume, such as using a ‘leading dot’, have been rejected in favour of explicitness (see https://mail.python.org/pipermail/python-ideas/2016-May/040070.html).

Why don’t generators support the with statement?

For technical reasons, a generator used directly as a context manager would not work correctly. When, as is most common, a generator is used as an iterator run to completion, no closing is needed. When it is, wrap it as `contextlib.closing(generator)` in the `with` statement.

Why are colons required for the if/while/def/class statements?

The colon is required primarily to enhance readability (one of the results of the experimental ABC language). Consider this:

```
if a == b
    print(a)
```

versus

```
if a == b:
    print(a)
```

Notice how the second one is slightly easier to read. Notice further how a colon sets off the example in this FAQ answer; it’s a standard usage in English.

Another minor reason is that the colon makes it easier for editors with syntax highlighting; they can look for colons to decide when indentation needs to be increased instead of having to do a more elaborate parsing of the program text.

Why does Python allow commas at the end of lists and tuples?

Python lets you add a trailing comma at the end of lists, tuples, and dictionaries:

```
[1, 2, 3,]
('a', 'b', 'c',)
d = {
    "A": [1, 5],
    "B": [6, 7],  # last trailing comma is optional but good
style
}
```

There are several reasons to allow this.

When you have a literal value for a list, tuple, or dictionary spread across multiple lines, it’s easier to add more elements because you don’t have to remember to add a comma to the previous line. The lines can also be reordered without creating a syntax error.

Accidentally omitting the comma can lead to errors that are hard to diagnose. For example:

```
x = [
  "fee",
  "fie"
  "foo",
  "fum"
]
```

This list looks like it has four elements, but it actually contains three: “fee”, “fiefoo” and “fum”. Always adding the comma avoids this source of error.

Allowing the trailing comma may also make programmatic code generation easier.

General Library Questions

How do I find a module or application to perform task X?

Check the Library Reference to see if there’s a relevant standard library module. (Eventually you’ll learn what’s in the standard library and will be able to skip this step.)

For third-party packages, search the Python Package Index [https://pypi.org] or try Google [https://www.google.com] or another web search engine. Searching for “Python” plus a keyword or two for your topic of interest will usually find something helpful.

Where is the math.py (socket.py, regex.py, etc.) source file?

If you can’t find a source file for a module it may be a built-in or dynamically loaded module implemented in C, C++ or other compiled language. In this case you may not have the source file or it may be something like `mathmodule.c`, somewhere in a C source directory (not on the Python Path).

There are (at least) three kinds of modules in Python:

1. modules written in Python (.py);
2. modules written in C and dynamically loaded (.dll, .pyd, .so, .sl, etc);
3. modules written in C and linked with the interpreter; to get a list of these, type:

   ```
   import sys
   print(sys.builtin_module_names)
   ```

How do I make a Python script executable on Unix?

You need to do two things: the script file’s mode must be executable and the first line must begin with `#!` followed by the path of the Python interpreter.

The first is done by executing `chmod +x scriptfile` or perhaps `chmod 755 scriptfile`.

The second can be done in a number of ways. The most straightforward way is to write

```
#!/usr/local/bin/python
```

as the very first line of your file, using the pathname for where the Python interpreter is installed on your platform.

If you would like the script to be independent of where the Python interpreter lives, you can use the **env** program. Almost all Unix variants support the following, assuming the Python interpreter is in a directory on the user's **`PATH`**:

```
#!/usr/bin/env python
```

Don't do this for CGI scripts. The **`PATH`** variable for CGI scripts is often very minimal, so you need to use the actual absolute pathname of the interpreter.

Occasionally, a user's environment is so full that the **/usr/bin/env** program fails; or there's no env program at all. In that case, you can try the following hack (due to Alex Rezinsky):

```
#! /bin/sh
""":"
exec python $0 ${1+"$@"}
"""
```

The minor disadvantage is that this defines the script's __doc__ string. However, you can fix that by adding

```
__doc__ = """...Whatever..."""
```

Is there a curses/termcap package for Python?

For Unix variants: The standard Python source distribution comes with a curses module in the Modules [https://github.com/python/cpython/tree/3.14/Modules] subdirectory, though it’s not compiled by default. (Note that this is not available in the Windows distribution – there is no curses module for Windows.)

The `curses` module supports basic curses features as well as many additional functions from ncurses and SYSV curses such as colour, alternative character set support, pads, and mouse support. This means the module isn’t compatible with operating systems that only have BSD curses, but there don’t seem to be any currently maintained OSes that fall into this category.

Is there an equivalent to C’s onexit() in Python?

The `atexit` module provides a register function that is similar to C’s **`onexit()`**.

Why don’t my signal handlers work?

The most common problem is that the signal handler is declared with the wrong argument list. It is called as

```
handler(signum, frame)
```

so it should be declared with two parameters:

```
def handler(signum, frame):
    ...
```

Common tasks

How do I test a Python program or component?

Python comes with two testing frameworks. The `doctest` module finds examples in the docstrings for a module and runs them, comparing the output with the expected output given in the docstring.

The `unittest` module is a fancier testing framework modelled on Java and Smalltalk testing frameworks.

To make testing easier, you should use good modular design in your program. Your program should have almost all functionality encapsulated in either functions or class methods – and this sometimes has the surprising and delightful effect of making the program run faster (because local variable accesses are faster than global accesses). Furthermore the program should avoid depending on mutating global variables, since this makes testing much more difficult to do.

The “global main logic” of your program may be as simple as

```
if __name__ == "__main__":
    main_logic()
```

at the bottom of the main module of your program.

Once your program is organized as a tractable collection of function and class behaviours, you should write test functions that exercise the behaviours. A test suite that automates a sequence of tests can be associated with each module. This sounds like a lot of work, but since Python is so terse and flexible it’s surprisingly easy. You can make coding much more pleasant and fun by writing your test functions in parallel with the “production code”, since this makes it easy to find bugs and even design flaws earlier.

“Support modules” that are not intended to be the main module of a program may include a self-test of the module.

```
if __name__ == "__main__":
    self_test()
```

Even programs that interact with complex external interfaces may be tested when the external interfaces are unavailable by using “fake” interfaces implemented in Python.

How do I create documentation from doc strings?

The `pydoc` module can create HTML from the doc strings in your Python source code. An alternative for creating API documentation purely from docstrings is epydoc [https://epydoc.sourceforge.net/]. Sphinx [https://www.sphinx-doc.org] can also include docstring content.

How do I get a single keypress at a time?

For Unix variants there are several solutions. It’s straightforward to do this using curses, but curses is a fairly large module to learn.

Threads

How do I program using threads?

Be sure to use the `threading` module and not the `_thread` module. The `threading` module builds convenient abstractions on top of the low-level primitives provided by the `_thread` module.

None of my threads seem to run: why?

As soon as the main thread exits, all threads are killed. Your main thread is running too quickly, giving the threads no time to do any work.

A simple fix is to add a sleep to the end of the program that’s long enough for all the threads to finish:

```
import threading, time

def thread_task(name, n):
    for i in range(n):
        print(name, i)

for i in range(10):
    T = threading.Thread(target=thread_task, args=(str(i), i))
    T.start()

time.sleep(10)  # <----------------------------!
```

But now (on many platforms) the threads don’t run in parallel, but appear to run sequentially, one at a time! The reason is that the OS thread scheduler doesn’t start a new thread until the previous thread is blocked.

A simple fix is to add a tiny sleep to the start of the run function:

```
def thread_task(name, n):
    time.sleep(0.001)  # <---------------------!
    for i in range(n):
        print(name, i)

for i in range(10):
    T = threading.Thread(target=thread_task, args=(str(i), i))
    T.start()

time.sleep(10)
```

Instead of trying to guess a good delay value for `time.sleep()`, it’s better to use some kind of semaphore mechanism. One idea is to use the `queue` module to create a queue object, let each thread append a token to the queue when it finishes, and let the main thread read as many tokens from the queue as there are threads.

How do I parcel out work among a bunch of worker threads?

The easiest way is to use the `concurrent.futures` module, especially the `ThreadPoolExecutor` class.

Or, if you want fine control over the dispatching algorithm, you can write your own logic manually. Use the `queue` module to create a queue containing a list of jobs. The `Queue` class maintains a list of objects and has a `.put(obj)` method that adds items to the queue and a `.get()` method to return them. The class will take care of the locking necessary to ensure that each job is handed out exactly once.

Here’s a trivial example:

```
import threading, queue, time

# The worker thread gets jobs off the queue.  When the queue is
empty, it
# assumes there will be no more work and exits.
# (Realistically workers will run until terminated.)
def worker():
    print('Running worker')
    time.sleep(0.1)
    while True:
        try:
            arg = q.get(block=False)
        except queue.Empty:
            print('Worker', threading.current_thread(), end='
')
            print('queue empty')
            break
        else:
            print('Worker', threading.current_thread(), end='
')
            print('running with argument', arg)
            time.sleep(0.5)

# Create queue
q = queue.Queue()

# Start a pool of 5 workers
for i in range(5):
    t = threading.Thread(target=worker, name='worker %i' %
(i+1))
    t.start()

# Begin adding work to the queue
for i in range(50):
    q.put(i)

# Give threads time to run
print('Main thread sleeping')
time.sleep(5)
```

When run, this will produce the following output:

```
Running worker
Running worker
Running worker
Running worker
Running worker
Main thread sleeping
Worker <Thread(worker 1, started 130283832797456)> running with
argument 0
Worker <Thread(worker 2, started 130283824404752)> running with
argument 1
Worker <Thread(worker 3, started 130283816012048)> running with
argument 2
Worker <Thread(worker 4, started 130283807619344)> running with
argument 3
Worker <Thread(worker 5, started 130283799226640)> running with
argument 4
Worker <Thread(worker 1, started 130283832797456)> running with
argument 5
...
```

Consult the module’s documentation for more details; the `Queue` class provides a featureful interface.

What kinds of global value mutation are thread-safe?

A global interpreter lock (GIL) is used internally to ensure that only one thread runs in the Python VM at a time. In general, Python offers to switch among threads only between bytecode instructions; how frequently it switches can be set via `sys.setswitchinterval()`. Each bytecode instruction and therefore all the C implementation code reached from each instruction is therefore atomic from the point of view of a Python program.

In theory, this means an exact accounting requires an exact understanding of the PVM bytecode implementation. In practice, it means that operations on shared variables of built-in data types (ints, lists, dicts, etc) that “look atomic” really are.

For example, the following operations are all atomic (L, L1, L2 are lists, D, D1, D2 are dicts, x, y are objects, i, j are ints):

```
L.append(x)
L1.extend(L2)
x = L[i]
x = L.pop()
L1[i:j] = L2
L.sort()
x = y
x.field = y
D[x] = y
D1.update(D2)
D.keys()
```

These aren’t:

```
i = i+1
L.append(L[-1])
L[i] = L[j]
D[x] = D[x] + 1
```

Operations that replace other objects may invoke those other objects' `__del__()` method when their reference count reaches zero, and that can affect things. This is especially true for the mass updates to dictionaries and lists. When in doubt, use a mutex!

Can't we get rid of the Global Interpreter Lock?

The global interpreter lock (GIL) is often seen as a hindrance to Python's deployment on high-end multiprocessor server machines, because a multi-threaded Python program effectively only uses one CPU, due to the insistence that (almost) all Python code can only run while the GIL is held.

With the approval of **PEP 703** [https://peps.python.org/pep-0703/] work is now underway to remove the GIL from the CPython implementation of Python. Initially it will be implemented as an optional compiler flag when building the interpreter, and so separate builds will be available with and without the GIL. Long-term, the hope is to settle on a single build, once the performance implications of removing the GIL are fully understood. Python 3.13 is likely to be the first release containing this work, although it may not be completely functional in this release.

The current work to remove the GIL is based on a fork of Python 3.9 with the GIL removed [https://github.com/colesbury/nogil] by Sam Gross. Prior to that, in the days of Python 1.5, Greg Stein actually implemented a comprehensive patch set (the "free threading" patches) that removed the GIL and replaced it with fine-grained locking. Adam Olsen did a similar experiment in his python-safethread [https://code.google.com/archive/p/python-safethread] project. Unfortunately, both of these earlier experiments exhibited a sharp drop in single-thread performance (at least 30% slower), due to the amount of fine-grained locking necessary to compensate for the removal of the GIL. The Python 3.9 fork is the first attempt at removing the GIL with an acceptable performance impact.

The presence of the GIL in current Python releases doesn't mean that you can't make good use of Python on multi-CPU machines! You just have to be creative with dividing the work up between multiple *processes* rather than multiple *threads*. The **`ProcessPoolExecutor`** class in the new **`concurrent.futures`** module provides an easy way of doing so; the **`multiprocessing`** module provides a lower-level API in case you want more control over dispatching of tasks.

Judicious use of C extensions will also help; if you use a C extension to perform a time-consuming task, the extension can release the GIL while the thread of execution is in the C code and allow other threads to get some work done. Some standard library modules such as **`zlib`** and **`hashlib`** already do this.

An alternative approach to reducing the impact of the GIL is to make the GIL a per-interpreter-state lock rather than truly global. This was first implemented in Python 3.12 and is available in the C API. A Python interface to it is expected in Python 3.13. The main limitation to it at the moment is likely to be 3rd party extension modules, since these must be written with multiple interpreters in mind in order to be usable, so many older extension modules will not be usable.

Input and Output

How do I delete a file? (And other file questions…)

Use `os.remove(filename)` or `os.unlink(filename)`; for documentation, see the **`os`** module. The two functions are identical; **`unlink()`** is simply the name of the Unix system call for this function.

To remove a directory, use **`os.rmdir()`**; use **`os.mkdir()`** to create one. `os.makedirs(path)` will create any intermediate directories in `path` that don't exist. `os.removedirs(path)` will remove intermediate directories as long as they're empty; if you want to delete an entire directory tree and its contents, use **`shutil.rmtree()`**.

To rename a file, use `os.rename(old_path, new_path)`.

To truncate a file, open it using `f = open(filename, "rb+")`, and use `f.truncate(offset)`; offset defaults to the current seek position. There's also `os.ftruncate(fd, offset)` for files opened with **`os.open()`**, where *fd* is the file descriptor (a small integer).

The **`shutil`** module also contains a number of functions to work on files including **`copyfile()`**, **`copytree()`**, and **`rmtree()`**.

How do I copy a file?

The **`shutil`** module contains a **`copyfile()`** function. Note that on Windows NTFS volumes, it does not copy alternate data streams [https://en.wikipedia.org/wiki/NTFS#Alternate_data_stream_(ADS)] nor resource forks [https://en.wikipedia.org/wiki/Resource_fork] on macOS HFS+ volumes, though both are now rarely used. It also doesn't copy file permissions and metadata, though using **`shutil.copy2()`** instead will preserve most (though not all) of it.

How do I read (or write) binary data?

To read or write complex binary data formats, it’s best to use the `struct` module. It allows you to take a string containing binary data (usually numbers) and convert it to Python objects; and vice versa.

For example, the following code reads two 2-byte integers and one 4-byte integer in big-endian format from a file:

```
import struct

with open(filename, "rb") as f:
    s = f.read(8)
    x, y, z = struct.unpack(">hhl", s)
```

The ‘>’ in the format string forces big-endian data; the letter ‘h’ reads one “short integer” (2 bytes), and ‘l’ reads one “long integer” (4 bytes) from the string.

For data that is more regular (e.g. a homogeneous list of ints or floats), you can also use the `array` module.

Note

To read and write binary data, it is mandatory to open the file in binary mode (here, passing `"rb"` to `open()`). If you use `"r"` instead (the default), the file will be open in text mode and `f.read()` will return `str` objects rather than `bytes` objects.

I can’t seem to use os.read() on a pipe created with os.popen(); why?

`os.read()` is a low-level function which takes a file descriptor, a small integer representing the opened file. `os.popen()`

creates a high-level file object, the same type returned by the built-in `open()` function. Thus, to read *n* bytes from a pipe *p* created with `os.popen()`, you need to use `p.read(n)`.

How do I access the serial (RS232) port?

For Win32, OSX, Linux, BSD, Jython, IronPython:

> pyserial [https://pypi.org/project/pyserial/]

For Unix, see a Usenet post by Mitch Chapman:

> https://groups.google.com/groups?selm=34A04430.CF9@ohioee.com

Why doesn't closing sys.stdout (stdin, stderr) really close it?

Python file objects are a high-level layer of abstraction on low-level C file descriptors.

For most file objects you create in Python via the built-in `open()` function, `f.close()` marks the Python file object as being closed from Python's point of view, and also arranges to close the underlying C file descriptor. This also happens automatically in `f`'s destructor, when `f` becomes garbage.

But stdin, stdout and stderr are treated specially by Python, because of the special status also given to them by C. Running `sys.stdout.close()` marks the Python-level file object as being closed, but does *not* close the associated C file descriptor.

To close the underlying C file descriptor for one of these three, you should first be sure that's what you really want to do (e.g., you may confuse extension modules trying to do I/O). If it is, use `os.close()`:

```
os.close(stdin.fileno())
os.close(stdout.fileno())
os.close(stderr.fileno())
```

Or you can use the numeric constants 0, 1 and 2, respectively.

Network/Internet Programming

What WWW tools are there for Python?

See the chapters titled Internet Protocols and Support and Internet Data Handling in the Library Reference Manual. Python has many modules that will help you build server-side and client-side web systems.

A summary of available frameworks is maintained by Paul Boddie at https://wiki.python.org/moin/WebProgramming.

What module should I use to help with generating HTML?

You can find a collection of useful links on the Web Programming wiki page [https://wiki.python.org/moin/WebProgramming].

How do I send mail from a Python script?

Use the standard library module `smtplib`.

Here’s a very simple interactive mail sender that uses it. This method will work on any host that supports an SMTP listener.

```
import sys, smtplib

fromaddr = input("From: ")
toaddrs  = input("To: ").split(',')
print("Enter message, end with ^D:")
msg = ''
while True:
    line = sys.stdin.readline()
    if not line:
        break
    msg += line

# The actual mail send
server = smtplib.SMTP('localhost')
server.sendmail(fromaddr, toaddrs, msg)
server.quit()
```

A Unix-only alternative uses sendmail. The location of the sendmail program varies between systems; sometimes it is `/usr/lib/sendmail`, sometimes `/usr/sbin/sendmail`. The sendmail manual page will help you out. Here's some sample code:

```
import os

SENDMAIL = "/usr/sbin/sendmail"  # sendmail location
p = os.popen("%s -t -i" % SENDMAIL, "w")
p.write("To: receiver@example.com\n")
p.write("Subject: test\n")
p.write("\n")  # blank line separating headers from body
p.write("Some text\n")
p.write("some more text\n")
sts = p.close()
if sts != 0:
    print("Sendmail exit status", sts)
```

How do I avoid blocking in the connect() method of a socket?

The `select` module is commonly used to help with asynchronous I/O on sockets.

To prevent the TCP connect from blocking, you can set the socket to non-blocking mode. Then when you do the `connect()`, you will either connect immediately (unlikely) or get an exception that contains the error number as `.errno`. `errno.EINPROGRESS` indicates that the connection is in progress, but hasn't finished yet. Different OSes will return different values, so you're going to have to check what's returned on your system.

You can use the `connect_ex()` method to avoid creating an exception. It will just return the errno value. To poll, you can call `connect_ex()` again later – `0` or `errno.EISCONN` indicate that you're connected – or you can pass this socket to `select.select()` to check if it's writable.

Note

The `asyncio` module provides a general purpose single-threaded and concurrent asynchronous library, which can be used for writing non-blocking network code. The third-party Twisted [https://twisted.org/] library is a popular and feature-rich alternative.

Databases

Are there any interfaces to database packages in Python?

Yes.

Interfaces to disk-based hashes such as **`DBM`** and **`GDBM`** are also included with standard Python. There is also the **`sqlite3`** module, which provides a lightweight disk-based relational database.

Support for most relational databases is available. See the DatabaseProgramming wiki page [https://wiki.python.org/moin/DatabaseProgramming] for details.

How do you implement persistent objects in Python?

The **`pickle`** library module solves this in a very general way (though you still can’t store things like open files, sockets or windows), and the **`shelve`** library module uses pickle and (g)dbm to create persistent mappings containing arbitrary Python objects.

Mathematics and Numerics

How do I generate random numbers in Python?

The standard module **`random`** implements a random number generator. Usage is simple:

```
import random
random.random()
```

This returns a random floating-point number in the range [0, 1).

There are also many other specialized generators in this module, such as:

- `randrange(a, b)` chooses an integer in the range [a, b).

- `uniform(a, b)` chooses a floating-point number in the range [a, b).
- `normalvariate(mean, sdev)` samples the normal (Gaussian) distribution.

Some higher-level functions operate on sequences directly, such as:

- `choice(S)` chooses a random element from a given sequence.
- `shuffle(L)` shuffles a list in-place, i.e. permutes it randomly.

There’s also a `Random` class you can instantiate to create independent multiple random number generators.

    - I want to compile a Python module on my Linux system, but some files are missing. Why?
    - How do I tell “incomplete input” from “invalid input”?
    - How do I find undefined g++ symbols __builtin_new or __pure_virtual?
    - Can I create an object class with some methods implemented in C and others in Python (e.g.

through inheritance)?

Can I create my own functions in C?

Yes, you can create built-in modules containing functions, variables, exceptions and even new types in C. This is explained in the document Extending and Embedding the Python Interpreter.

Most intermediate or advanced Python books will also cover this topic.

Can I create my own functions in C++?

Yes, using the C compatibility features found in C++. Place `extern "C" { ... }` around the Python include files and put `extern "C"` before each function that is going to be called by the Python interpreter. Global or static C++ objects with constructors are probably not a good idea.

Writing C is hard; are there any alternatives?

There are a number of alternatives to writing your own C extensions, depending on what you’re trying to do. Recommended third party tools offer both simpler and more sophisticated approaches to creating C and C++ extensions for Python.

How can I execute arbitrary Python statements from C?

The highest-level function to do this is `PyRun_SimpleString()` which takes a single string argument to be executed in the context of the module `__main__` and returns `0` for success and `-1` when an exception occurred (including `SyntaxError`). If you want more control, use `PyRun_String()`; see the source for `PyRun_SimpleString()` in `Python/pythonrun.c`.

How can I evaluate an arbitrary Python expression from C?

Call the function `PyRun_String()` from the previous question with the start symbol `Py_eval_input`; it parses an expression, evaluates it and returns its value.

How do I extract C values from a Python object?

That depends on the object's type. If it's a tuple, `PyTuple_Size()` returns its length and `PyTuple_GetItem()` returns the item at a specified index. Lists have similar functions, `PyList_Size()` and `PyList_GetItem()`.

For bytes, `PyBytes_Size()` returns its length and `PyBytes_AsStringAndSize()` provides a pointer to its value and its length. Note that Python bytes objects may contain null bytes so C's **`strlen()`** should not be used.

To test the type of an object, first make sure it isn't `NULL`, and then use `PyBytes_Check()`, `PyTuple_Check()`, `PyList_Check()`, etc.

There is also a high-level API to Python objects which is provided by the so-called 'abstract' interface – read `Include/abstract.h` for further details. It allows interfacing with any kind of Python sequence using calls like

`PySequence_Length()`, `PySequence_GetItem()`, etc. as well as many other useful protocols such as numbers (`PyNumber_Index()` et al.) and mappings in the PyMapping APIs.

How do I use Py_BuildValue() to create a tuple of arbitrary length?

You can’t. Use `PyTuple_Pack()` instead.

How do I call an object’s method from C?

The `PyObject_CallMethod()` function can be used to call an arbitrary method of an object. The parameters are the object, the name of the method to call, a format string like that used with `Py_BuildValue()`, and the argument values:

```
PyObject *
PyObject_CallMethod(PyObject *object, const char *method_name,
                    const char *arg_format, ...);
```

This works for any object that has methods – whether built-in or user-defined. You are responsible for eventually `Py_DECREF()`‘ing the return value.

To call, e.g., a file object’s “seek” method with arguments 10, 0 (assuming the file object pointer is “f”):

```
res = PyObject_CallMethod(f, "seek", "(ii)", 10, 0);
if (res == NULL) {
        ... an exception occurred ...
}
else {
        Py_DECREF(res);
}
```

Note that since `PyObject_CallObject()` *always* wants a tuple for the argument list, to call a function without arguments, pass “()” for the format, and to call a function with one argument, surround the argument in parentheses, e.g. “(i)”.

How do I catch the output from PyErr_Print() (or anything that prints to stdout/stderr)?

In Python code, define an object that supports the `write()` method. Assign this object to `sys.stdout` and `sys.stderr`. Call print_error, or just allow the standard traceback mechanism to work. Then, the output will go wherever your `write()` method sends it.

The easiest way to do this is to use the `io.StringIO` class:

```
>>> import io, sys
>>> sys.stdout = io.StringIO()
>>> print('foo')
>>> print('hello world!')
>>> sys.stderr.write(sys.stdout.getvalue())
foo
hello world!
```

A custom object to do the same would look like this:

```
>>> import io, sys
>>> class StdoutCatcher(io.TextIOBase):
...     def __init__(self):
...         self.data = []
...     def write(self, stuff):
...         self.data.append(stuff)
...
>>> import sys
>>> sys.stdout = StdoutCatcher()
>>> print('foo')
>>> print('hello world!')
>>> sys.stderr.write(''.join(sys.stdout.data))
foo
hello world!
```

How do I access a module written in Python from C?

You can get a pointer to the module object as follows:

```
module = PyImport_ImportModule("<modulename>");
```

If the module hasn’t been imported yet (i.e. it is not yet present in `sys.modules`), this initializes the module; otherwise it simply returns the value of `sys.modules["<modulename>"]`. Note that it doesn’t enter the module into any namespace – it only ensures it has been initialized and is stored in `sys.modules`.

You can then access the module’s attributes (i.e. any name defined in the module) as follows:

```
attr = PyObject_GetAttrString(module, "<attrname>");
```

Calling `PyObject_SetAttrString()` to assign to variables in the module also works.

How do I interface to C++ objects from Python?

Depending on your requirements, there are many approaches. To do this manually, begin by reading the “Extending and Embedding” document. Realize that for the Python run-time system, there isn’t a whole lot of difference between C and C++ – so the strategy of building a new Python type around a C structure (pointer) type will also work for C++ objects.

For C++ libraries, see Writing C is hard; are there any alternatives?.

I added a module using the Setup file and the make fails; why?

Setup must end in a newline, if there is no newline there, the build process fails. (Fixing this requires some ugly shell script hackery, and this bug is so minor that it doesn’t seem worth the effort.)

How do I debug an extension?

When using GDB with dynamically loaded extensions, you can’t set a breakpoint in your extension until your extension is loaded.

In your `.gdbinit` file (or interactively), add the command:

```
br _PyImport_LoadDynamicModule
```

Then, when you run GDB:

```
$ gdb /local/bin/python
gdb) run myscript.py
gdb) continue # repeat until your extension is loaded
gdb) finish   # so that your extension is loaded
gdb) br myfunction.c:50
gdb) continue
```

I want to compile a Python module on my Linux system, but some files are missing. Why?

Most packaged versions of Python omit some files required for compiling Python extensions.

For Red Hat, install the python3-devel RPM to get the necessary files.

For Debian, run `apt-get install python3-dev`.

How do I tell “incomplete input” from “invalid input”?

Sometimes you want to emulate the Python interactive interpreter’s behavior, where it gives you a continuation prompt when the input is incomplete (e.g. you typed the start of an “if” statement or you didn’t close your parentheses or triple string quotes), but it gives you a syntax error message immediately when the input is invalid.

In Python you can use the `codeop` module, which approximates the parser’s behavior sufficiently. IDLE uses this, for example.

The easiest way to do it in C is to call `PyRun_InteractiveLoop()` (perhaps in a separate thread) and let the Python interpreter handle the input for you. You can also set the `PyOS_ReadlineFunctionPointer()` to point at your custom input function. See `Modules/readline.c` and `Parser/myreadline.c` for more hints.

How do I find undefined g++ symbols __builtin_new or __pure_virtual?

To dynamically load g++ extension modules, you must recompile Python, relink it using g++ (change LINKCC in the

Python Modules Makefile), and link your extension module using g++ (e.g., `g++ -shared -o mymodule.so mymodule.o`).

Can I create an object class with some methods implemented in C and others in Python (e.g. through inheritance)?

Yes, you can inherit from built-in classes such as **`int`**, **`list`**, **`dict`**, etc.

The Boost Python Library (BPL, https://www.boost.org/libs/python/doc/index.html) provides a way of doing this from C++ (i.e. you can inherit from an extension class written in C++ using the BPL).

How do I run a Python program under Windows?

This is not necessarily a straightforward question. If you are already familiar with running programs from the Windows command line then everything will seem obvious; otherwise, you might need a little more guidance.

Unless you use some sort of integrated development environment, you will end up *typing* Windows commands into what is referred to as a “Command prompt window”. Usually you can create such a window from your search bar by searching for `cmd`. You should be able to recognize when you have started such a window because you will see a Windows “command prompt”, which usually looks like this:

```
C:\>
```

The letter may be different, and there might be other things after it, so you might just as easily see something like:

```
D:\YourName\Projects\Python>
```

depending on how your computer has been set up and what else you have recently done with it. Once you have started such a window, you are well on the way to running Python programs.

You need to realize that your Python scripts have to be processed by another program called the Python *interpreter*. The interpreter reads your script, compiles it into bytecodes, and then executes the bytecodes to run your program. So, how do you arrange for the interpreter to handle your Python?

First, you need to make sure that your command window recognises the word “py” as an instruction to start the interpreter. If you have opened a command window, you should try entering the command `py` and hitting return:

```
C:\Users\YourName> py
```

You should then see something like:

```
Python 3.6.4 (v3.6.4:d48eceb, Dec 19 2017, 06:04:45) [MSC
v.1900 32 bit (Intel)] on win32
Type "help", "copyright", "credits" or "license" for more
information.
>>>
```

You have started the interpreter in “interactive mode”. That means you can enter Python statements or expressions interactively and have them executed or evaluated while you wait. This is one of Python’s strongest features. Check it by entering a few expressions of your choice and seeing the results:

```
>>> print("Hello")
Hello
>>> "Hello" * 3
'HelloHelloHello'
```

Many people use the interactive mode as a convenient yet highly programmable calculator. When you want to end your interactive Python session, call the `exit()` function or hold the `Ctrl` key down while you enter a `Z`, then hit the “`Enter`” key to get back to your Windows command prompt.

You may also find that you have a Start-menu entry such as *Start* ‣ *Programs* ‣ *Python 3.x* ‣ *Python (command line)* that results in you seeing the `>>>` prompt in a new window. If so, the window will disappear after you call the `exit()` function or enter the `Ctrl-Z` character; Windows is running a single “python” command in the window, and closes it when you terminate the interpreter.

Now that we know the `py` command is recognized, you can give your Python script to it. You’ll have to give either an absolute or a relative path to the Python script. Let’s say your Python script is located in your desktop and is named `hello.py`, and your command prompt is nicely opened in your home directory so you’re seeing something similar to:

```
C:\Users\YourName>
```

So now you’ll ask the `py` command to give your script to Python by typing `py` followed by your script path:

```
C:\Users\YourName> py Desktop\hello.py
hello
```

How do I make Python scripts executable?

On Windows, the standard Python installer already associates the .py extension with a file type (Python.File) and gives that file type an open command that runs the interpreter (`D:\Program Files\Python\python.exe "%1" %*`). This is enough to make scripts executable from the command prompt as ‘foo.py’. If you’d rather be able to execute the script by simple typing ‘foo’ with no extension you need to add .py to the PATHEXT environment variable.

Why does Python sometimes take so long to start?

Usually Python starts very quickly on Windows, but occasionally there are bug reports that Python suddenly begins to take a long time to start up. This is made even more puzzling because Python will work fine on other Windows systems which appear to be configured identically.

The problem may be caused by a misconfiguration of virus checking software on the problem machine. Some virus scanners have been known to introduce startup overhead of two orders of magnitude when the scanner is configured to monitor all reads from the filesystem. Try checking the configuration of virus scanning software on your systems to ensure that they are indeed configured identically. McAfee, when configured to scan all file system read activity, is a particular offender.

How do I make an executable from a Python script?

See How can I create a stand-alone binary from a Python script? for a list of tools that can be used to make executables.

Is a `*.pyd` file the same as a DLL?

Yes, .pyd files are dll's, but there are a few differences. If you have a DLL named `foo.pyd`, then it must have a function `PyInit_foo()`. You can then write Python "import foo", and Python will search for foo.pyd (as well as foo.py, foo.pyc) and if it finds it, will attempt to call `PyInit_foo()` to initialize it. You do not link your .exe with foo.lib, as that would cause Windows to require the DLL to be present.

Note that the search path for foo.pyd is PYTHONPATH, not the same as the path that Windows uses to search for foo.dll. Also, foo.pyd need not be present to run your program, whereas if you linked your program with a dll, the dll is required. Of course, foo.pyd is required if you want to say `import foo`. In a DLL, linkage is declared in the source code with `__declspec(dllexport)`. In a .pyd, linkage is defined in a list of available functions.

How can I embed Python into a Windows application?

Embedding the Python interpreter in a Windows app can be summarized as follows:

1. Do **not** build Python into your .exe file directly. On Windows, Python must be a DLL to handle importing

modules that are themselves DLL's. (This is the first key undocumented fact.) Instead, link to `python`*`NN`*`.dll`; it is typically installed in `C:\Windows\System`. *NN* is the Python version, a number such as "33" for Python 3.3.

You can link to Python in two different ways. Load-time linking means linking against `python`*`NN`*`.lib`, while run-time linking means linking against `python`*`NN`*`.dll`. (General note: `python`*`NN`*`.lib` is the so-called "import lib" corresponding to `python`*`NN`*`.dll`. It merely defines symbols for the linker.)

Run-time linking greatly simplifies link options; everything happens at run time. Your code must load `python`*`NN`*`.dll` using the Windows `LoadLibraryEx()` routine. The code must also use access routines and data in `python`*`NN`*`.dll` (that is, Python's C API's) using pointers obtained by the Windows `GetProcAddress()` routine. Macros can make using these pointers transparent to any C code that calls routines in Python's C API.

2. If you use SWIG, it is easy to create a Python "extension module" that will make the app's data and methods available to Python. SWIG will handle just about all the grungy details for you. The result is C code that you link *into* your .exe file (!) You do **not** have to create a DLL file, and this also simplifies linking.

3. SWIG will create an init function (a C function) whose name depends on the name of the extension module. For example, if the name of the module is leo, the init function will be called initleo(). If you use SWIG shadow classes, as you should, the init function will be called initleoc(). This initializes a mostly hidden helper class used by the shadow class.

The reason you can link the C code in step 2 into your .exe file is that calling the initialization function is equivalent to importing the module into Python! (This is the second key undocumented fact.)

4. In short, you can use the following code to initialize the Python interpreter with your extension module.

   ```
   #include <Python.h>
   ...
   Py_Initialize();  // Initialize Python.
   initmyAppc();  // Initialize (import) the helper class.
   PyRun_SimpleString("import myApp");  // Import the shadow
   class.
   ```

5. There are two problems with Python’s C API which will become apparent if you use a compiler other than MSVC, the compiler used to build pythonNN.dll.

   Problem 1: The so-called “Very High Level” functions that take `FILE *` arguments will not work in a multi-compiler environment because each compiler’s notion of a `struct FILE` will be different. From an implementation standpoint these are very low level functions.

   Problem 2: SWIG generates the following code when generating wrappers to void functions:

   ```
   Py_INCREF(Py_None);
   _resultobj = Py_None;
   return _resultobj;
   ```

   Alas, Py_None is a macro that expands to a reference to a complex data structure called _Py_NoneStruct inside pythonNN.dll. Again, this code will fail in a mult-compiler environment. Replace such code by:

   ```
   return Py_BuildValue("");
   ```

It may be possible to use SWIG's `%typemap` command to make the change automatically, though I have not been able to get this to work (I'm a complete SWIG newbie).

6. Using a Python shell script to put up a Python interpreter window from inside your Windows app is not a good idea; the resulting window will be independent of your app's windowing system. Rather, you (or the wxPythonWindow class) should create a “native” interpreter window. It is easy to connect that window to the Python interpreter. You can redirect Python's i/o to _any_ object that supports read and write, so all you need is a Python object (defined in your extension module) that contains read() and write() methods.

How do I keep editors from inserting tabs into my Python source?

The FAQ does not recommend using tabs, and the Python style guide, **PEP 8** [https://peps.python.org/pep-0008/], recommends 4 spaces for distributed Python code; this is also the Emacs python-mode default.

Under any editor, mixing tabs and spaces is a bad idea. MSVC is no different in this respect, and is easily configured to use spaces: Take *Tools* ‣ *Options* ‣ *Tabs*, and for file type “Default” set “Tab size” and “Indent size” to 4, and select the “Insert spaces” radio button.

Python raises `IndentationError` or `TabError` if mixed tabs and spaces are causing problems in leading whitespace. You may also run the `tabnanny` module to check a directory tree in batch mode.

How do I check for a keypress without blocking?

Use the `msvcrt` module. This is a standard Windows-specific extension module. It defines a function `kbhit()` which checks whether a keyboard hit is present, and `getch()` which gets one character without echoing it.

How do I solve the missing api-ms-win-crt-runtime-l1-1-0.dll error?

This can occur on Python 3.5 and later when using Windows 8.1 or earlier without all updates having been installed. First ensure your operating system is supported and is up to date, and if that does not resolve the issue, visit the Microsoft support page [https://support.microsoft.com/en-us/help/3118401/] for guidance on manually installing the C Runtime update.

Graphic User Interface FAQ

  - General GUI Questions
  - What GUI toolkits exist for Python?
  - Tkinter questions
    - How do I freeze Tkinter applications?
    - Can I have Tk events handled while waiting for I/O?
    - I can’t get key bindings to work in Tkinter: why?

General GUI Questions

What GUI toolkits exist for Python?

Standard builds of Python include an object-oriented interface to the Tcl/Tk widget set, called tkinter. This is probably the easiest to install (since it comes included with most binary distributions [https://www.python.org/downloads/] of Python) and use. For more info about Tk, including pointers to the source, see the Tcl/Tk home page [https://www.tcl.tk]. Tcl/Tk is fully portable to the macOS, Windows, and Unix platforms.

Depending on what platform(s) you are aiming at, there are also several alternatives. A list of cross-platform [https://wiki.python.org/moin/GuiProgramming#Cross-Platform_Frameworks] and platform-specific [https://wiki.python.org/moin/GuiProgramming#Platform-specific_Frameworks] GUI frameworks can be found on the python wiki.

Tkinter questions

How do I freeze Tkinter applications?

Freeze is a tool to create stand-alone applications. When freezing Tkinter applications, the applications will not be truly stand-alone, as the application will still need the Tcl and Tk libraries.

One solution is to ship the application with the Tcl and Tk libraries, and point to them at run-time using the `TCL_LIBRARY` and `TK_LIBRARY` environment variables.

Various third-party freeze libraries such as py2exe and cx_Freeze have handling for Tkinter applications built-in.

Can I have Tk events handled while waiting for I/O?

On platforms other than Windows, yes, and you don’t even need threads! But you’ll have to restructure your I/O code a bit. Tk has the equivalent of Xt’s `XtAddInput()` call, which allows you to register a callback function which will be called from the Tk mainloop when I/O is possible on a file descriptor. See File Handlers.

I can’t get key bindings to work in Tkinter: why?

An often-heard complaint is that event handlers bound to events with the **`bind()`** method don’t get handled even when the appropriate key is pressed.

The most common cause is that the widget to which the binding applies doesn’t have “keyboard focus”. Check out the Tk documentation for the focus command. Usually a widget is given the keyboard focus by clicking in it (but not for labels; see the takefocus option).

“Why is Python Installed on my Computer?” FAQ

What is Python?

Python is a programming language. It’s used for many different applications. It’s used in some high schools and colleges as an introductory programming language because Python is easy to learn, but it’s also used by professional software developers at places such as Google, NASA, and Lucasfilm Ltd.

If you wish to learn more about Python, start with the Beginner’s Guide to Python [https://wiki.python.org/moin/BeginnersGuide].

Why is Python installed on my machine?

If you find Python installed on your system but don’t remember installing it, there are several possible ways it could have gotten there.

- Perhaps another user on the computer wanted to learn programming and installed it; you’ll have to figure out who’s been using the machine and might have installed it.
- A third-party application installed on the machine might have been written in Python and included a Python installation. There are many such applications, from GUI programs to network servers and administrative scripts.

- Some Windows machines also have Python installed. At this writing we’re aware of computers from Hewlett-Packard and Compaq that include Python. Apparently some of HP/Compaq’s administrative tools are written in Python.
- Many Unix-compatible operating systems, such as macOS and some Linux distributions, have Python installed by default; it’s included in the base installation.

Can I delete Python?

That depends on where Python came from.

If someone installed it deliberately, you can remove it without hurting anything. On Windows, use the Add/Remove Programs icon in the Control Panel.

If Python was installed by a third-party application, you can also remove it, but that application will no longer work. You should use that application’s uninstaller rather than removing Python directly.

If Python came with your operating system, removing it is not recommended. If you remove it, whatever tools were written in Python will no longer run, and some of them might be important to you. Reinstalling the whole system would then be required to fix things again.

Deprecations

Pending removal in Python 3.15

- The import system:
    - Setting `__cached__` on a module while failing to set `__spec__.cached` is deprecated. In Python 3.15, **`__cached__`** will cease to be set or take into consideration by the import system or standard library. (gh-97879 [https://github.com/python/cpython/issues/97879])
    - Setting `__package__` on a module while failing to set `__spec__.parent` is deprecated. In Python 3.15, **`__package__`** will cease to be set or take into consideration by the import system or standard library. (gh-97879 [https://github.com/python/cpython/issues/97879])
- `ctypes`:
    - The undocumented **`ctypes.SetPointerType()`** function has been deprecated since Python 3.13.
- `http.server`:
    - The obsolete and rarely used `CGIHTTPRequestHandler` has been deprecated since Python 3.13. No direct replacement exists. *Anything* is better than CGI to interface a web server with a request handler.
    - The **`--cgi`** flag to the **python -m http.server** command-line interface has been deprecated since Python 3.13.
- `importlib`:
    - `load_module()` method: use `exec_module()` instead.
- `locale`:
    - The `getdefaultlocale()` function has been deprecated since Python 3.11. Its removal was originally

planned for Python 3.13 (gh-90817 [https://github.com/python/cpython/issues/90817]), but has been postponed to Python 3.15. Use **`getlocale()`**, **`setlocale()`**, and **`getencoding()`** instead. (Contributed by Hugo van Kemenade in gh-111187 [https://github.com/python/cpython/issues/111187].)

- **`pathlib`**:
  - **`PurePath.is_reserved()`** has been deprecated since Python 3.13. Use **`os.path.isreserved()`** to detect reserved paths on Windows.
- **`platform`**:
  - **`java_ver()`** has been deprecated since Python 3.13. This function is only useful for Jython support, has a confusing API, and is largely untested.
- **`sysconfig`**:
  - The *check_home* argument of **`sysconfig.is_python_build()`** has been deprecated since Python 3.12.
- **`threading`**:
  - **`RLock()`** will take no arguments in Python 3.15. Passing any arguments has been deprecated since Python 3.14, as the Python version does not permit any arguments, but the C version allows any number of positional or keyword arguments, ignoring every argument.
- **`types`**:
  - **`types.CodeType`**: Accessing **`co_lnotab`** was deprecated in **PEP 626** [https://peps.python.org/pep-0626/] since 3.10 and was planned to be removed in 3.12, but it only got a proper **`DeprecationWarning`** in 3.12. May be removed in 3.15. (Contributed by Nikita Sobolev in gh-101866 [https://github.com/python/cpython/issues/101866].)
- **`typing`**:
  - The undocumented keyword argument syntax for creating **`NamedTuple`** classes (for example, `Point = NamedTuple("Point", x=int, y=int)`) has been

    deprecated since Python 3.13. Use the class-based syntax or the functional syntax instead.
  - When using the functional syntax of `TypedDict`s, failing to pass a value to the *fields* parameter (`TD = TypedDict("TD")`) or passing `None` (`TD = TypedDict("TD", None)`) has been deprecated since Python 3.13. Use `class TD(TypedDict): pass` or `TD = TypedDict("TD", {})` to create a TypedDict with zero field.
  - The `typing.no_type_check_decorator()` decorator function has been deprecated since Python 3.13. After eight years in the `typing` module, it has yet to be supported by any major type checker.
- `wave`:
  - The `getmark()`, **`setmark()`**, and `getmarkers()` methods of the `Wave_read` and `Wave_write` classes have been deprecated since Python 3.13.
- `zipimport`:
  - `load_module()` has been deprecated since Python 3.10. Use `exec_module()` instead. (Contributed by Jiahao Li in gh-125746 [https://github.com/python/cpython/issues/125746].)

Pending removal in Python 3.16

- The import system:

  - Setting `__loader__` on a module while failing to set `__spec__.loader` is deprecated. In Python 3.16, **`__loader__`** will cease to be set or taken into consideration by the import system or the standard library.

- `array`:

  - The `'u'` format code (**`wchar_t`**) has been deprecated in documentation since Python 3.3 and at runtime since Python 3.13. Use the `'w'` format code (`Py_UCS4`) for Unicode characters instead.

- `asyncio`:
    - **`asyncio.iscoroutinefunction()`** is deprecated and will be removed in Python 3.16; use `inspect.iscoroutinefunction()` instead. (Contributed by Jiahao Li and Kumar Aditya in gh-122875 [https://github.com/python/cpython/issues/122875].)
    - `asyncio` policy system is deprecated and will be removed in Python 3.16. In particular, the following classes and functions are deprecated:
        - `asyncio.AbstractEventLoopPolicy`
        - `asyncio.DefaultEventLoopPolicy`
        - `asyncio.WindowsSelectorEventLoopPolicy`
        - `asyncio.WindowsProactorEventLoopPolicy`
        - `asyncio.get_event_loop_policy()`
        - `asyncio.set_event_loop_policy()`

      Users should use `asyncio.run()` or `asyncio.Runner` with *loop_factory* to use the desired event loop implementation.

      For example, to use `asyncio.SelectorEventLoop` on Windows:

      ```
      import asyncio

      async def main():
          ...

      asyncio.run(main(),
      loop_factory=asyncio.SelectorEventLoop)
      ```

(Contributed by Kumar Aditya in gh-127949 [https://github.com/python/cpython/issues/127949].)

- **`builtins`**:
  - Bitwise inversion on boolean types, `~True` or `~False` has been deprecated since Python 3.12, as it produces surprising and unintuitive results (`-2` and `-1`). Use `not x` instead for the logical negation of a Boolean. In the rare case that you need the bitwise inversion of the underlying integer, convert to `int` explicitly (`~int(x)`).
- **`functools`**:
  - Calling the Python implementation of **`functools.reduce()`** with *function* or *sequence* as keyword arguments has been deprecated since Python 3.14.
- **`logging`**:

  Support for custom logging handlers with the *strm* argument is deprecated and scheduled for removal in Python 3.16. Define handlers with the *stream* argument instead. (Contributed by Mariusz Felisiak in gh-115032 [https://github.com/python/cpython/issues/115032].)
- **`mimetypes`**:
  - Valid extensions start with a '.' or are empty for **`mimetypes.MimeTypes.add_type()`**. Undotted extensions are deprecated and will raise a **`ValueError`** in Python 3.16. (Contributed by Hugo van Kemenade in gh-75223 [https://github.com/python/cpython/issues/75223].)
- **`shutil`**:

  - The **`ExecError`** exception has been deprecated since Python 3.14. It has not been used by any function in **`shutil`** since Python 3.4, and is now an alias of [`RuntimeError`].

- [`symtable`]:

  - The [`Class.get_methods`] method has been deprecated since Python 3.14.

- [`sys`]:

  - The [`_enablelegacywindowsfsencoding()`] function has been deprecated since Python 3.13. Use the [`PYTHONLEGACYWINDOWSFSENCODING`] environment variable instead.

- [`sysconfig`]:

  - The **`sysconfig.expand_makefile_vars()`** function has been deprecated since Python 3.14. Use the `vars` argument of [`sysconfig.get_paths()`] instead.

- [`tarfile`]:

  - The undocumented and unused **`TarFile.tarfile`** attribute has been deprecated since Python 3.13.

Pending removal in Python 3.17

- [`collections.abc`]:

  - [`collections.abc.ByteString`] is scheduled for removal in Python 3.17.

    Use `isinstance(obj, collections.abc.Buffer)` to test if `obj` implements the [buffer protocol] at runtime. For use in type annotations, either use **`Buffer`** or a union that explicitly specifies the types your code supports (e.g., `bytes | bytearray | memoryview`).

`ByteString` was originally intended to be an abstract class that would serve as a supertype of both **`bytes`** and **`bytearray`**. However, since the ABC never had any methods, knowing that an object was an instance of **`ByteString`** never actually told you anything useful about the object. Other common buffer types such as **`memoryview`** were also never understood as subtypes of **`ByteString`** (either at runtime or by static type checkers).

See **PEP 688** [https://peps.python.org/pep-0688/#current-options] for more details. (Contributed by Shantanu Jain in gh-91896 [https://github.com/python/cpython/issues/91896].)

- **`typing`**:
  - Before Python 3.14, old-style unions were implemented using the private class `typing._UnionGenericAlias`. This class is no longer needed for the implementation, but it has been retained for backward compatibility, with removal scheduled for Python 3.17. Users should use documented introspection helpers like **`typing.get_origin()`** and **`typing.get_args()`** instead of relying on private implementation details.
  - **`typing.ByteString`**, deprecated since Python 3.9, is scheduled for removal in Python 3.17.

    Use `isinstance(obj, collections.abc.Buffer)` to test if `obj` implements the buffer protocol at runtime. For use in type annotations, either use **`Buffer`** or a union that explicitly specifies the types your code supports (e.g., `bytes | bytearray | memoryview`).

`ByteString` was originally intended to be an abstract class that would serve as a supertype of both **`bytes`** and **`bytearray`**. However, since the ABC never had any methods, knowing that an object was an instance of **`ByteString`** never actually told you anything useful about the object. Other common buffer types such as **`memoryview`** were also never understood as subtypes of **`ByteString`** (either at runtime or by static type checkers).

See **PEP 688** [https://peps.python.org/pep-0688/#current-options] for more details. (Contributed by Shantanu Jain in gh-91896 [https://github.com/python/cpython/issues/91896].)

Pending removal in Python 3.18

- **`decimal`**:
  - The non-standard and undocumented **`Decimal`** format specifier `'N'`, which is only supported in the **`decimal`** module’s C implementation, has been deprecated since Python 3.13. (Contributed by Serhiy Storchaka in gh-89902 [https://github.com/python/cpython/issues/89902].)

Pending removal in Python 3.19

- **`ctypes`**:
  - Implicitly switching to the MSVC-compatible struct layout by setting **`_pack_`** but not **`_layout_`** on non-Windows platforms.

Pending removal in future versions

The following APIs will be removed in the future, although there is currently no date scheduled for their removal.

- `argparse`:
    - Nesting argument groups and nesting mutually exclusive groups are deprecated.
    - Passing the undocumented keyword argument *prefix_chars* to `add_argument_group()` is now deprecated.
    - The `argparse.FileType` type converter is deprecated.
- `builtins`:
    - Generators: `throw(type, exc, tb)` and `athrow(type, exc, tb)` signature is deprecated: use `throw(exc)` and `athrow(exc)` instead, the single argument signature.
    - Currently Python accepts numeric literals immediately followed by keywords, for example `0in x`, `1or x`, `0if 1else 2`. It allows confusing and ambiguous expressions like `[0x1for x in y]` (which can be interpreted as `[0x1 for x in y]` or `[0x1f or x in y]`). A syntax warning is raised if the numeric literal is immediately followed by one of keywords **`and`**, **`else`**, **`for`**, **`if`**, **`in`**, **`is`** and **`or`**. In a future release it will be changed to a syntax error. (gh-87999 [https://github.com/python/cpython/issues/87999])
    - Support for `__index__()` and `__int__()` method returning non-int type: these methods will be required to return an instance of a strict subclass of `int`.
    - Support for `__float__()` method returning a strict subclass of `float`: these methods will be required to return an instance of `float`.
    - Support for `__complex__()` method returning a strict subclass of `complex`: these methods will be required to return an instance of `complex`.
    - Delegation of `int()` to `__trunc__()` method.

  - Passing a complex number as the *real* or *imag* argument in the **`complex()`** constructor is now deprecated; it should only be passed as a single positional argument. (Contributed by Serhiy Storchaka in gh-109218 [https://github.com/python/cpython/issues/109218].)
- **`calendar`**: `calendar.January` and `calendar.February` constants are deprecated and replaced by **`calendar.JANUARY`** and **`calendar.FEBRUARY`**. (Contributed by Prince Roshan in gh-103636 [https://github.com/python/cpython/issues/103636].)
- **`codecs`**: use **`open()`** instead of **`codecs.open()`**. (gh-133038 [https://github.com/python/cpython/issues/133038])
- **`codeobject.co_lnotab`**: use the **`codeobject.co_lines()`** method instead.
- **`datetime`**:
  - **`utcnow()`**: use `datetime.datetime.now(tz=datetime.UTC)`.
  - **`utcfromtimestamp()`**: use `datetime.datetime.fromtimestamp(timestamp, tz=datetime.UTC)`.
- **`gettext`**: Plural value must be an integer.
- **`importlib`**:
  - **`cache_from_source()`** *debug_override* parameter is deprecated: use the *optimization* parameter instead.
- **`importlib.metadata`**:
  - `EntryPoints` tuple interface.
  - Implicit `None` on return values.
- **`logging`**: the `warn()` method has been deprecated since Python 3.3, use **`warning()`** instead.
- **`mailbox`**: Use of StringIO input and text mode is deprecated, use BytesIO and binary mode instead.
- **`os`**: Calling **`os.register_at_fork()`** in multi-threaded process.
- **`pydoc.ErrorDuringImport`**: A tuple value for *exc_info* parameter is deprecated, use an exception instance.

- **re**: More strict rules are now applied for numerical group references and group names in regular expressions. Only sequence of ASCII digits is now accepted as a numerical reference. The group name in bytes patterns and replacement strings can now only contain ASCII letters and digits and underscore. (Contributed by Serhiy Storchaka in gh-91760 [https://github.com/python/cpython/issues/91760].)
- **`sre_compile`**, **`sre_constants`** and **`sre_parse`** modules.
- **`shutil`**: **`rmtree()`**'s *onerror* parameter is deprecated in Python 3.12; use the *onexc* parameter instead.
- **`ssl`** options and protocols:
  - **`ssl.SSLContext`** without protocol argument is deprecated.
  - **`ssl.SSLContext`**: **`set_npn_protocols()`** and **`selected_npn_protocol()`** are deprecated: use ALPN instead.
  - `ssl.OP_NO_SSL*` options
  - `ssl.OP_NO_TLS*` options
  - `ssl.PROTOCOL_SSLv3`
  - `ssl.PROTOCOL_TLS`
  - `ssl.PROTOCOL_TLSv1`
  - `ssl.PROTOCOL_TLSv1_1`
  - `ssl.PROTOCOL_TLSv1_2`
  - `ssl.TLSVersion.SSLv3`
  - `ssl.TLSVersion.TLSv1`
  - `ssl.TLSVersion.TLSv1_1`
- **`threading`** methods:
  - **`threading.Condition.notifyAll()`**: use **`notify_all()`**.
  - **`threading.Event.isSet()`**: use **`is_set()`**.
  - **`threading.Thread.isDaemon()`**, **`threading.Thread.setDaemon()`**: use **`threading.Thread.daemon`** attribute.
  - **`threading.Thread.getName()`**, **`threading.Thread.setName()`**: use **`threading.Thread.name`** attribute.

  - **`threading.currentThread()`**: use `threading.current_thread()`.
  - **`threading.activeCount()`**: use `threading.active_count()`.
- `typing.Text` (gh-92332 [https://github.com/python/cpython/issues/92332]).
- The internal class `typing._UnionGenericAlias` is no longer used to implement `typing.Union`. To preserve compatibility with users using this private class, a compatibility shim will be provided until at least Python 3.17. (Contributed by Jelle Zijlstra in gh-105499 [https://github.com/python/cpython/issues/105499].)
- `unittest.IsolatedAsyncioTestCase`: it is deprecated to return a value that is not `None` from a test case.
- `urllib.parse` deprecated functions: `urlparse()` instead
  - `splitattr()`
  - `splithost()`
  - `splitnport()`
  - `splitpasswd()`
  - `splitport()`
  - `splitquery()`
  - `splittag()`
  - `splittype()`
  - `splituser()`
  - `splitvalue()`
  - `to_bytes()`
- `wsgiref`: `SimpleHandler.stdout.write()` should not do partial writes.
- `xml.etree.ElementTree`: Testing the truth value of an `Element` is deprecated. In a future release it will always return `True`. Prefer explicit `len(elem)` or `elem is not None` tests instead.
- `sys._clear_type_cache()` is deprecated: use `sys._clear_internal_caches()` instead.

C API deprecations

Pending removal in Python 3.15

- The `PyImport_ImportModuleNoBlock()`: Use `PyImport_ImportModule()` instead.
- `PyWeakref_GetObject()` and `PyWeakref_GET_OBJECT()`: Use `PyWeakref_GetRef()` instead. The pythoncapi-compat project [https://github.com/python/pythoncapi-compat/] can be used to get `PyWeakref_GetRef()` on Python 3.12 and older.
- `Py_UNICODE` type and the **`Py_UNICODE_WIDE`** macro: Use **`wchar_t`** instead.
- **`PyUnicode_AsDecodedObject()`**: Use `PyCodec_Decode()` instead.
- **`PyUnicode_AsDecodedUnicode()`**: Use `PyCodec_Decode()` instead; Note that some codecs (for example, “base64”) may return a type other than `str`, such as `bytes`.
- **`PyUnicode_AsEncodedObject()`**: Use `PyCodec_Encode()` instead.
- **`PyUnicode_AsEncodedUnicode()`**: Use `PyCodec_Encode()` instead; Note that some codecs (for example, “base64”) may return a type other than `bytes`, such as `str`.
- Python initialization functions, deprecated in Python 3.13:
  - `Py_GetPath()`: Use `PyConfig_Get("module_search_paths")` (`sys.path`) instead.
  - `Py_GetPrefix()`: Use `PyConfig_Get("base_prefix")` (`sys.base_prefix`) instead. Use `PyConfig_Get("prefix")` (`sys.prefix`) if virtual environments need to be handled.
  - `Py_GetExecPrefix()`: Use `PyConfig_Get("base_exec_prefix")` (`sys.base_exec_prefix`) instead. Use `PyConfig_Get("exec_prefix")`

    (`sys.exec_prefix`) if virtual environments need to be handled.
  - `Py_GetProgramFullPath()`: Use `PyConfig_Get("executable")` (`sys.executable`) instead.
  - `Py_GetProgramName()`: Use `PyConfig_Get("executable")` (`sys.executable`) instead.
  - `Py_GetPythonHome()`: Use `PyConfig_Get("home")` or the `PYTHONHOME` environment variable instead.

  The pythoncapi-compat project [https://github.com/python/pythoncapi-compat/] can be used to get `PyConfig_Get()` on Python 3.13 and older.

- Functions to configure Python's initialization, deprecated in Python 3.11:

  - `PySys_SetArgvEx()`: Set `PyConfig.argv` instead.
  - `PySys_SetArgv()`: Set `PyConfig.argv` instead.
  - `Py_SetProgramName()`: Set `PyConfig.program_name` instead.
  - `Py_SetPythonHome()`: Set `PyConfig.home` instead.
  - `PySys_ResetWarnOptions()`: Clear `sys.warnoptions` and `warnings.filters` instead.

  The `Py_InitializeFromConfig()` API should be used with `PyConfig` instead.

- Global configuration variables:

  - `Py_DebugFlag`: Use `PyConfig.parser_debug` or `PyConfig_Get("parser_debug")` instead.
  - `Py_VerboseFlag`: Use `PyConfig.verbose` or `PyConfig_Get("verbose")` instead.
  - `Py_QuietFlag`: Use `PyConfig.quiet` or `PyConfig_Get("quiet")` instead.
  - `Py_InteractiveFlag`: Use `PyConfig.interactive` or `PyConfig_Get("interactive")` instead.

  - `Py_InspectFlag`: Use `PyConfig.inspect` or `PyConfig_Get("inspect")` instead.
  - `Py_OptimizeFlag`: Use `PyConfig.optimization_level` or `PyConfig_Get("optimization_level")` instead.
  - `Py_NoSiteFlag`: Use `PyConfig.site_import` or `PyConfig_Get("site_import")` instead.
  - `Py_BytesWarningFlag`: Use `PyConfig.bytes_warning` or `PyConfig_Get("bytes_warning")` instead.
  - `Py_FrozenFlag`: Use `PyConfig.pathconfig_warnings` or `PyConfig_Get("pathconfig_warnings")` instead.
  - `Py_IgnoreEnvironmentFlag`: Use `PyConfig.use_environment` or `PyConfig_Get("use_environment")` instead.
  - `Py_DontWriteBytecodeFlag`: Use `PyConfig.write_bytecode` or `PyConfig_Get("write_bytecode")` instead.
  - `Py_NoUserSiteDirectory`: Use `PyConfig.user_site_directory` or `PyConfig_Get("user_site_directory")` instead.
  - `Py_UnbufferedStdioFlag`: Use `PyConfig.buffered_stdio` or `PyConfig_Get("buffered_stdio")` instead.
  - `Py_HashRandomizationFlag`: Use `PyConfig.use_hash_seed` and `PyConfig.hash_seed` or `PyConfig_Get("hash_seed")` instead.
  - `Py_IsolatedFlag`: Use `PyConfig.isolated` or `PyConfig_Get("isolated")` instead.
  - `Py_LegacyWindowsFSEncodingFlag`: Use `PyPreConfig.legacy_windows_fs_encoding` or `PyConfig_Get("legacy_windows_fs_encoding")` instead.
  - `Py_LegacyWindowsStdioFlag`: Use `PyConfig.legacy_windows_stdio` or `PyConfig_Get("legacy_windows_stdio")` instead.
  - `Py_FileSystemDefaultEncoding`, `Py_HasFileSystemDefaultEncoding`: Use `PyConfig.filesystem_encoding` or `PyConfig_Get("filesystem_encoding")` instead.
  - `Py_FileSystemDefaultEncodeErrors`: Use `PyConfig.filesystem_errors` or

    `PyConfig_Get("filesystem_errors")` instead.
  - **`Py_UTF8Mode`**: Use `PyPreConfig.utf8_mode` or `PyConfig_Get("utf8_mode")` instead. (see `Py_PreInitialize()`)

  The `Py_InitializeFromConfig()` API should be used with `PyConfig` to set these options. Or `PyConfig_Get()` can be used to get these options at runtime.

Pending removal in Python 3.18

- The following private functions are deprecated and planned for removal in Python 3.18:
  - **`_PyBytes_Join()`**: use `PyBytes_Join()`.
  - **`_PyDict_GetItemStringWithError()`**: use `PyDict_GetItemStringRef()`.
  - **`_PyDict_Pop()`**: use `PyDict_Pop()`.
  - **`_PyLong_Sign()`**: use `PyLong_GetSign()`.
  - **`_PyLong_FromDigits()`** and **`_PyLong_New()`**: use `PyLongWriter_Create()`.
  - **`_PyThreadState_UncheckedGet()`**: use `PyThreadState_GetUnchecked()`.
  - **`_PyUnicode_AsString()`**: use `PyUnicode_AsUTF8()`.
  - **`_PyUnicodeWriter_Init()`**: replace `_PyUnicodeWriter_Init(&writer)` with `writer = PyUnicodeWriter_Create(0)`.
  - **`_PyUnicodeWriter_Finish()`**: replace `_PyUnicodeWriter_Finish(&writer)` with `PyUnicodeWriter_Finish(writer)`.
  - **`_PyUnicodeWriter_Dealloc()`**: replace `_PyUnicodeWriter_Dealloc(&writer)` with `PyUnicodeWriter_Discard(writer)`.
  - **`_PyUnicodeWriter_WriteChar()`**: replace `_PyUnicodeWriter_WriteChar(&writer, ch)` with `PyUnicodeWriter_WriteChar(writer, ch)`.

  - **`_PyUnicodeWriter_WriteStr()`**: replace `_PyUnicodeWriter_WriteStr(&writer, str)` with `PyUnicodeWriter_WriteStr(writer, str)`.
  - **`_PyUnicodeWriter_WriteSubstring()`**: replace `_PyUnicodeWriter_WriteSubstring(&writer, str, start, end)` with `PyUnicodeWriter_WriteSubstring(writer, str, start, end)`.
  - **`_PyUnicodeWriter_WriteASCIIString()`**: replace `_PyUnicodeWriter_WriteASCIIString(&writer, str)` with `PyUnicodeWriter_WriteASCII(writer, str)`.
  - **`_PyUnicodeWriter_WriteLatin1String()`**: replace `_PyUnicodeWriter_WriteLatin1String(&writer, str)` with `PyUnicodeWriter_WriteUTF8(writer, str)`.
  - **`_PyUnicodeWriter_Prepare()`**: (no replacement).
  - **`_PyUnicodeWriter_PrepareKind()`**: (no replacement).
  - **`_Py_HashPointer()`**: use `Py_HashPointer()`.
  - **`_Py_fopen_obj()`**: use `Py_fopen()`.

  The pythoncapi-compat project [https://github.com/python/pythoncapi-compat/] can be used to get these new public functions on Python 3.13 and older. (Contributed by Victor Stinner in gh-128863 [https://github.com/python/cpython/issues/128863].)

Pending removal in future versions

The following APIs are deprecated and will be removed, although there is currently no date scheduled for their removal.

- `Py_TPFLAGS_HAVE_FINALIZE`: Unneeded since Python 3.8.
- `PyErr_Fetch()`: Use `PyErr_GetRaisedException()` instead.
- `PyErr_NormalizeException()`: Use `PyErr_GetRaisedException()` instead.
- `PyErr_Restore()`: Use `PyErr_SetRaisedException()` instead.

- `PyModule_GetFilename()`: Use `PyModule_GetFilenameObject()` instead.
- `PyOS_AfterFork()`: Use `PyOS_AfterFork_Child()` instead.
- `PySlice_GetIndicesEx()`: Use `PySlice_Unpack()` and `PySlice_AdjustIndices()` instead.
- `PyUnicode_READY()`: Unneeded since Python 3.12
- `PyErr_Display()`: Use `PyErr_DisplayException()` instead.
- `_PyErr_ChainExceptions()`: Use `_PyErr_ChainExceptions1()` instead.
- `PyBytesObject.ob_shash` member: call `PyObject_Hash()` instead.
- Thread Local Storage (TLS) API:
  - `PyThread_create_key()`: Use `PyThread_tss_alloc()` instead.
  - `PyThread_delete_key()`: Use `PyThread_tss_free()` instead.
  - `PyThread_set_key_value()`: Use `PyThread_tss_set()` instead.
  - `PyThread_get_key_value()`: Use `PyThread_tss_get()` instead.
  - `PyThread_delete_key_value()`: Use `PyThread_tss_delete()` instead.
  - `PyThread_ReInitTLS()`: Unneeded since Python 3.7.

Glossary

>>>

The default Python prompt of the interactive shell. Often seen for code examples which can be executed interactively in the interpreter.

...

Can refer to:

- The default Python prompt of the interactive shell when entering the code for an indented code block, when within a pair of matching left and right delimiters (parentheses, square brackets, curly braces or triple quotes), or after specifying a decorator.
- The three dots form of the Ellipsis object.

abstract base class

Abstract base classes complement duck-typing by providing a way to define interfaces when other techniques like `hasattr()` would be clumsy or subtly wrong (for example with magic methods). ABCs introduce virtual subclasses, which are classes that don’t inherit from a class but are still recognized by `isinstance()` and `issubclass()`; see the `abc` module documentation. Python comes with many built-in ABCs for data structures (in the `collections.abc` module), numbers (in the `numbers` module), streams (in the `io` module), import finders and loaders (in the `importlib.abc` module). You can create your own ABCs with the `abc` module.

annotate function

A function that can be called to retrieve the annotations of an object. This function is accessible as the `__annotate__` attribute of functions, classes, and modules. Annotate functions are a subset of evaluate functions.

annotation

A label associated with a variable, a class attribute or a function parameter or return value, used by convention as a type hint.

Annotations of local variables cannot be accessed at runtime, but annotations of global variables, class attributes, and functions can be retrieved by calling `annotationlib.get_annotations()` on modules, classes, and functions, respectively.

See variable annotation, function annotation, **PEP 484** [https://peps.python.org/pep-0484/], **PEP 526** [https://peps.python.org/pep-0526/], and **PEP 649** [https://peps.python.org/pep-0649/], which describe this functionality. Also see Annotations Best Practices for best practices on working with annotations.

argument

A value passed to a function (or method) when calling the function. There are two kinds of argument:

- *keyword argument*: an argument preceded by an identifier (e.g. `name=`) in a function call or passed as a value in a dictionary preceded by `**`. For example, `3` and `5` are both keyword arguments in the following calls to `complex()`:

  ```
  complex(real=3, imag=5)
  complex(**{'real': 3, 'imag': 5})
  ```

- *positional argument*: an argument that is not a keyword argument. Positional arguments can appear at the beginning of an argument list and/or be passed as elements of an iterable preceded by `*`. For example, `3` and `5` are both positional arguments in the following calls:

  ```
  complex(3, 5)
  complex(*(3, 5))
  ```

Arguments are assigned to the named local variables in a function body. See the Calls section for the rules governing this assignment. Syntactically, any expression can be used to represent an argument; the evaluated value is assigned to the local variable.

See also the parameter glossary entry, the FAQ question on the difference between arguments and parameters, and **PEP 362** [https://peps.python.org/pep-0362/].

asynchronous context manager

An object which controls the environment seen in an **`async with`** statement by defining **`__aenter__()`** and **`__aexit__()`** methods. Introduced by **PEP 492** [https://peps.python.org/pep-0492/].

asynchronous generator

A function which returns an asynchronous generator iterator. It looks like a coroutine function defined with **`async def`** except that it contains **`yield`** expressions for producing a series of values usable in an **`async for`** loop.

Usually refers to an asynchronous generator function, but may refer to an *asynchronous generator iterator* in some contexts. In cases where the intended meaning isn’t clear, using the full terms avoids ambiguity.

An asynchronous generator function may contain `await` expressions as well as `async for`, and `async with` statements.

asynchronous generator iterator

An object created by an asynchronous generator function.

This is an asynchronous iterator which when called using the `__anext__()` method returns an awaitable object which will execute the body of the asynchronous generator function until the next `yield` expression.

Each `yield` temporarily suspends processing, remembering the execution state (including local variables and pending try-statements). When the *asynchronous generator iterator* effectively resumes with another awaitable returned by `__anext__()`, it picks up where it left off. See **PEP 492** [https://peps.python.org/pep-0492/] and **PEP 525** [https://peps.python.org/pep-0525/].

asynchronous iterable

An object, that can be used in an `async for` statement. Must return an asynchronous iterator from its `__aiter__()` method. Introduced by **PEP 492** [https://peps.python.org/pep-0492/].

asynchronous iterator

An object that implements the `__aiter__()` and `__anext__()` methods. `__anext__()` must return an awaitable object. `async for` resolves the awaitables returned by an asynchronous iterator's `__anext__()` method until it raises a `StopAsyncIteration` exception. Introduced by **PEP 492** [https://peps.python.org/pep-0492/].

atomic operation

An operation that appears to execute as a single, indivisible step: no other thread can observe it half-done, and its effects become visible all at once. Python does not guarantee that high-level statements are atomic (for example, `x += 1` performs multiple bytecode operations and is not atomic). Atomicity is only guaranteed where explicitly documented. See also race condition and data race.

attached thread state

A thread state that is active for the current OS thread.

When a thread state is attached, the OS thread has access to the full Python C API and can safely invoke the bytecode interpreter.

Unless a function explicitly notes otherwise, attempting to call the C API without an attached thread state will result in a fatal error or undefined behavior. A thread state can be attached and detached explicitly by the user through the C API, or implicitly by the runtime, including during blocking C calls and by the bytecode interpreter in between calls.

On most builds of Python, having an attached thread state implies that the caller holds the GIL for the current interpreter, so only one OS thread can have an attached thread state at a given moment. In free-threaded builds of Python, threads can concurrently hold an attached thread state, allowing for true parallelism of the bytecode interpreter.

attribute

A value associated with an object which is usually referenced by name using dotted expressions. For example, if an object *o* has an attribute *a* it would be referenced as *o.a*.

It is possible to give an object an attribute whose name is not an identifier as defined by Names (identifiers and keywords), for example using `setattr()`, if the object allows it. Such an attribute will not be accessible using a dotted expression, and would instead need to be retrieved with `getattr()`.

awaitable

An object that can be used in an `await` expression. Can be a coroutine or an object with an `__await__()` method. See also **PEP 492** [https://peps.python.org/pep-0492/].

BDFL

Benevolent Dictator For Life, a.k.a. Guido van Rossum [https://gvanrossum.github.io/], Python’s creator.

binary file

A file object able to read and write bytes-like objects. Examples of binary files are files opened in binary mode (`'rb'`, `'wb'` or `'rb+'`), `sys.stdin.buffer`, `sys.stdout.buffer`, and instances of `io.BytesIO` and `gzip.GzipFile`.

See also text file for a file object able to read and write `str` objects.

borrowed reference

In Python’s C API, a borrowed reference is a reference to an object, where the code using the object does not own the reference. It becomes a dangling pointer if the object is destroyed. For example, a garbage collection can remove the last strong reference to the object and so destroy it.

Calling `Py_INCREF()` on the borrowed reference is recommended to convert it to a strong reference in-place, except when the object cannot be destroyed before the last usage of the borrowed reference. The `Py_NewRef()` function can be used to create a new strong reference.

bytes-like object

An object that supports the Buffer Protocol and can export a C-contiguous buffer. This includes all `bytes`, `bytearray`, and `array.array` objects, as well as many common `memoryview` objects. Bytes-like objects can be used for various operations that work with binary data; these include compression, saving to a binary file, and sending over a socket.

Some operations need the binary data to be mutable. The documentation often refers to these as “read-write bytes-like objects”. Example mutable buffer objects include `bytearray` and a `memoryview` of a `bytearray`. Other operations require the binary data to be stored in immutable objects (“read-only bytes-like objects”); examples of these include `bytes` and a `memoryview` of a `bytes` object.

bytecode

Python source code is compiled into bytecode, the internal representation of a Python program in the CPython interpreter. The bytecode is also cached in `.pyc` files so that executing the same file is faster the second time (recompilation from source to bytecode can be avoided). This “intermediate language” is said to run on a virtual machine that executes the machine code corresponding to each bytecode. Do note that bytecodes are not expected to work between different Python virtual machines, nor to be stable between Python releases.

A list of bytecode instructions can be found in the documentation for the dis module.

callable

A callable is an object that can be called, possibly with a set of arguments (see argument), with the following syntax:

```
callable(argument1, argument2, argumentN)
```

A function, and by extension a method, is a callable. An instance of a class that implements the `__call__()` method is also a callable.

callback

A subroutine function which is passed as an argument to be executed at some point in the future.

class

A template for creating user-defined objects. Class definitions normally contain method definitions which operate on instances of the class.

class variable

A variable defined in a class and intended to be modified only at class level (i.e., not in an instance of the class).

closure variable

A free variable referenced from a nested scope that is defined in an outer scope rather than being resolved at runtime from the globals or builtin namespaces. May be explicitly defined with the `nonlocal` keyword to allow write access, or implicitly defined if the variable is only being read.

For example, in the `inner` function in the following code, both `x` and `print` are free variables, but only `x` is a *closure variable*:

```
def outer():
    x = 0
    def inner():
        nonlocal x
        x += 1
        print(x)
    return inner
```

Due to the **`codeobject.co_freevars`** attribute (which, despite its name, only includes the names of closure variables rather than listing all referenced free variables), the more general free variable term is sometimes used even when the intended meaning is to refer specifically to closure variables.

complex number

An extension of the familiar real number system in which all numbers are expressed as a sum of a real part and an imaginary part. Imaginary numbers are real multiples of the imaginary unit (the square root of `-1`), often written `i` in mathematics or `j` in engineering. Python has built-in support for complex numbers, which are written with this latter notation; the imaginary part is written with a `j` suffix, e.g., `3+1j`. To get access to complex equivalents of the **`math`** module, use **`cmath`**. Use of complex numbers is a fairly advanced mathematical feature. If you’re not aware of a need for them, it’s almost certain you can safely ignore them.

concurrency

The ability of a computer program to perform multiple tasks at the same time. Python provides libraries for writing programs that make use of different forms of concurrency. `asyncio` is a library for dealing with asynchronous tasks and coroutines. `threading` provides access to operating system threads and `multiprocessing` to operating system processes. Multi-core processors can execute threads and processes on different CPU cores at the same time (see parallelism).

concurrent modification

When multiple threads modify shared data at the same time. Concurrent modification without proper synchronization can cause race conditions, and might also trigger a data race, data corruption, or both.

context

This term has different meanings depending on where and how it is used. Some common meanings:

- The temporary state or environment established by a context manager via a `with` statement.
- The collection of keyvalue bindings associated with a particular `contextvars.Context` object and accessed via `ContextVar` objects. Also see context variable.
- A `contextvars.Context` object. Also see current context.

context management protocol

The `__enter__()` and `__exit__()` methods called by the `with` statement. See **PEP 343** [https://peps.python.org/pep-0343/].

context manager

An object which implements the context management protocol and controls the environment seen in a `with` statement. See **PEP 343** [https://peps.python.org/pep-0343/].

context variable

A variable whose value depends on which context is the current context. Values are accessed via `contextvars.ContextVar` objects. Context variables are primarily used to isolate state between concurrent asynchronous tasks.

contiguous

A buffer is considered contiguous exactly if it is either *C-contiguous* or *Fortran contiguous*. Zero-dimensional buffers are C and Fortran contiguous. In one-dimensional arrays, the items must be laid out in memory next to each other, in order of increasing indexes starting from zero. In multidimensional C-contiguous arrays, the last index varies the fastest when visiting items in order of memory address. However, in Fortran contiguous arrays, the first index varies the fastest.

coroutine

Coroutines are a more generalized form of subroutines. Subroutines are entered at one point and exited at another point. Coroutines can be entered, exited, and resumed at many different points. They can be implemented with the `async def` statement. See also **PEP 492** [https://peps.python.org/pep-0492/].

coroutine function

A function which returns a coroutine object. A coroutine function may be defined with the `async def` statement, and may contain `await`, `async for`, and `async with` keywords. These were introduced by **PEP 492** [https://peps.python.org/pep-0492/].

CPython

The canonical implementation of the Python programming language, as distributed on python.org [https://www.python.org]. The term “CPython” is used when necessary to distinguish this implementation from others such as Jython or IronPython.

current context

The context (`contextvars.Context` object) that is currently used by `ContextVar` objects to access (get or set) the values of context variables. Each thread has its own current context. Frameworks for executing asynchronous tasks (see `asyncio`) associate each task with a context which becomes the current context whenever the task starts or resumes execution.

cyclic isolate

A subgroup of one or more objects that reference each other in a reference cycle, but are not referenced by objects outside the group. The goal of the cyclic garbage collector is to identify these groups and break the reference cycles so that the memory can be reclaimed.

data race

A situation where multiple threads access the same memory location concurrently, at least one of the accesses is a write, and the threads do not use any synchronization to control their access. Data races lead to non-deterministic behavior and can cause data corruption. Proper use of locks and other synchronization primitives prevents data races. Note that data races can only happen in native code, but that native code might be exposed in a Python API. See also race condition and thread-safe.

deadlock

A situation in which two or more tasks (threads, processes, or coroutines) wait indefinitely for each other to release resources or complete actions, preventing any from making progress. For example, if thread A holds lock 1 and waits for lock 2, while thread B holds lock 2 and waits for lock 1, both threads will wait indefinitely. In Python this often arises from acquiring multiple locks in conflicting orders or from circular join/await dependencies. Deadlocks can be avoided by always acquiring multiple locks in a consistent order. See also lock and reentrant.

decorator

A function returning another function, usually applied as a function transformation using the `@wrapper` syntax. Common examples for decorators are **`classmethod()`** and **`staticmethod()`**.

The decorator syntax is merely syntactic sugar, the following two function definitions are semantically equivalent:

```
def f(arg):
    ...
f = staticmethod(f)

@staticmethod
def f(arg):
    ...
```

The same concept exists for classes, but is less commonly used there. See the documentation for function definitions and class definitions for more about decorators.

descriptor

Any object which defines the methods `__get__()`, `__set__()`, or `__delete__()`. When a class attribute is a descriptor, its special binding behavior is triggered upon attribute lookup. Normally, using *a.b* to get, set or delete an attribute looks up the object named *b* in the class dictionary for *a*, but if *b* is a descriptor, the respective descriptor method gets called. Understanding descriptors is a key to a deep understanding of Python because they are the basis for many features including functions, methods, properties, class methods, static methods, and reference to super classes.

For more information about descriptors' methods, see Implementing Descriptors or the Descriptor How To Guide.

dictionary

An associative array, where arbitrary keys are mapped to values. The keys can be any object with `__hash__()` and `__eq__()` methods. Called a hash in Perl.

dictionary comprehension

A compact way to process all or part of the elements in an iterable and return a dictionary with the results. `results = {n: n ** 2 for n in range(10)}` generates a dictionary containing key `n` mapped to value `n ** 2`. See Displays for lists, sets and dictionaries.

dictionary view

The objects returned from `dict.keys()`, `dict.values()`, and `dict.items()` are called dictionary views. They provide a dynamic view on the dictionary's entries, which means that when the dictionary changes, the view reflects these changes. To force the dictionary view to become a full list use `list(dictview)`. See Dictionary view objects.

docstring

A string literal which appears as the first expression in a class, function or module. While ignored when the suite is executed, it is recognized by the compiler and put into the `__doc__` attribute of the enclosing class, function or module. Since it is available via introspection, it is the canonical place for documentation of the object.

duck-typing

A programming style which does not look at an object's type to determine if it has the right interface; instead, the method or attribute is simply called or used ("If it looks like a duck and quacks like a duck, it must be a duck.") By emphasizing interfaces rather than specific types, well-designed code improves its flexibility by allowing polymorphic substitution. Duck-typing avoids tests using `type()` or `isinstance()`. (Note, however, that duck-typing can be complemented with abstract base classes.) Instead, it typically employs `hasattr()` tests or EAFP programming.

dunder

An informal short-hand for "double underscore", used when talking about a special method. For example, `__init__` is often pronounced "dunder init".

EAFP

Easier to ask for forgiveness than permission. This common Python coding style assumes the existence of valid keys or attributes and catches exceptions if the assumption proves false. This clean and fast style is characterized by the presence of many `try` and `except` statements. The technique contrasts with the LBYL style common to many other languages such as C.

evaluate function

A function that can be called to evaluate a lazily evaluated attribute of an object, such as the value of type aliases created with the `type` statement.

expression

A piece of syntax which can be evaluated to some value. In other words, an expression is an accumulation of expression elements like literals, names, attribute access, operators or function calls which all return a value. In contrast to many other languages, not all language constructs are expressions. There are also statements which cannot be used as expressions, such as `while`. Assignments are also statements, not expressions.

extension module

A module written in C or C++, using Python's C API to interact with the core and with user code.

f-string
f-strings

String literals prefixed with `f` or `F` are commonly called "f-strings" which is short for formatted string literals. See also **PEP 498** [https://peps.python.org/pep-0498/].

file object

An object exposing a file-oriented API (with methods such as `read()` or `write()`) to an underlying resource. Depending on the way it was created, a file object can mediate access to a real on-disk file or to another type of storage or communication device (for example standard input/output, in-memory buffers, sockets, pipes, etc.). File objects are also called *file-like objects* or *streams*.

There are actually three categories of file objects: raw binary files, buffered binary files and text files. Their interfaces are defined in the `io` module. The canonical way to create a file object is by using the `open()` function.

file-like object

A synonym for file object.

filesystem encoding and error handler

Encoding and error handler used by Python to decode bytes from the operating system and encode Unicode to the operating system.

The filesystem encoding must guarantee to successfully decode all bytes below 128. If the file system encoding fails to provide this guarantee, API functions can raise `UnicodeError`.

The `sys.getfilesystemencoding()` and `sys.getfilesystemencodeerrors()` functions can be used to get the filesystem encoding and error handler.

The filesystem encoding and error handler are configured at Python startup by the `PyConfig_Read()` function: see `filesystem_encoding` and `filesystem_errors` members of `PyConfig`.

See also the locale encoding.

finder

An object that tries to find the loader for a module that is being imported.

There are two types of finder: meta path finders for use with `sys.meta_path`, and path entry finders for use with `sys.path_hooks`.

See Finders and loaders and **`importlib`** for much more detail.

floor division

Mathematical division that rounds down to nearest integer. The floor division operator is `//`. For example, the expression `11 // 4` evaluates to `2` in contrast to the `2.75` returned by float true division. Note that `(-11) // 4` is `-3` because that is `-2.75` rounded *downward*. See **PEP 238** [https://peps.python.org/pep-0238/].

free threading

A threading model where multiple threads can run Python bytecode simultaneously within the same interpreter. This is in contrast to the global interpreter lock which allows only one thread to execute Python bytecode at a time. See **PEP 703** [https://peps.python.org/pep-0703/].

free variable

Formally, as defined in the language execution model, a free variable is any variable used in a namespace which is not a local variable in that namespace. See closure variable for an example. Pragmatically, due to the name of the **`codeobject.co_freevars`** attribute, the term is also sometimes used as a synonym for closure variable.

function

A series of statements which returns some value to a caller. It can also be passed zero or more arguments which may be used in the execution of the body. See also parameter, method, and the Function definitions section.

function annotation

An annotation of a function parameter or return value.

Function annotations are usually used for type hints: for example, this function is expected to take two **`int`** arguments and is also expected to have an **`int`** return value:

```
def sum_two_numbers(a: int, b: int) -> int:
   return a + b
```

Function annotation syntax is explained in section Function definitions.

See variable annotation and **PEP 484** [https://peps.python.org/pep-0484/], which describe this functionality. Also see Annotations Best Practices for best practices on working with annotations.

__future__

A future statement, `from __future__ import <feature>`, directs the compiler to compile the current module using syntax or semantics that will become standard in a future release of Python. The **`__future__`** module documents the possible values of *feature*. By importing this module and evaluating its variables, you can see when a new feature was first added to the language and when it will (or did) become the default:

```
>>> import __future__
>>> __future__.division
_Feature((2, 2, 0, 'alpha', 2), (3, 0, 0, 'alpha', 0), 8192)
```

garbage collection

The process of freeing memory when it is not used anymore. Python performs garbage collection via reference counting and a cyclic garbage collector that is able to detect and break reference cycles. The garbage collector can be controlled using the **`gc`** module.

generator

A function which returns a generator iterator. It looks like a normal function except that it contains **`yield`** expressions for producing a series of values usable in a for-loop or that can be retrieved one at a time with the **`next()`** function.

Usually refers to a generator function, but may refer to a *generator iterator* in some contexts. In cases where the intended meaning isn’t clear, using the full terms avoids ambiguity.

generator iterator

An object created by a generator function.

Each **`yield`** temporarily suspends processing, remembering the execution state (including local variables and pending try-statements). When the *generator iterator* resumes, it picks up where it left off (in contrast to functions which start fresh on every invocation).

generator expression

An expression that returns an iterator. It looks like a normal expression followed by a **`for`** clause defining a loop variable, range, and an optional **`if`** clause. The combined expression generates values for an enclosing function:

```
>>> sum(i*i for i in range(10))         # sum of squares 0,
1, 4, ... 81
285
```

generic function

A function composed of multiple functions implementing the same operation for different types. Which implementation should be used during a call is determined by the dispatch algorithm.

See also the single dispatch glossary entry, the `functools.singledispatch()` decorator, and **PEP 443** [https://peps.python.org/pep-0443/].

generic type

A type that can be parameterized; typically a container class such as `list` or `dict`. Used for type hints and annotations.

For more details, see generic alias types, **PEP 483** [https://peps.python.org/pep-0483/], **PEP 484** [https://peps.python.org/pep-0484/], **PEP 585** [https://peps.python.org/pep-0585/], and the `typing` module.

GIL

See global interpreter lock.

global interpreter lock

The mechanism used by the CPython interpreter to assure that only one thread executes Python bytecode at a time. This simplifies the CPython implementation by making the object model (including critical built-in types such as `dict`) implicitly safe against concurrent access. Locking the entire interpreter makes it easier for the interpreter to be multi-threaded, at the expense of much of the parallelism afforded by multi-processor machines.

However, some extension modules, either standard or third-party, are designed so as to release the GIL when doing computationally intensive tasks such as compression or hashing. Also, the GIL is always released when doing I/O.

As of Python 3.13, the GIL can be disabled using the `--disable-gil` build configuration. After building Python with this option, code must be run with `-X gil=0` or after setting the `PYTHON_GIL=0` environment variable. This feature enables improved performance for multi-threaded applications and makes it easier to use multi-core CPUs efficiently. For more details, see **PEP 703** [https://peps.python.org/pep-0703/].

In prior versions of Python's C API, a function might declare that it requires the GIL to be held in order to use it. This refers to having an attached thread state.

global state

Data that is accessible throughout a program, such as module-level variables, class variables, or C static variables in extension modules. In multi-threaded programs, global state shared between threads typically requires synchronization to avoid race conditions and data races.

hash-based pyc

A bytecode cache file that uses the hash rather than the last-modified time of the corresponding source file to determine its validity. See Cached bytecode invalidation.

hashable

An object is *hashable* if it has a hash value which never changes during its lifetime (it needs a `__hash__()` method), and can be compared to other objects (it needs an `__eq__()` method). Hashable objects which compare equal must have the same hash value.

Hashability makes an object usable as a dictionary key and a set member, because these data structures use the hash value internally.

Most of Python’s immutable built-in objects are hashable; mutable containers (such as lists or dictionaries) are not; immutable containers (such as tuples and frozensets) are only hashable if their elements are hashable. Objects which are instances of user-defined classes are hashable by default. They all compare unequal (except with themselves), and their hash value is derived from their `id()`.

IDLE

An Integrated Development and Learning Environment for Python. IDLE — Python editor and shell is a basic editor and interpreter environment which ships with the standard distribution of Python.

immortal

Immortal objects are a CPython implementation detail introduced in **PEP 683** [https://peps.python.org/pep-0683/].

If an object is immortal, its reference count is never modified, and therefore it is never deallocated while the interpreter is running. For example, `True` and `None` are immortal in CPython.

Immortal objects can be identified via `sys._is_immortal()`, or via `PyUnstable_IsImmortal()` in the C API.

immutable

An object with a fixed value. Immutable objects include numbers, strings and tuples. Such an object cannot be altered. A new object has to be created if a different value has to be stored. They play an important role in places where a constant hash value is needed, for example as a key in a dictionary. Immutable objects are inherently thread-safe because their state cannot be modified after creation, eliminating concerns about improperly synchronized concurrent modification.

import path

A list of locations (or path entries) that are searched by the path based finder for modules to import. During import, this list of locations usually comes from **`sys.path`**, but for subpackages it may also come from the parent package's `__path__` attribute.

importing

The process by which Python code in one module is made available to Python code in another module.

importer

An object that both finds and loads a module; both a finder and loader object.

interactive

Python has an interactive interpreter which means you can enter statements and expressions at the interpreter prompt, immediately execute them and see their results. Just launch `python` with no arguments (possibly by selecting it from your computer's main menu). It is a very powerful way to test out new ideas or inspect modules and packages (remember `help(x)`). For more on interactive mode, see Interactive Mode.

interpreted

Python is an interpreted language, as opposed to a compiled one, though the distinction can be blurry because of the presence of the bytecode compiler. This means that source files can be run directly without explicitly creating an executable which is then run. Interpreted languages typically have a shorter development/debug cycle than compiled ones, though their programs generally also run more slowly. See also interactive.

interpreter shutdown

When asked to shut down, the Python interpreter enters a special phase where it gradually releases all allocated resources, such as modules and various critical internal structures. It also makes several calls to the garbage collector. This can trigger the execution of code in user-defined destructors or weakref callbacks. Code executed during the shutdown phase can encounter various exceptions as the resources it relies on may not function anymore (common examples are library modules or the warnings machinery).

The main reason for interpreter shutdown is that the `__main__` module or the script being run has finished executing.

iterable

An object capable of returning its members one at a time. Examples of iterables include all sequence types (such as **`list`**, **`str`**, and **`tuple`**) and some non-sequence types like **`dict`**, file objects, and objects of any classes you define with an **`__iter__()`** method or with a **`__getitem__()`** method that implements sequence semantics.

Iterables can be used in a **`for`** loop and in many other places where a sequence is needed (**`zip()`**, **`map()`**, …). When an iterable object is passed as an argument to the built-in function **`iter()`**, it returns an iterator for the object. This iterator is good for one pass over the set of values. When using iterables, it is usually not necessary to call **`iter()`** or deal with iterator objects yourself. The **`for`** statement does that automatically for you, creating a temporary unnamed variable to hold the iterator for the duration of the loop. See also iterator, sequence, and generator.

iterator

An object representing a stream of data. Repeated calls to the iterator's `__next__()` method (or passing it to the built-in function `next()`) return successive items in the stream. When no more data are available a `StopIteration` exception is raised instead. At this point, the iterator object is exhausted and any further calls to its `__next__()` method just raise `StopIteration` again. Iterators are required to have an `__iter__()` method that returns the iterator object itself so every iterator is also iterable and may be used in most places where other iterables are accepted. One notable exception is code which attempts multiple iteration passes. A container object (such as a `list`) produces a fresh new iterator each time you pass it to the `iter()` function or use it in a `for` loop. Attempting this with an iterator will just return the same exhausted iterator object used in the previous iteration pass, making it appear like an empty container.

More information can be found in Iterator Types.

CPython implementation detail: CPython does not consistently apply the requirement that an iterator define `__iter__()`. And also please note that free-threaded CPython does not guarantee thread-safe behavior of iterator operations.

key function

A key function or collation function is a callable that returns a value used for sorting or ordering. For example, `locale.strxfrm()` is used to produce a sort key that is aware of locale specific sort conventions.

A number of tools in Python accept key functions to control how elements are ordered or grouped. They include **`min()`**, **`max()`**, **`sorted()`**, **`list.sort()`**, **`heapq.merge()`**, **`heapq.nsmallest()`**, **`heapq.nlargest()`**, and **`itertools.groupby()`**.

There are several ways to create a key function. For example. the **`str.casefold()`** method can serve as a key function for case insensitive sorts. Alternatively, a key function can be built from a **`lambda`** expression such as `lambda r: (r[0], r[2])`. Also, **`operator.attrgetter()`**, **`operator.itemgetter()`**, and **`operator.methodcaller()`** are three key function constructors. See the Sorting HOW TO for examples of how to create and use key functions.

keyword argument

See argument.

lambda

An anonymous inline function consisting of a single expression which is evaluated when the function is called. The syntax to create a lambda function is `lambda [parameters]: expression`

LBYL

Look before you leap. This coding style explicitly tests for pre-conditions before making calls or lookups. This style contrasts with the EAFP approach and is characterized by the presence of many **`if`** statements.

In a multi-threaded environment, the LBYL approach can risk introducing a race condition between “the looking” and “the leaping”. For example, the code, `if key in mapping: return mapping[key]` can fail if another thread removes *key* from *mapping* after the test, but before the lookup. This issue can be solved with locks or by using the EAFP approach. See also thread-safe.

lexical analyzer

Formal name for the *tokenizer*; see token.

list

A built-in Python sequence. Despite its name it is more akin to an array in other languages than to a linked list since access to elements is *O*(1).

list comprehension

A compact way to process all or part of the elements in a sequence and return a list with the results. `result = ['{:#04x}'.format(x) for x in range(256) if x % 2 == 0]` generates a list of strings containing even hex numbers (0x..) in the range from 0 to 255. The **`if`** clause is optional. If omitted, all elements in `range(256)` are processed.

lock

A synchronization primitive that allows only one thread at a time to access a shared resource. A thread must acquire a lock before accessing the protected resource and release it afterward. If a thread attempts to acquire a lock that is already held by another thread, it will block until the lock becomes available. Python’s **`threading`** module provides **`Lock`** (a basic lock) and **`RLock`** (a reentrant lock). Locks are used to prevent race conditions and ensure thread-safe access to shared data. Alternative design patterns to locks exist such as queues, producer/consumer patterns, and thread-local state. See also deadlock, and reentrant.

loader

An object that loads a module. It must define the **`exec_module()`** and **`create_module()`** methods to implement the `Loader` interface. A loader is typically returned by a finder. See also:

- Finders and loaders
- `importlib.abc.Loader`
- **PEP 302** [https://peps.python.org/pep-0302/]

locale encoding

On Unix, it is the encoding of the LC_CTYPE locale. It can be set with `locale.setlocale(locale.LC_CTYPE, new_locale)`.

On Windows, it is the ANSI code page (ex: `"cp1252"`).

On Android and VxWorks, Python uses `"utf-8"` as the locale encoding.

`locale.getencoding()` can be used to get the locale encoding.

See also the filesystem encoding and error handler.

magic method

An informal synonym for special method.

mapping

A container object that supports arbitrary key lookups and implements the methods specified in the `collections.abc.Mapping` or `collections.abc.MutableMapping` abstract base classes. Examples include `dict`, `collections.defaultdict`, `collections.OrderedDict` and `collections.Counter`.

meta path finder

A finder returned by a search of `sys.meta_path`. Meta path finders are related to, but different from path entry finders.

See `importlib.abc.MetaPathFinder` for the methods that meta path finders implement.

metaclass

The class of a class. Class definitions create a class name, a class dictionary, and a list of base classes. The metaclass is responsible for taking those three arguments and creating the class. Most object oriented programming languages provide a default implementation. What makes Python special is that it is possible to create custom metaclasses. Most users never need this tool, but when the need arises, metaclasses can provide powerful, elegant solutions. They have been used for logging attribute access, adding thread-safety, tracking object creation, implementing singletons, and many other tasks.

More information can be found in Metaclasses.

method

A function which is defined inside a class body. If called as an attribute of an instance of that class, the method will get the instance object as its first argument (which is usually called `self`). See function and nested scope.

method resolution order

Method Resolution Order is the order in which base classes are searched for a member during lookup. See The Python 2.3 Method Resolution Order for details of the algorithm used by the Python interpreter since the 2.3 release.

module

An object that serves as an organizational unit of Python code. Modules have a namespace containing arbitrary

Python objects. Modules are loaded into Python by the process of importing.

See also package.

module spec

A namespace containing the import-related information used to load a module. An instance of `importlib.machinery.ModuleSpec`.

See also Module specs.

MRO

See method resolution order.

mutable

An object with state that is allowed to change during the course of the program. In multi-threaded programs, mutable objects that are shared between threads require careful synchronization to avoid race conditions. See also immutable, thread-safe, and concurrent modification.

named tuple

The term “named tuple” applies to any type or class that inherits from tuple and whose indexable elements are also accessible using named attributes. The type or class may have other features as well.

Several built-in types are named tuples, including the values returned by `time.localtime()` and `os.stat()`. Another example is `sys.float_info`:

```
>>> sys.float_info[1]                   # indexed access
1024
>>> sys.float_info.max_exp              # named field access
1024
```

```
>>> isinstance(sys.float_info, tuple)   # kind of tuple
True
```

Some named tuples are built-in types (such as the above examples). Alternatively, a named tuple can be created from a regular class definition that inherits from **`tuple`** and that defines named fields. Such a class can be written by hand, or it can be created by inheriting **`typing.NamedTuple`**, or with the factory function **`collections.namedtuple()`**. The latter techniques also add some extra methods that may not be found in hand-written or built-in named tuples.

namespace

The place where a variable is stored. Namespaces are implemented as dictionaries. There are the local, global and built-in namespaces as well as nested namespaces in objects (in methods). Namespaces support modularity by preventing naming conflicts. For instance, the functions **`builtins.open`** and **`os.open()`** are distinguished by their namespaces. Namespaces also aid readability and maintainability by making it clear which module implements a function. For instance, writing **`random.seed()`** or **`itertools.islice()`** makes it clear that those functions are implemented by the **`random`** and **`itertools`** modules, respectively.

namespace package

A package which serves only as a container for subpackages. Namespace packages may have no physical representation, and specifically are not like a regular package because they have no `__init__.py` file.

Namespace packages allow several individually installable packages to have a common parent package. Otherwise, it is recommended to use a regular package.

For more information, see **PEP 420** [https://peps.python.org/pep-0420/] and Namespace packages.

See also module.

native code

Code that is compiled to machine instructions and runs directly on the processor, as opposed to code that is interpreted or runs in a virtual machine. In the context of Python, native code typically refers to C, C++, Rust or Fortran code in extension modules that can be called from Python. See also extension module.

nested scope

The ability to refer to a variable in an enclosing definition. For instance, a function defined inside another function can refer to variables in the outer function. Note that nested scopes by default work only for reference and not for assignment. Local variables both read and write in the innermost scope. Likewise, global variables read and write to the global namespace. The `nonlocal` allows writing to outer scopes.

new-style class

Old name for the flavor of classes now used for all class objects. In earlier Python versions, only new-style classes could use Python’s newer, versatile features like `__slots__`, descriptors, properties, `__getattribute__()`, class methods, and static methods.

non-deterministic

Behavior where the outcome of a program can vary between executions with the same inputs. In multi-threaded programs, non-deterministic behavior often results from race conditions where the relative timing or interleaving of threads affects the result. Proper synchronization using locks and other synchronization primitives helps ensure deterministic behavior.

object

Any data with state (attributes or value) and defined behavior (methods). Also the ultimate base class of any new-style class.

optimized scope

A scope where target local variable names are reliably known to the compiler when the code is compiled, allowing optimization of read and write access to these names. The local namespaces for functions, generators, coroutines, comprehensions, and generator expressions are optimized in this fashion. Note: most interpreter optimizations are applied to all scopes, only those relying on a known set of local and nonlocal variable names are restricted to optimized scopes.

optional module

An extension module that is part of the standard library, but may be absent in some builds of CPython, usually due to missing third-party libraries or because the module is not available for a given platform.

See Requirements for optional modules for a list of optional modules that require third-party libraries.

package

A Python module which can contain submodules or recursively, subpackages. Technically, a package is a Python module with a `__path__` attribute.

See also regular package and namespace package.

parallelism

Executing multiple operations at the same time (e.g. on multiple CPU cores). In Python builds with the global interpreter lock (GIL), only one thread runs Python bytecode at a time, so taking advantage of multiple CPU cores typically involves multiple processes (e.g. **`multiprocessing`**) or native extensions that release the GIL. In free-threaded Python, multiple Python threads can run Python code simultaneously on different cores.

parameter

A named entity in a function (or method) definition that specifies an argument (or in some cases, arguments) that the function can accept. There are five kinds of parameter:

- *positional-or-keyword*: specifies an argument that can be passed either positionally or as a keyword argument. This is the default kind of parameter, for example *foo* and *bar* in the following:

  ```
  def func(foo, bar=None): ...
  ```

- *positional-only*: specifies an argument that can be supplied only by position. Positional-only parameters can be defined by including a `/` character in the parameter list of the function definition after them, for example *posonly1* and *posonly2* in the following:

  ```
  def func(posonly1, posonly2, /, positional_or_keyword):
  ...
  ```

- *keyword-only*: specifies an argument that can be supplied only by keyword. Keyword-only parameters can be defined by including a single var-positional parameter or bare `*` in the parameter list of the function definition before them, for example *kw_only1* and *kw_only2* in the following:

```
def func(arg, *, kw_only1, kw_only2): ...
```

- *var-positional*: specifies that an arbitrary sequence of positional arguments can be provided (in addition to any positional arguments already accepted by other parameters). Such a parameter can be defined by prepending the parameter name with `*`, for example *args* in the following:

  ```
  def func(*args, **kwargs): ...
  ```

- *var-keyword*: specifies that arbitrarily many keyword arguments can be provided (in addition to any keyword arguments already accepted by other parameters). Such a parameter can be defined by prepending the parameter name with `**`, for example *kwargs* in the example above.

Parameters can specify both optional and required arguments, as well as default values for some optional arguments.

See also the argument glossary entry, the FAQ question on the difference between arguments and parameters, the **`inspect.Parameter`** class, the Function definitions section, and **PEP 362** [https://peps.python.org/pep-0362/].

path entry

A single location on the import path which the path based finder consults to find modules for importing.

path entry finder

A finder returned by a callable on **`sys.path_hooks`** (i.e. a path entry hook) which knows how to locate modules given a path entry.

See **`importlib.abc.PathEntryFinder`** for the methods that path entry finders implement.

path entry hook

A callable on the `sys.path_hooks` list which returns a path entry finder if it knows how to find modules on a specific path entry.

path based finder

One of the default meta path finders which searches an import path for modules.

path-like object

An object representing a file system path. A path-like object is either a `str` or `bytes` object representing a path, or an object implementing the `os.PathLike` protocol. An object that supports the `os.PathLike` protocol can be converted to a `str` or `bytes` file system path by calling the `os.fspath()` function; `os.fsdecode()` and `os.fsencode()` can be used to guarantee a `str` or `bytes` result instead, respectively. Introduced by **PEP 519** [https://peps.python.org/pep-0519/].

PEP

Python Enhancement Proposal. A PEP is a design document providing information to the Python community, or describing a new feature for Python or its processes or environment. PEPs should provide a concise technical specification and a rationale for proposed features.

PEPs are intended to be the primary mechanisms for proposing major new features, for collecting community input on an issue, and for documenting the design decisions that have gone into Python. The PEP author is responsible for building consensus within the community and documenting dissenting opinions.

See **PEP 1** [https://peps.python.org/pep-0001/].

portion

A set of files in a single directory (possibly stored in a zip file) that contribute to a namespace package, as defined in **PEP 420** [https://peps.python.org/pep-0420/].

positional argument

See argument.

provisional API

A provisional API is one which has been deliberately excluded from the standard library's backwards compatibility guarantees. While major changes to such interfaces are not expected, as long as they are marked provisional, backwards incompatible changes (up to and including removal of the interface) may occur if deemed necessary by core developers. Such changes will not be made gratuitously – they will occur only if serious fundamental flaws are uncovered that were missed prior to the inclusion of the API.

Even for provisional APIs, backwards incompatible changes are seen as a "solution of last resort" - every attempt will still be made to find a backwards compatible resolution to any identified problems.

This process allows the standard library to continue to evolve over time, without locking in problematic design errors for extended periods of time. See **PEP 411** [https://peps.python.org/pep-0411/] for more details.

provisional package

See provisional API.

Python 3000

Nickname for the Python 3.x release line (coined long ago when the release of version 3 was something in the distant future.) This is also abbreviated “Py3k”.

Pythonic

An idea or piece of code which closely follows the most common idioms of the Python language, rather than implementing code using concepts common to other languages. For example, a common idiom in Python is to loop over all elements of an iterable using a `for` statement. Many other languages don’t have this type of construct, so people unfamiliar with Python sometimes use a numerical counter instead:

```
for i in range(len(food)):
    print(food[i])
```

As opposed to the cleaner, Pythonic method:

```
for piece in food:
    print(piece)
```

qualified name

A dotted name showing the “path” from a module’s global scope to a class, function or method defined in that module, as defined in **PEP 3155** [https://peps.python.org/pep-3155/]. For top-level functions and classes, the qualified name is the same as the object’s name:

```
>>> class C:
...     class D:
...         def meth(self):
...             pass
...
>>> C.__qualname__
'C'
>>> C.D.__qualname__
'C.D'
```

```
>>> C.D.meth.__qualname__
'C.D.meth'
```

When used to refer to modules, the *fully qualified name* means the entire dotted path to the module, including any parent packages, e.g. `email.mime.text`:

```
>>> import email.mime.text
>>> email.mime.text.__name__
'email.mime.text'
```

race condition

A condition of a program where the its behavior depends on the relative timing or ordering of events, particularly in multi-threaded programs. Race conditions can lead to non-deterministic behavior and bugs that are difficult to reproduce. A data race is a specific type of race condition involving unsynchronized access to shared memory. The LBYL coding style is particularly susceptible to race conditions in multi-threaded code. Using locks and other synchronization primitives helps prevent race conditions.

reference count

The number of references to an object. When the reference count of an object drops to zero, it is deallocated. Some objects are immortal and have reference counts that are never modified, and therefore the objects are never deallocated. Reference counting is generally not visible to Python code, but it is a key element of the CPython implementation. Programmers can call the `sys.getrefcount()` function to return the reference count for a particular object.

In CPython, reference counts are not considered to be stable or well-defined values; the number of references to an object, and how that number is affected by Python code, may be different between versions.

regular package

A traditional package, such as a directory containing an `__init__.py` file.

See also namespace package.

reentrant

A property of a function or lock that allows it to be called or acquired multiple times by the same thread without causing errors or a deadlock.

For functions, reentrancy means the function can be safely called again before a previous invocation has completed, which is important when functions may be called recursively or from signal handlers. Thread-unsafe functions may be non-deterministic if they're called reentrantly in a multithreaded program.

For locks, Python's **`threading.RLock`** (reentrant lock) is reentrant, meaning a thread that already holds the lock can acquire it again without blocking. In contrast, **`threading.Lock`** is not reentrant - attempting to acquire it twice from the same thread will cause a deadlock.

See also lock and deadlock.

REPL

An acronym for the "read–eval–print loop", another name for the interactive interpreter shell.

__slots__

A declaration inside a class that saves memory by pre-declaring space for instance attributes and eliminating instance dictionaries. Though popular, the technique is somewhat tricky to get right and is best reserved for rare cases where there are large numbers of instances in a memory-critical application.

sequence

An iterable which supports efficient element access using integer indices via the `__getitem__()` special method and defines a `__len__()` method that returns the length of the sequence. Some built-in sequence types are `list`, `str`, `tuple`, and `bytes`. Note that `dict` also supports `__getitem__()` and `__len__()`, but is considered a mapping rather than a sequence because the lookups use arbitrary hashable keys rather than integers.

The `collections.abc.Sequence` abstract base class defines a much richer interface that goes beyond just `__getitem__()` and `__len__()`, adding `count()`, `index()`, `__contains__()`, and `__reversed__()`. Types that implement this expanded interface can be registered explicitly using `register()`. For more documentation on sequence methods generally, see Common Sequence Operations.

set comprehension

A compact way to process all or part of the elements in an iterable and return a set with the results. `results = {c for c in 'abracadabra' if c not in 'abc'}` generates the set of strings `{'r', 'd'}`. See Displays for lists, sets and dictionaries.

single dispatch

A form of generic function dispatch where the implementation is chosen based on the type of a single argument.

slice

An object usually containing a portion of a sequence. A slice is created using the subscript notation, `[]` with colons between numbers when several are given, such as in `variable_name[1:3:5]`. The bracket (subscript) notation uses **`slice`** objects internally.

soft deprecated

A soft deprecated API should not be used in new code, but it is safe for already existing code to use it. The API remains documented and tested, but will not be enhanced further.

Soft deprecation, unlike normal deprecation, does not plan on removing the API and will not emit warnings.

See PEP 387: Soft Deprecation [https://peps.python.org/pep-0387/#soft-deprecation].

special method

A method that is called implicitly by Python to execute a certain operation on a type, such as addition. Such methods have names starting and ending with double underscores. Special methods are documented in Special method names.

standard library

The collection of packages, modules and extension modules distributed as a part of the official Python interpreter package. The exact membership of the collection may vary based on platform, available system libraries, or other criteria. Documentation can be found at The Python Standard Library.

See also **`sys.stdlib_module_names`** for a list of all possible standard library module names.

statement

A statement is part of a suite (a “block” of code). A statement is either an expression or one of several constructs with a keyword, such as **`if`**, **`while`** or **`for`**.

static type checker

An external tool that reads Python code and analyzes it, looking for issues such as incorrect types. See also type hints and the **`typing`** module.

stdlib

An abbreviation of standard library.

strong reference

In Python’s C API, a strong reference is a reference to an object which is owned by the code holding the reference. The strong reference is taken by calling **`Py_INCREF()`** when the reference is created and released with **`Py_DECREF()`** when the reference is deleted.

The **`Py_NewRef()`** function can be used to create a strong reference to an object. Usually, the **`Py_DECREF()`** function must be called on the strong reference before exiting the scope of the strong reference, to avoid leaking one reference.

See also borrowed reference.

synchronization primitive

A basic building block for coordinating (synchronizing) the execution of multiple threads to ensure thread-safe access to shared resources. Python’s **`threading`** module provides several synchronization primitives including **`Lock`**, **`RLock`**, **`Semaphore`**, **`Condition`**, **`Event`**, and **`Barrier`**. Additionally, the **`queue`** module provides multi-producer, multi-consumer queues that are especially useful in multithreaded programs. These primitives help prevent race conditions and coordinate thread execution. See also lock.

t-string
t-strings

String literals prefixed with `t` or `T` are commonly called “t-strings” which is short for template string literals.

text encoding

A string in Python is a sequence of Unicode code points (in range `U+0000`–`U+10FFFF`). To store or transfer a string, it needs to be serialized as a sequence of bytes.

Serializing a string into a sequence of bytes is known as “encoding”, and recreating the string from the sequence of bytes is known as “decoding”.

There are a variety of different text serialization codecs, which are collectively referred to as “text encodings”.

text file

A file object able to read and write **`str`** objects. Often, a text file actually accesses a byte-oriented datastream and handles the text encoding automatically. Examples of text files are files opened in text mode (`'r'` or `'w'`), **`sys.stdin`**, **`sys.stdout`**, and instances of **`io.StringIO`**.

See also binary file for a file object able to read and write bytes-like objects.

thread state

The information used by the CPython runtime to run in an OS thread. For example, this includes the current exception, if any, and the state of the bytecode interpreter.

Each thread state is bound to a single OS thread, but threads may have many thread states available. At most, one of them may be attached at once.

An attached thread state is required to call most of Python’s C API, unless a function explicitly documents otherwise. The bytecode interpreter only runs under an attached thread state.

Each thread state belongs to a single interpreter, but each interpreter may have many thread states, including multiple for the same OS thread. Thread states from multiple interpreters may be bound to the same thread, but only one can be attached in that thread at any given moment.

See Thread State and the Global Interpreter Lock for more information.

thread-safe

A module, function, or class that behaves correctly when used by multiple threads concurrently. Thread-safe code uses appropriate synchronization primitives like locks to protect shared mutable state, or is designed to avoid shared mutable state entirely. In the free-threaded build, built-in types like `dict`, `list`, and `set` use internal locking to make many operations thread-safe, although thread safety is not necessarily guaranteed. Code that is not thread-safe may experience race conditions and data races when used in multi-threaded programs.

token

A small unit of source code, generated by the lexical analyzer (also called the *tokenizer*). Names, numbers, strings, operators, newlines and similar are represented by tokens.

The `tokenize` module exposes Python’s lexical analyzer. The `token` module contains information on the various types of tokens.

triple-quoted string

A string which is bound by three instances of either a quotation mark (”) or an apostrophe (‘). While they don’t provide any functionality not available with single-quoted strings, they are useful for a number of reasons. They allow you to include unescaped single and double quotes within a string and they can span multiple lines without the use of the continuation character, making them especially useful when writing docstrings.

type

The type of a Python object determines what kind of object it is; every object has a type. An object’s type is accessible as its `__class__` attribute or can be retrieved with `type(obj)`.

type alias

A synonym for a type, created by assigning the type to an identifier.

Type aliases are useful for simplifying type hints. For example:

```
def remove_gray_shades(
        colors: list[tuple[int, int, int]]) ->
list[tuple[int, int, int]]:
    pass
```

could be made more readable like this:

```
Color = tuple[int, int, int]

def remove_gray_shades(colors: list[Color]) -> list[Color]:
    pass
```

See **`typing`** and **PEP 484** [https://peps.python.org/pep-0484/], which describe this functionality.

type hint

An annotation that specifies the expected type for a variable, a class attribute, or a function parameter or return value.

Type hints are optional and are not enforced by Python but they are useful to static type checkers. They can also aid IDEs with code completion and refactoring.

Type hints of global variables, class attributes, and functions, but not local variables, can be accessed using **`typing.get_type_hints()`**.

See **`typing`** and **PEP 484** [https://peps.python.org/pep-0484/], which describe this functionality.

universal newlines

A manner of interpreting text streams in which all of the following are recognized as ending a line: the Unix end-of-line convention `'\n'`, the Windows convention `'\r\n'`, and the old Macintosh convention `'\r'`. See **PEP 278** [https://peps.python.org/pep-0278/] and **PEP 3116** [https://peps.python.org/pep-3116/], as well as **`bytes.splitlines()`** for an additional use.

variable annotation

An annotation of a variable or a class attribute.

When annotating a variable or a class attribute, assignment is optional:

```
class C:
    field: 'annotation'
```

Variable annotations are usually used for type hints: for example this variable is expected to take `int` values:

```
count: int = 0
```

Variable annotation syntax is explained in section Annotated assignment statements.

See function annotation, **PEP 484** [https://peps.python.org/pep-0484/] and **PEP 526** [https://peps.python.org/pep-0526/], which describe this functionality. Also see Annotations Best Practices for best practices on working with annotations.

virtual environment

A cooperatively isolated runtime environment that allows Python users and applications to install and upgrade Python distribution packages without interfering with the behaviour of other Python applications running on the same system.

See also `venv`.

virtual machine

A computer defined entirely in software. Python’s virtual machine executes the bytecode emitted by the bytecode compiler.

walrus operator

A light-hearted way to refer to the assignment expression operator `:=` because it looks a bit like a walrus if you turn your head.

Zen of Python

Listing of Python design principles and philosophies that are helpful in understanding and using the language. The listing can be found by typing “`import this`” at the interactive prompt.

About this documentation

Python's documentation is generated from reStructuredText [https://docutils.sourceforge.io/rst.html] sources using Sphinx [https://www.sphinx-doc.org/], a documentation generator originally created for Python and now maintained as an independent project.

Development of the documentation and its toolchain is an entirely volunteer effort, just like Python itself. If you want to contribute, please take a look at the Dealing with Bugs page for information on how to do so. New volunteers are always welcome!

Many thanks go to:

- Fred L. Drake, Jr., the creator of the original Python documentation toolset and author of much of the content;
- the Docutils [https://docutils.sourceforge.io/] project for creating reStructuredText and the Docutils suite;
- Fredrik Lundh for his Alternative Python Reference project from which Sphinx got many good ideas.

Contributors to the Python documentation

Many people have contributed to the Python language, the Python standard library, and the Python documentation. See Misc/ACKS [https://github.com/python/cpython/tree/3.14/Misc/ACKS] in the Python source distribution for a partial list of contributors.

It is only with the input and contributions of the Python community that Python has such wonderful documentation – Thank You!

Dealing with Bugs

Python is a mature programming language which has established a reputation for stability. In order to maintain this reputation, the developers would like to know of any deficiencies you find in Python.

It can be sometimes faster to fix bugs yourself and contribute patches to Python as it streamlines the process and involves less people. Learn how to contribute.

Documentation bugs

If you find a bug in this documentation or would like to propose an improvement, please submit a bug report on the issue tracker. If you have a suggestion on how to fix it, include that as well.

You can also open a discussion item on our Documentation Discourse forum [https://discuss.python.org/c/documentation/26].

If you find a bug in the theme (HTML / CSS / JavaScript) of the documentation, please submit a bug report on the python-doc-theme issue tracker [https://github.com/python/python-docs-theme].

See also

Documentation bugs [https://github.com/python/cpython/issues?q=is%3Aissue+is%3Aopen+label%3Adocs]
A list of documentation bugs that have been submitted to the Python issue tracker.

Issue Tracking **[https://devguide.python.org/tracker/]**

Helping with Documentation **[https://devguide.python.org/docquality/#helping-with-documentation]**
Comprehensive guide for individuals that are interested in contributing to Python documentation.

Documentation Translations **[https://devguide.python.org/documentation/translating/]**
A list of GitHub pages for documentation translation and their primary contacts.

Using the Python issue tracker

Issue reports for Python itself should be submitted via the GitHub issues tracker (https://github.com/python/cpython/issues). The GitHub issues tracker offers a web form which allows pertinent information to be entered and submitted to the developers.

The first step in filing a report is to determine whether the problem has already been reported. The advantage in doing so, aside from saving the developers' time, is that you learn what has been done to fix it; it may be that the problem has already been fixed for the next release, or additional information is needed (in which case you are welcome to provide it if you can!). To do this, search the tracker using the search box at the top of the page.

If the problem you're reporting is not already in the list, log in to GitHub. If you don't already have a GitHub account, create a new account using the “Sign up” link. It is not possible to submit a bug report anonymously.

Being now logged in, you can submit an issue. Click on the “New issue” button in the top bar to report a new issue.

The submission form has two fields, “Title” and “Comment”.

For the “Title” field, enter a *very* short description of the problem; fewer than ten words is good.

In the “Comment” field, describe the problem in detail, including what you expected to happen and what did happen. Be sure to include whether any extension modules were involved, and what hardware and software platform you were using (including version information as appropriate).

Each issue report will be reviewed by a developer who will determine what needs to be done to correct the problem. You will receive an update each time an action is taken on the issue.

See also

How to Report Bugs Effectively [https://www.chiark.greenend.org.uk/~sgtatham/bugs.html]
Article which goes into some detail about how to create a useful bug report. This describes what kind of information is useful and why it is useful.

Bug Writing Guidelines [https://bugzilla.mozilla.org/page.cgi?id=bug-writing.html]

> Information about writing a good bug report. Some of this is specific to the Mozilla project, but describes general good practices.

Getting started contributing to Python yourself

Beyond just reporting bugs that you find, you are also welcome to submit patches to fix them. You can find more information on how to get started patching Python in the Python Developer's Guide [https://devguide.python.org/]. If you have questions, the core-mentorship mailing list [https://mail.python.org/mailman3/lists/core-mentorship.python.org/] is a friendly place to get answers to any and all questions pertaining to the process of fixing issues in Python.

History and License

History of the software

Python was created in the early 1990s by Guido van Rossum at Stichting Mathematisch Centrum (CWI, see https://www.cwi.nl) in the Netherlands as a successor of a language called ABC. Guido remains Python’s principal author, although it includes many contributions from others.

In 1995, Guido continued his work on Python at the Corporation for National Research Initiatives (CNRI, see https://www.cnri.reston.va.us) in Reston, Virginia where he released several versions of the software.

In May 2000, Guido and the Python core development team moved to BeOpen.com to form the BeOpen PythonLabs team. In October of the same year, the PythonLabs team moved to Digital Creations, which became Zope Corporation. In 2001, the Python Software Foundation (PSF, see https://www.python.org/psf/) was formed, a non-profit organization created specifically to own Python-related Intellectual Property. Zope Corporation was a sponsoring member of the PSF.

All Python releases are Open Source (see https://opensource.org for the Open Source Definition). Historically, most, but not all, Python releases have also been GPL-compatible; the table below summarizes the various releases.

Release	Derived from	Year	Owner	GPL-compatible? (1)
0.9.0 thru 1.2	n/a	1991-1995	CWI	yes
1.3 thru 1.5.2	1.2	1995-1999	CNRI	yes
1.6	1.5.2	2000	CNRI	no
2.0	1.6	2000	BeOpen.com	no
1.6.1	1.6	2001	CNRI	yes (2)
2.1	2.0+1.6.1	2001	PSF	no
2.0.1	2.0+1.6.1	2001	PSF	yes
2.1.1	2.1+2.0.1	2001	PSF	yes
2.1.2	2.1.1	2002	PSF	yes
2.1.3	2.1.2	2002	PSF	yes

Release	Derived from	Year	Owner	GPL-compatible? (1)
2.2 and above	2.1.1	2001-now	PSF	yes

Note

1. GPL-compatible doesn’t mean that we’re distributing Python under the GPL. All Python licenses, unlike the GPL, let you distribute a modified version without making your changes open source. The GPL-compatible licenses make it possible to combine Python with other software that is released under the GPL; the others don’t.
2. According to Richard Stallman, 1.6.1 is not GPL-compatible, because its license has a choice of law clause. According to CNRI, however, Stallman’s lawyer has told CNRI’s lawyer that 1.6.1 is “not incompatible” with the GPL.

Thanks to the many outside volunteers who have worked under Guido’s direction to make these releases possible.

Terms and conditions for accessing or otherwise using Python

Python software and documentation are licensed under the Python Software Foundation License Version 2.

Starting with Python 3.8.6, examples, recipes, and other code in the documentation are dual licensed under the PSF License Version 2 and the Zero-Clause BSD license.

Some software incorporated into Python is under different licenses. The licenses are listed with code falling under that license. See Licenses and Acknowledgements for Incorporated Software for an incomplete list of these licenses.

PYTHON SOFTWARE FOUNDATION LICENSE VERSION 2

```
1. This LICENSE AGREEMENT is between the Python Software
Foundation ("PSF"), and
   the Individual or Organization ("Licensee") accessing and
otherwise using this
   software ("Python") in source or binary form and its
associated documentation.

2. Subject to the terms and conditions of this License
Agreement, PSF hereby
   grants Licensee a nonexclusive, royalty-free, world-wide
license to reproduce,
   analyze, test, perform and/or display publicly, prepare
derivative works,
   distribute, and otherwise use Python alone or in any
derivative
   version, provided, however, that PSF's License Agreement and
PSF's notice of
   copyright, i.e., "Copyright © 2001 Python Software
Foundation; All Rights
   Reserved" are retained in Python alone or in any derivative
version
   prepared by Licensee.

3. In the event Licensee prepares a derivative work that is
based on or
   incorporates Python or any part thereof, and wants to make
the
```

derivative work available to others as provided herein, then Licensee hereby agrees to include in any such work a brief summary of the changes made to Python.

4. PSF is making Python available to Licensee on an "AS IS" basis. PSF MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, PSF MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF PYTHON WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

5. PSF SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF PYTHON FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

6. This License Agreement will automatically terminate upon a material breach of its terms and conditions.

7. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between PSF and Licensee. This License Agreement does not grant permission to use PSF trademarks or trade name in a trademark sense to endorse or promote products or services of Licensee, or any third party.

8. By copying, installing or otherwise using Python, Licensee agrees to be bound by the terms and conditions of this License Agreement.

BEOPEN.COM LICENSE AGREEMENT FOR PYTHON 2.0

BEOPEN PYTHON OPEN SOURCE LICENSE AGREEMENT VERSION 1

1. This LICENSE AGREEMENT is between BeOpen.com ("BeOpen"), having an office at 160 Saratoga Avenue, Santa Clara, CA 95051, and the Individual or Organization ("Licensee") accessing and otherwise using this software in source or binary form and its associated documentation ("the Software").

2. Subject to the terms and conditions of this BeOpen Python License Agreement, BeOpen hereby grants Licensee a non-exclusive, royalty-free, world-wide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use the Software alone or in any derivative version, provided, however, that the BeOpen Python License is retained in the Software, alone or in any derivative version prepared by Licensee.

3. BeOpen is making the Software available to Licensee on an "AS IS" basis. BEOPEN MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, BEOPEN MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF THE SOFTWARE WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

4. BEOPEN SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF THE SOFTWARE FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS

A RESULT OF USING, MODIFYING OR DISTRIBUTING THE SOFTWARE, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

5. This License Agreement will automatically terminate upon a material breach of its terms and conditions.

6. This License Agreement shall be governed by and interpreted in all respects by the law of the State of California, excluding conflict of law provisions. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between BeOpen and Licensee. This License Agreement does not grant permission to use BeOpen trademarks or trade names in a trademark sense to endorse or promote products or services of Licensee, or any third party. As an exception, the "BeOpen Python" logos available at http://www.pythonlabs.com/logos.html may be used according to the permissions granted on that web page.

7. By copying, installing or otherwise using the software, Licensee agrees to be bound by the terms and conditions of this License Agreement.

CNRI LICENSE AGREEMENT FOR PYTHON 1.6.1

1. This LICENSE AGREEMENT is between the Corporation for National Research Initiatives, having an office at 1895 Preston White Drive, Reston, VA 20191 ("CNRI"), and the Individual or Organization ("Licensee") accessing and otherwise using Python 1.6.1 software in source or binary form and its associated documentation.

2. Subject to the terms and conditions of this License Agreement, CNRI hereby grants Licensee a nonexclusive, royalty-free, world-wide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use Python 1.6.1 alone or in any derivative version, provided, however, that CNRI's License Agreement and CNRI's notice of copyright, i.e., "Copyright © 1995-2001 Corporation for National Research Initiatives; All Rights Reserved" are retained in Python 1.6.1 alone or in any derivative version prepared by Licensee. Alternately, in lieu of CNRI's License Agreement, Licensee may substitute the following text (omitting the quotes): "Python 1.6.1 is made available subject to the terms and conditions in CNRI's License Agreement. This Agreement together with Python 1.6.1 may be located on the internet using the following unique, persistent identifier (known as a handle): 1895.22/1013. This Agreement may also be obtained from a proxy server on the internet using the following URL: http://hdl.handle.net/1895.22/1013".

3. In the event Licensee prepares a derivative work that is based on or incorporates Python 1.6.1 or any part thereof, and wants to make the derivative work available to others as provided herein, then Licensee hereby agrees to include in any such work a brief summary of the changes made to Python 1.6.1.

4. CNRI is making Python 1.6.1 available to Licensee on an "AS IS" basis. CNRI MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE,

BUT NOT LIMITATION, CNRI MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF PYTHON 1.6.1 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

5. CNRI SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF PYTHON 1.6.1 FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 1.6.1, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

6. This License Agreement will automatically terminate upon a material breach of its terms and conditions.

7. This License Agreement shall be governed by the federal intellectual property law of the United States, including without limitation the federal copyright law, and, to the extent such U.S. federal law does not apply, by the law of the Commonwealth of Virginia, excluding Virginia's conflict of law provisions. Notwithstanding the foregoing, with regard to derivative works based on Python 1.6.1 that incorporate non-separable material that was previously distributed under the GNU General Public License (GPL), the law of the Commonwealth of Virginia shall govern this License Agreement only as to issues arising under or with respect to Paragraphs 4, 5, and 7 of this License Agreement. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between CNRI and Licensee. This License Agreement does not grant permission to use CNRI trademarks or trade name in a trademark sense to endorse or promote products or services of

Licensee, or any third party.

8. By clicking on the "ACCEPT" button where indicated, or by copying, installing or otherwise using Python 1.6.1, Licensee agrees to be bound by the terms and conditions of this License Agreement.

Licenses and Acknowledgements for Incorporated Software

This section is an incomplete, but growing list of licenses and acknowledgements for third-party software incorporated in the Python distribution.

Mersenne Twister

The **`_random`** C extension underlying the **`random`** module includes code based on a download from http://www.math.sci.hiroshima-u.ac.jp/~m-mat/MT/MT2002/emt19937ar.html. The following are the verbatim comments from the original code:

A C-program for MT19937, with initialization improved 2002/1/26.
Coded by Takuji Nishimura and Makoto Matsumoto.

Before using, initialize the state by using init_genrand(seed) or init_by_array(init_key, key_length).

Copyright (C) 1997 - 2002, Makoto Matsumoto and Takuji Nishimura,
All rights reserved.

Redistribution and use in source and binary forms, with or without modification, are permitted provided that the following conditions are met:

1. Redistributions of source code must retain the above copyright notice, this list of conditions and the following disclaimer.

2. Redistributions in binary form must reproduce the above copyright notice, this list of conditions and the following disclaimer in the documentation and/or other materials provided with the distribution.

3. The names of its contributors may not be used to endorse or promote products derived from this software without specific prior written permission.

THIS SOFTWARE IS PROVIDED BY THE COPYRIGHT HOLDERS AND CONTRIBUTORS "AS IS" AND ANY EXPRESS OR IMPLIED WARRANTIES, INCLUDING, BUT NOT LIMITED TO, THE IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS FOR A PARTICULAR PURPOSE ARE DISCLAIMED. IN NO EVENT SHALL THE COPYRIGHT OWNER OR

```
CONTRIBUTORS BE LIABLE FOR ANY DIRECT, INDIRECT, INCIDENTAL,
SPECIAL,
EXEMPLARY, OR CONSEQUENTIAL DAMAGES (INCLUDING, BUT NOT LIMITED
TO,
PROCUREMENT OF SUBSTITUTE GOODS OR SERVICES; LOSS OF USE, DATA,
OR
PROFITS; OR BUSINESS INTERRUPTION) HOWEVER CAUSED AND ON ANY
THEORY OF
LIABILITY, WHETHER IN CONTRACT, STRICT LIABILITY, OR TORT
(INCLUDING
NEGLIGENCE OR OTHERWISE) ARISING IN ANY WAY OUT OF THE USE OF
THIS
SOFTWARE, EVEN IF ADVISED OF THE POSSIBILITY OF SUCH DAMAGE.

Any feedback is very welcome.

DAMAGES
WHATSOEVER RESULTING FROM LOSS OF USE, DATA OR PROFITS, WHETHER
IN AN
ACTION OF CONTRACT, NEGLIGENCE OR OTHER TORTIOUS ACTION,
ARISING OUT
OF OR IN CONNECTION WITH THE USE OR PERFORMANCE OF THIS
SOFTWARE.

Modified by Jack Jansen, CWI, July 1995:
- Use binascii module to do the actual line-by-line conversion
  between ascii and binary. This results in a 1000-fold
speedup. The C
  version is still 5 times faster, though.
- Arguments more compliant with Python standard
```

XML Remote Procedure Calls

The `xmlrpc.client` module contains the following notice:

```
    The XML-RPC client interface is

   Jean-Philippe Aumasson (https://131002.net/siphash/siphash24.c)
```

strtod and dtoa

The file `Python/dtoa.c`, which supplies C functions dtoa and strtod for conversion of C doubles to and from strings, is derived from the file of the same name by David M. Gay, currently available from https://web.archive.org/web/20220517033456/http://www.netlib.org/fp/dtoa.c. The original file, as retrieved on March 16, 2009, contains the following copyright and licensing notice:

```
/**************************************************************
**
 *
 * The author of this software is David M. Gay.
 *
 * Copyright (c) 1991, 2000, 2001 by Lucent Technologies.
 *
 * Permission to use, copy, modify, and distribute this
software for any
 * purpose without fee is hereby granted, provided that this
entire notice

OpenSSL

The modules `hashlib`, `posix` and `ssl` use the OpenSSL library for added performance if made available by the operating system. Additionally, the Windows and macOS installers for Python may include a copy of the OpenSSL libraries, so we include a copy of the OpenSSL license here. For the OpenSSL 3.0 release, and later releases derived from that, the Apache License v2 applies:

```
                              Apache License
                        Version 2.0, January 2004
```

https://www.apache.org/licenses/

TERMS AND CONDITIONS FOR USE, REPRODUCTION, AND DISTRIBUTION

1. Definitions.

"License" shall mean the terms and conditions for use, reproduction, and distribution as defined by Sections 1 through 9 of this document.

"Licensor" shall mean the copyright owner or entity authorized by the copyright owner that is granting the License.

"Legal Entity" shall mean the union of the acting entity and all other entities that control, are controlled by, or are under common control with that entity. For the purposes of this definition, "control" means (i) the power, direct or indirect, to cause the direction or management of such entity, whether by contract or otherwise, or (ii) ownership of fifty percent (50%) or more of the outstanding shares, or (iii) beneficial ownership of such entity.

"You" (or "Your") shall mean an individual or Legal Entity exercising permissions granted by this License.

"Source" form shall mean the preferred form for making modifications, including but not limited to software source code, documentation source, and configuration files.

"Object" form shall mean any form resulting from mechanical transformation or translation of a Source form, including but not limited to compiled object code, generated documentation, and conversions to other media types.

"Work" shall mean the work of authorship, whether in Source or Object form, made available under the License, as indicated by a copyright notice that is included in or attached to the work (an example is provided in the Appendix below).

"Derivative Works" shall mean any work, whether in Source or Object form, that is based on (or derived from) the Work and for which the editorial revisions, annotations, elaborations, or other modifications represent, as a whole, an original work of authorship. For the purposes of this License, Derivative Works shall not include works that remain separable from, or merely link (or bind by name) to the interfaces of, the Work and Derivative Works thereof.

"Contribution" shall mean any work of authorship, including the original version of the Work and any modifications or additions to that Work or Derivative Works thereof, that is intentionally submitted to Licensor for inclusion in the Work by the copyright owner or by an individual or Legal Entity authorized to submit on behalf of the copyright owner. For the purposes of this definition, "submitted" means any form of electronic, verbal, or written communication sent to the Licensor or its representatives, including but not limited to communication on electronic mailing lists, source code control systems, and issue tracking systems that are managed by, or on behalf of, the

Licensor for the purpose of discussing and improving the Work, but excluding communication that is conspicuously marked or otherwise designated in writing by the copyright owner as "Not a Contribution."

"Contributor" shall mean Licensor and any individual or Legal Entity on behalf of whom a Contribution has been received by Licensor and subsequently incorporated within the Work.

2. Grant of Copyright License. Subject to the terms and conditions of this License, each Contributor hereby grants to You a perpetual, worldwide, non-exclusive, no-charge, royalty-free, irrevocable copyright license to reproduce, prepare Derivative Works of, publicly display, publicly perform, sublicense, and distribute the Work and such Derivative Works in Source or Object form.

3. Grant of Patent License. Subject to the terms and conditions of this License, each Contributor hereby grants to You a perpetual, worldwide, non-exclusive, no-charge, royalty-free, irrevocable (except as stated in this section) patent license to make, have made, use, offer to sell, sell, import, and otherwise transfer the Work, where such license applies only to those patent claims licensable by such Contributor that are necessarily infringed by their Contribution(s) alone or by combination of their Contribution(s) with the Work to which such Contribution(s) was submitted. If You institute patent litigation against any entity (including a cross-claim or counterclaim in a lawsuit) alleging that the

Work or a Contribution incorporated within the Work constitutes direct or contributory patent infringement, then any patent licenses granted to You under this License for that Work shall terminate as of the date such litigation is filed.

4. Redistribution. You may reproduce and distribute copies of the Work or Derivative Works thereof in any medium, with or without modifications, and in Source or Object form, provided that You meet the following conditions:

(a) You must give any other recipients of the Work or Derivative Works a copy of this License; and

(b) You must cause any modified files to carry prominent notices stating that You changed the files; and

(c) You must retain, in the Source form of any Derivative Works that You distribute, all copyright, patent, trademark, and attribution notices from the Source form of the Work, excluding those notices that do not pertain to any part of the Derivative Works; and

(d) If the Work includes a "NOTICE" text file as part of its distribution, then any Derivative Works that You distribute must include a readable copy of the attribution notices contained within such NOTICE file, excluding those notices that do not pertain to any part of the Derivative Works, in at least one of the following places: within a NOTICE text file distributed as part of the Derivative Works; within the Source form or documentation, if provided along with the Derivative Works; or, within a display generated by the Derivative Works, if and wherever such third-party notices normally appear. The contents of the NOTICE file are for informational purposes only and do not modify the License. You may add Your own attribution notices within Derivative Works that You distribute, alongside or as an addendum to the NOTICE text from the Work, provided that such additional attribution notices cannot be construed as modifying the License.

You may add Your own copyright statement to Your modifications and may provide additional or different license terms and conditions for use, reproduction, or distribution of Your modifications, or for any such Derivative Works as a whole, provided Your use, reproduction, and distribution of the Work otherwise complies with the conditions stated in this License.

5. Submission of Contributions. Unless You explicitly state otherwise, any Contribution intentionally submitted for inclusion in the Work by You to the Licensor shall be under the terms and conditions of this License, without any additional terms or conditions. Notwithstanding the above, nothing herein shall supersede or modify the terms of any separate license agreement you may have executed

with Licensor regarding such Contributions.

6. Trademarks. This License does not grant permission to use the trade names, trademarks, service marks, or product names of the Licensor, except as required for reasonable and customary use in describing the origin of the Work and reproducing the content of the NOTICE file.

7. Disclaimer of Warranty. Unless required by applicable law or agreed to in writing, Licensor provides the Work (and each Contributor provides its Contributions) on an "AS IS" BASIS, WITHOUT WARRANTIES OR CONDITIONS OF ANY KIND, either express or implied, including, without limitation, any warranties or conditions of TITLE, NON-INFRINGEMENT, MERCHANTABILITY, or FITNESS FOR A PARTICULAR PURPOSE. You are solely responsible for determining the appropriateness of using or redistributing the Work and assume any risks associated with Your exercise of permissions under this License.

8. Limitation of Liability. In no event and under no legal theory, whether in tort (including negligence), contract, or otherwise, unless required by applicable law (such as deliberate and grossly negligent acts) or agreed to in writing, shall any Contributor be liable to You for damages, including any direct, indirect, special, incidental, or consequential damages of any character arising as a result of this License or out of the use or inability to use the Work (including but not limited to damages for loss of goodwill,

work stoppage, computer failure or malfunction, or any and all other commercial damages or losses), even if such Contributor has been advised of the possibility of such damages.

9. Accepting Warranty or Additional Liability. While redistributing the Work or Derivative Works thereof, You may choose to offer, and charge a fee for, acceptance of support, warranty, indemnity, or other liability obligations and/or rights consistent with this License. However, in accepting such obligations, You may act only on Your own behalf and on Your sole responsibility, not on behalf of any other Contributor, and only if You agree to indemnify, defend, and hold each Contributor harmless for any liability incurred by, or claims asserted against, such Contributor by reason of your accepting any such warranty or additional liability.

END OF TERMS AND CONDITIONS

expat

The `pyexpat` extension is built using an included copy of the expat sources unless the build is configured `--with-system-expat`:

Python Module Index

_ | a | b | c | d | e | f | g | h | i | j | k | l | m | n | o | p | q | r | s | t | u | v | w | x | z

_	
`__future__`	*Future statement definitions*
`__main__`	*The environment where top-level code is run. Covers command-line interfaces, import-time behavior, and ``__name__ == '__main__'``.*
`_thread`	*Low-level threading API.*
`_tkinter`	*A binary module that contains the low-level interface to Tcl/Tk.*
a	
`abc`	*Abstract base classes according to :pep:`3119`.*
`aifc`	**Deprecated:** *Removed in 3.13.*
`annotationlib`	*Functionality for introspecting annotations*
`argparse`	*Command-line option and argument parsing library.*
`array`	*Space efficient arrays of uniformly typed numeric values.*

`ast`	*Abstract Syntax Tree classes and manipulation.*
`asynchat`	**Deprecated:** *Removed in 3.12.*
`asyncio`	*Asynchronous I/O.*
`asyncore`	**Deprecated:** *Removed in 3.12.*
`atexit`	*Register and execute cleanup functions.*
`audioop`	**Deprecated:** *Removed in 3.13.*
b	
`base64`	*RFC 4648: Base16, Base32, Base64 Data Encodings; Base85 and Ascii85*
`bdb`	*Debugger framework.*
`binascii`	*Tools for converting between binary and various ASCII-encoded binary representations.*
`bisect`	*Array bisection algorithms for binary searching.*
`builtins`	*The module that provides the built-in namespace.*
`bz2`	*Interfaces for bzip2 compression and decompression.*
c	

`calendar`	*Functions for working with calendars, including some emulation of the Unix cal program.*
`cgi`	**Deprecated:** *Removed in 3.13.*
`cgitb`	**Deprecated:** *Removed in 3.13.*
`chunk`	**Deprecated:** *Removed in 3.13.*
`cmath`	*Mathematical functions for complex numbers.*
`cmd`	*Build line-oriented command interpreters.*
`code`	*Facilities to implement read-eval-print loops.*
`codecs`	*Encode and decode data and streams.*
`codeop`	*Compile (possibly incomplete) Python code.*
`collections`	*Container datatypes*
`collections.abc`	*Abstract base classes for containers*
`colorsys`	*Conversion functions between RGB and other color systems.*
`compileall`	*Tools for byte-compiling all Python source files in a directory tree.*
`compression`	
`compression.zstd`	*Low-level interface to compression and*

	decompression routines in the zstd library.
`concurrent`	
`concurrent.futures`	*Execute computations concurrently using threads or processes.*
`concurrent.interpreters`	*Multiple interpreters in the same process*
`configparser`	*Configuration file parser.*
`contextlib`	*Utilities for with-statement contexts.*
`contextvars`	*Context Variables*
`copy`	*Shallow and deep copy operations.*
`copyreg`	*Register pickle support functions.*
`cProfile`	
`crypt`	**Deprecated:** *Removed in 3.13.*
`csv`	*Write and read tabular data to and from delimited files.*
`ctypes`	*A foreign function library for Python.*
`curses` *(Unix)*	*An interface to the curses library, providing portable terminal handling.*
`curses.ascii`	*Constants and set-membership functions for ASCII characters.*
`curses.panel`	*A panel stack extension that adds depth to curses windows.*

`curses.textpad`	*Emacs-like input editing in a curses window.*
d	
`dataclasses`	*Generate special methods on user-defined classes.*
`datetime`	*Basic date and time types.*
`dbm`	*Interfaces to various Unix "database" formats.*
`dbm.dumb`	*Portable implementation of the simple DBM interface.*
`dbm.gnu` *(Unix)*	*GNU database manager*
`dbm.ndbm` *(Unix)*	*The New Database Manager*
`dbm.sqlite3` *(All)*	*SQLite backend for dbm*
`decimal`	*Implementation of the General Decimal Arithmetic Specification.*
`difflib`	*Helpers for computing differences between objects.*
`dis`	*Disassembler for Python bytecode.*
`distutils`	**Deprecated:** *Removed in 3.12.*
`doctest`	*Test pieces of code within docstrings.*
e	
`email`	*Package supporting the parsing, manipulating, and generating email messages.*
`email.charset`	*Character Sets*

`email.contentmanager`	*Storing and Retrieving Content from MIME Parts*
`email.encoders`	*Encoders for email message payloads.*
`email.errors`	*The exception classes used by the email package.*
`email.generator`	*Generate flat text email messages from a message structure.*
`email.header`	*Representing non-ASCII headers*
`email.headerregistry`	*Automatic Parsing of headers based on the field name*
`email.iterators`	*Iterate over a message object tree.*
`email.message`	*The base class representing email messages.*
`email.mime`	*Build MIME messages.*
`email.mime.application`	
`email.mime.audio`	
`email.mime.base`	
`email.mime.image`	
`email.mime.message`	
`email.mime.multipart`	
`email.mime.nonmultipart`	
`email.mime.text`	
`email.parser`	*Parse flat text email messages to produce a message object structure.*
`email.policy`	*Controlling the parsing and generating of messages*

`email.utils`	*Miscellaneous email package utilities.*
`encodings`	*Encodings package*
`encodings.idna`	*Internationalized Domain Names implementation*
`encodings.mbcs`	*Windows ANSI codepage*
`encodings.utf_8_sig`	*UTF-8 codec with BOM signature*
`ensurepip`	*Bootstrapping the "pip" installer into an existing Python installation or virtual environment.*
`enum`	*Implementation of an enumeration class.*
`errno`	*Standard errno system symbols.*
f	
`faulthandler`	*Dump the Python traceback.*
`fcntl` *(Unix)*	*The fcntl() and ioctl() system calls.*
`filecmp`	*Compare files efficiently.*
`fileinput`	*Loop over standard input or a list of files.*
`fnmatch`	*Unix shell style filename pattern matching.*
`fractions`	*Rational numbers.*
`ftplib`	*FTP protocol client (requires sockets).*
`functools`	*Higher-order functions and operations on callable objects.*

g	
`gc`	*Interface to the cycle-detecting garbage collector.*
`getopt`	*Portable parser for command line options; support both short and long option names.*
`getpass`	*Portable reading of passwords and retrieval of the userid.*
`gettext`	*Multilingual internationalization services.*
`glob`	*Unix shell style pathname pattern expansion.*
`graphlib`	*Functionality to operate with graph-like structures*
`grp` *(Unix)*	*The group database (getgrnam() and friends).*
`gzip`	*Interfaces for gzip compression and decompression using file objects.*

h	
`hashlib`	*Secure hash and message digest algorithms.*
`heapq`	*Heap queue algorithm (a.k.a. priority queue).*
`hmac`	*Keyed-Hashing for Message Authentication (HMAC) implementation*
`html`	*Helpers for manipulating HTML.*

`html.entities`	*Definitions of HTML general entities.*
`html.parser`	*A simple parser that can handle HTML and XHTML.*
`http`	*HTTP status codes and messages*
`http.client`	*HTTP and HTTPS protocol client (requires sockets).*
`http.cookiejar`	*Classes for automatic handling of HTTP cookies.*
`http.cookies`	*Support for HTTP state management (cookies).*
`http.server`	*HTTP server and request handlers.*
i	
`idlelib`	*Implementation package for the IDLE shell/editor.*
`imaplib`	*IMAP4 protocol client (requires sockets).*
`imghdr`	**Deprecated:** *Removed in 3.13.*
`imp`	**Deprecated:** *Removed in 3.12.*
`importlib`	*The implementation of the import machinery.*
`importlib.abc`	*Abstract base classes related to import*
`importlib.machinery`	*Importers and path hooks*
`importlib.metadata`	*Accessing package metadata*

importlib.resources	*Package resource reading, opening, and access*
importlib.resources.abc	*Abstract base classes for resources*
importlib.util	*Utility code for importers*
inspect	*Extract information and source code from live objects.*
io	*Core tools for working with streams.*
ipaddress	*IPv4/IPv6 manipulation library.*
itertools	*Functions creating iterators for efficient looping.*
j	
json	*Encode and decode the JSON format.*
json.tool	*A command-line interface to validate and pretty-print JSON.*
k	
keyword	*Test whether a string is a keyword in Python.*
l	
linecache	*Provides random access to individual lines from text files.*
locale	*Internationalization services.*
logging	*Flexible event logging system for applications.*
logging.config	*Configuration of the logging module.*

`logging.handlers`	*Handlers for the logging module.*
`lzma`	*A Python wrapper for the liblzma compression library.*
m	
`mailbox`	*Manipulate mailboxes in various formats*
`mailcap`	**Deprecated:** *Removed in 3.13.*
`marshal`	*Convert Python objects to streams of bytes and back (with different constraints).*
`math`	*Mathematical functions (sin() etc.).*
`mimetypes`	*Mapping of filename extensions to MIME types.*
`mmap`	*Interface to memory-mapped files for Unix and Windows.*
`modulefinder`	*Find modules used by a script.*
`msilib`	**Deprecated:** *Removed in 3.13.*
`msvcrt` *(Windows)*	*Miscellaneous useful routines from the MS VC++ runtime.*
`multiprocessing`	*Process-based parallelism.*
`multiprocessing.connection`	*API for dealing with sockets.*
`multiprocessing.dummy`	*Dumb wrapper around threading.*
`multiprocessing.managers`	*Share data between process with shared objects.*
`multiprocessing.pool`	*Create pools of processes.*

multiprocessing.shared_memory	*Provides shared memory for direct access across processes.*
multiprocessing.sharedctypes	*Allocate ctypes objects from shared memory.*
n	
netrc	*Loading of .netrc files.*
nis	**Deprecated:** *Removed in 3.13.*
nntplib	**Deprecated:** *Removed in 3.13.*
numbers	*Numeric abstract base classes (Complex, Real, Integral, etc.).*
o	
operator	*Functions corresponding to the standard operators.*
optparse	*Command-line option parsing library.*
os	*Miscellaneous operating system interfaces.*
os.path	*Operations on pathnames.*
ossaudiodev	**Deprecated:** *Removed in 3.13.*
p	
pathlib	*Object-oriented filesystem paths*
pathlib.types	*pathlib types for static type checking*

`pdb`	*The Python debugger for interactive interpreters.*
`pickle`	*Convert Python objects to streams of bytes and back.*
`pickletools`	*Contains extensive comments about the pickle protocols and pickle-machine opcodes, as well as some useful functions.*
`pipes`	**Deprecated:** *Removed in 3.13.*
`pkgutil`	*Utilities for the import system.*
`platform`	*Retrieves as much platform identifying data as possible.*
`plistlib`	*Generate and parse Apple plist files.*
`poplib`	*POP3 protocol client (requires sockets).*
`posix` *(Unix)*	*The most common POSIX system calls (normally used via module os).*
`pprint`	*Data pretty printer.*
`profile`	*Python source profiler.*
`pstats`	*Statistics object for use with the profiler.*
`pty` *(Unix)*	*Pseudo-Terminal Handling for Unix.*
`pwd` *(Unix)*	*The password database (getpwnam() and friends).*
`py_compile`	*Generate byte-code files from Python source files.*
`pyclbr`	*Supports information extraction for a Python*

	module browser.
`pydoc`	*Documentation generator and online help system.*
q	
`queue`	*A synchronized queue class.*
`quopri`	*Encode and decode files using the MIME quoted-printable encoding.*
r	
`random`	*Generate pseudo-random numbers with various common distributions.*
`re`	*Regular expression operations.*
`readline` *(Unix)*	*GNU readline support for Python.*
`reprlib`	*Alternate repr() implementation with size limits.*
`resource` *(Unix)*	*An interface to provide resource usage information on the current process.*
`rlcompleter`	*Python identifier completion, suitable for the GNU readline library.*
`runpy`	*Locate and run Python modules without importing them first.*

s	
`sched`	*General purpose event scheduler.*
`secrets`	*Generate secure random numbers for managing secrets.*
`select`	*Wait for I/O completion on multiple streams.*
`selectors`	*High-level I/O multiplexing.*
`shelve`	*Python object persistence.*
`shlex`	*Simple lexical analysis for Unix shell-like languages.*
`shutil`	*High-level file operations, including copying.*
`signal`	*Set handlers for asynchronous events.*
`site`	*Module responsible for site-specific configuration.*
`sitecustomize`	
`smtpd`	**Deprecated:** *Removed in 3.12.*
`smtplib`	*SMTP protocol client (requires sockets).*
`sndhdr`	**Deprecated:** *Removed in 3.13.*
`socket`	*Low-level networking interface.*
`socketserver`	*A framework for network servers.*
`spwd`	**Deprecated:** *Removed in 3.13.*

`sqlite3`	*A DB-API 2.0 implementation using SQLite 3.x.*
`ssl`	*TLS/SSL wrapper for socket objects*
`stat`	*Utilities for interpreting the results of os.stat(), os.lstat() and os.fstat().*
`statistics`	*Mathematical statistics functions*
`string`	*Common string operations.*
`string.templatelib`	*Support for template string literals.*
`stringprep`	*String preparation, as per RFC 3453*
`struct`	*Interpret bytes as packed binary data.*
`subprocess`	*Subprocess management.*
`sunau`	**Deprecated:** *Removed in 3.13.*
`symtable`	*Interface to the compiler's internal symbol tables.*
`sys`	*Access system-specific parameters and functions.*
`sys.monitoring`	*Access and control event monitoring*
`sysconfig`	*Python's configuration information*
`syslog` *(Unix)*	*An interface to the Unix syslog library routines.*
t	

`tabnanny`	*Tool for detecting white space related problems in Python source files in a directory tree.*
`tarfile`	*Read and write tar-format archive files.*
`telnetlib`	**Deprecated:** *Removed in 3.13.*
`tempfile`	*Generate temporary files and directories.*
`termios` *(Unix)*	*POSIX style tty control.*
`test`	*Regression tests package containing the testing suite for Python.*
`test.regrtest`	*Drives the regression test suite.*
`test.support`	*Support for Python's regression test suite.*
`test.support.bytecode_helper`	*Support tools for testing correct bytecode generation.*
`test.support.import_helper`	*Support for import tests.*
`test.support.os_helper`	*Support for os tests.*
`test.support.script_helper`	*Support for Python's script execution tests.*
`test.support.socket_helper`	*Support for socket tests.*
`test.support.threading_helper`	*Support for threading tests.*
`test.support.warnings_helper`	*Support for warnings tests.*
`textwrap`	*Text wrapping and filling*
`threading`	*Thread-based parallelism.*
`time`	*Time access and conversions.*

`timeit`	*Measure the execution time of small code snippets.*
`tkinter`	*Interface to Tcl/Tk for graphical user interfaces*
`tkinter.colorchooser` *(Tk)*	*Color choosing dialog*
`tkinter.commondialog` *(Tk)*	*Tkinter base class for dialogs*
`tkinter.dnd` *(Tk)*	*Tkinter drag-and-drop interface*
`tkinter.filedialog` *(Tk)*	*Dialog classes for file selection*
`tkinter.font` *(Tk)*	*Tkinter font-wrapping class*
`tkinter.messagebox` *(Tk)*	*Various types of alert dialogs*
`tkinter.scrolledtext` *(Tk)*	*Text widget with a vertical scroll bar.*
`tkinter.simpledialog` *(Tk)*	*Simple dialog windows*
`tkinter.ttk`	*Tk themed widget set*
`token`	*Constants representing terminal nodes of the parse tree.*
`tokenize`	*Lexical scanner for Python source code.*
`tomllib`	*Parse TOML files.*
`trace`	*Trace or track Python statement execution.*
`traceback`	*Print or retrieve a stack traceback.*
`tracemalloc`	*Trace memory allocations.*
`tty` *(Unix)*	*Utility functions that perform common terminal control operations.*

`turtle`	*An educational framework for simple graphics applications*
`turtledemo`	*A viewer for example turtle scripts*
`types`	*Names for built-in types.*
`typing`	*Support for type hints (see :pep:`484`).*
u	
`unicodedata`	*Access the Unicode Database.*
`unittest`	*Unit testing framework for Python.*
`unittest.mock`	*Mock object library.*
`urllib`	
`urllib.error`	*Exception classes raised by urllib.request.*
`urllib.parse`	*Parse URLs into or assemble them from components.*
`urllib.request`	*Extensible library for opening URLs.*
`urllib.response`	*Response classes used by urllib.*
`urllib.robotparser`	*Load a robots.txt file and answer questions about fetchability of other URLs.*
`usercustomize`	
`uu`	**Deprecated:** *Removed in 3.13.*
`uuid`	*UUID objects (universally unique identifiers) according to RFC 9562*

v	
`venv`	*Creation of virtual environments.*
w	
`warnings`	*Issue warning messages and control their disposition.*
`wave`	*Provide an interface to the WAV sound format.*
`weakref`	*Support for weak references and weak dictionaries.*
`webbrowser`	*Easy-to-use controller for web browsers.*
`winreg` *(Windows)*	*Routines and objects for manipulating the Windows registry.*
`winsound` *(Windows)*	*Access to the sound-playing machinery for Windows.*
`wsgiref`	*WSGI Utilities and Reference Implementation.*
`wsgiref.handlers`	*WSGI server/gateway base classes.*
`wsgiref.headers`	*WSGI response header tools.*
`wsgiref.simple_server`	*A simple WSGI HTTP server.*
`wsgiref.types`	*WSGI types for static type checking*
`wsgiref.util`	*WSGI environment utilities.*
`wsgiref.validate`	*WSGI conformance checker.*
x	

`xdrlib`	**Deprecated:** *Removed in 3.13.*
`xml`	*Package containing XML processing modules*
`xml.dom`	*Document Object Model API for Python.*
`xml.dom.minidom`	*Minimal Document Object Model (DOM) implementation.*
`xml.dom.pulldom`	*Support for building partial DOM trees from SAX events.*
`xml.etree.ElementInclude`	
`xml.etree.ElementTree`	*Implementation of the ElementTree API.*
`xml.parsers.expat`	*An interface to the Expat non-validating XML parser.*
`xml.parsers.expat.errors`	
`xml.parsers.expat.model`	
`xml.sax`	*Package containing SAX2 base classes and convenience functions.*
`xml.sax.handler`	*Base classes for SAX event handlers.*
`xml.sax.saxutils`	*Convenience functions and classes for use with SAX.*
`xml.sax.xmlreader`	*Interface which SAX-compliant XML parsers must implement.*
`xmlrpc`	*Server and client modules implementing XML-RPC.*
`xmlrpc.client`	*XML-RPC client access.*
`xmlrpc.server`	*Basic XML-RPC server implementations.*

z	
`zipapp`	*Manage executable Python zip archives*
`zipfile`	*Read and write ZIP-format archive files.*
`zipimport`	*Support for importing Python modules from ZIP archives.*
`zlib`	*Low-level interface to compression and decompression routines compatible with gzip.*
`zoneinfo`	*IANA time zone support*

Pending removal in Python 3.14

- The `ma_version_tag` field in **`PyDictObject`** for extension modules (**PEP 699** [https://peps.python.org/pep-0699/]; gh-101193 [https://github.com/python/cpython/issues/101193]).
- Creating **`immutable types`** with mutable bases (gh-95388 [https://github.com/python/cpython/issues/95388]).

Pending removal in Python 3.15

- The `PyImport_ImportModuleNoBlock()`: Use `PyImport_ImportModule()` instead.
- `PyWeakref_GetObject()` and `PyWeakref_GET_OBJECT()`: Use `PyWeakref_GetRef()` instead. The pythoncapi-compat project [https://github.com/python/pythoncapi-compat/] can be used to get `PyWeakref_GetRef()` on Python 3.12 and older.
- `Py_UNICODE` type and the **`Py_UNICODE_WIDE`** macro: Use **`wchar_t`** instead.
- **`PyUnicode_AsDecodedObject()`**: Use `PyCodec_Decode()` instead.
- **`PyUnicode_AsDecodedUnicode()`**: Use `PyCodec_Decode()` instead; Note that some codecs (for example, “base64”) may return a type other than `str`, such as `bytes`.
- **`PyUnicode_AsEncodedObject()`**: Use `PyCodec_Encode()` instead.
- **`PyUnicode_AsEncodedUnicode()`**: Use `PyCodec_Encode()` instead; Note that some codecs (for example, “base64”) may return a type other than `bytes`, such as `str`.
- Python initialization functions, deprecated in Python 3.13:
  - `Py_GetPath()`: Use `PyConfig_Get("module_search_paths")` (`sys.path`) instead.
  - `Py_GetPrefix()`: Use `PyConfig_Get("base_prefix")` (`sys.base_prefix`) instead. Use `PyConfig_Get("prefix")`

    (`sys.prefix`) if virtual environments need to be handled.
  - `Py_GetExecPrefix()`: Use `PyConfig_Get("base_exec_prefix")` (`sys.base_exec_prefix`) instead. Use `PyConfig_Get("exec_prefix")` (`sys.exec_prefix`) if virtual environments need to be handled.
  - `Py_GetProgramFullPath()`: Use `PyConfig_Get("executable")` (`sys.executable`) instead.
  - `Py_GetProgramName()`: Use `PyConfig_Get("executable")` (`sys.executable`) instead.
  - `Py_GetPythonHome()`: Use `PyConfig_Get("home")` or the `PYTHONHOME` environment variable instead.

  The pythoncapi-compat project [https://github.com/python/pythoncapi-compat/] can be used to get `PyConfig_Get()` on Python 3.13 and older.

- Functions to configure Python's initialization, deprecated in Python 3.11:

  - `PySys_SetArgvEx()`: Set `PyConfig.argv` instead.
  - `PySys_SetArgv()`: Set `PyConfig.argv` instead.
  - `Py_SetProgramName()`: Set `PyConfig.program_name` instead.
  - `Py_SetPythonHome()`: Set `PyConfig.home` instead.
  - `PySys_ResetWarnOptions()`: Clear `sys.warnoptions` and `warnings.filters` instead.

  The `Py_InitializeFromConfig()` API should be used with `PyConfig` instead.

- Global configuration variables:

  - `Py_DebugFlag`: Use `PyConfig.parser_debug` or `PyConfig_Get("parser_debug")` instead.
  - `Py_VerboseFlag`: Use `PyConfig.verbose` or `PyConfig_Get("verbose")` instead.

  - `Py_QuietFlag`: Use `PyConfig.quiet` or `PyConfig_Get("quiet")` instead.
  - `Py_InteractiveFlag`: Use `PyConfig.interactive` or `PyConfig_Get("interactive")` instead.
  - `Py_InspectFlag`: Use `PyConfig.inspect` or `PyConfig_Get("inspect")` instead.
  - `Py_OptimizeFlag`: Use `PyConfig.optimization_level` or `PyConfig_Get("optimization_level")` instead.
  - `Py_NoSiteFlag`: Use `PyConfig.site_import` or `PyConfig_Get("site_import")` instead.
  - `Py_BytesWarningFlag`: Use `PyConfig.bytes_warning` or `PyConfig_Get("bytes_warning")` instead.
  - `Py_FrozenFlag`: Use `PyConfig.pathconfig_warnings` or `PyConfig_Get("pathconfig_warnings")` instead.
  - `Py_IgnoreEnvironmentFlag`: Use `PyConfig.use_environment` or `PyConfig_Get("use_environment")` instead.
  - `Py_DontWriteBytecodeFlag`: Use `PyConfig.write_bytecode` or `PyConfig_Get("write_bytecode")` instead.
  - `Py_NoUserSiteDirectory`: Use `PyConfig.user_site_directory` or `PyConfig_Get("user_site_directory")` instead.
  - `Py_UnbufferedStdioFlag`: Use `PyConfig.buffered_stdio` or `PyConfig_Get("buffered_stdio")` instead.
  - `Py_HashRandomizationFlag`: Use `PyConfig.use_hash_seed` and `PyConfig.hash_seed` or `PyConfig_Get("hash_seed")` instead.
  - `Py_IsolatedFlag`: Use `PyConfig.isolated` or `PyConfig_Get("isolated")` instead.
  - `Py_LegacyWindowsFSEncodingFlag`: Use `PyPreConfig.legacy_windows_fs_encoding` or `PyConfig_Get("legacy_windows_fs_encoding")` instead.
  - `Py_LegacyWindowsStdioFlag`: Use `PyConfig.legacy_windows_stdio` or `PyConfig_Get("legacy_windows_stdio")` instead.
  - `Py_FileSystemDefaultEncoding`, `Py_HasFileSystemDefaultEncoding`: Use

  `PyConfig.filesystem_encoding` or `PyConfig_Get("filesystem_encoding")` instead.
  - **`Py_FileSystemDefaultEncodeErrors`**: Use `PyConfig.filesystem_errors` or `PyConfig_Get("filesystem_errors")` instead.
  - **`Py_UTF8Mode`**: Use `PyPreConfig.utf8_mode` or `PyConfig_Get("utf8_mode")` instead. (see `Py_PreInitialize()`)

The `Py_InitializeFromConfig()` API should be used with `PyConfig` to set these options. Or `PyConfig_Get()` can be used to get these options at runtime.

Pending removal in Python 3.16

- The bundled copy of `libmpdec`.

Pending removal in Python 3.18

- The following private functions are deprecated and planned for removal in Python 3.18:
    - **`_PyBytes_Join()`**: use `PyBytes_Join()`.
    - **`_PyDict_GetItemStringWithError()`**: use `PyDict_GetItemStringRef()`.
    - **`_PyDict_Pop()`**: use `PyDict_Pop()`.
    - **`_PyLong_Sign()`**: use `PyLong_GetSign()`.
    - **`_PyLong_FromDigits()`** and **`_PyLong_New()`**: use `PyLongWriter_Create()`.
    - **`_PyThreadState_UncheckedGet()`**: use `PyThreadState_GetUnchecked()`.
    - **`_PyUnicode_AsString()`**: use `PyUnicode_AsUTF8()`.
    - **`_PyUnicodeWriter_Init()`**: replace `_PyUnicodeWriter_Init(&writer)` with `writer = PyUnicodeWriter_Create(0)`.
    - **`_PyUnicodeWriter_Finish()`**: replace `_PyUnicodeWriter_Finish(&writer)` with `PyUnicodeWriter_Finish(writer)`.
    - **`_PyUnicodeWriter_Dealloc()`**: replace `_PyUnicodeWriter_Dealloc(&writer)` with `PyUnicodeWriter_Discard(writer)`.
    - **`_PyUnicodeWriter_WriteChar()`**: replace `_PyUnicodeWriter_WriteChar(&writer, ch)` with `PyUnicodeWriter_WriteChar(writer, ch)`.
    - **`_PyUnicodeWriter_WriteStr()`**: replace `_PyUnicodeWriter_WriteStr(&writer, str)` with `PyUnicodeWriter_WriteStr(writer, str)`.

- **`_PyUnicodeWriter_WriteSubstring()`**: replace `_PyUnicodeWriter_WriteSubstring(&writer, str, start, end)` with **`PyUnicodeWriter_WriteSubstring(writer, str, start, end)`**.
- **`_PyUnicodeWriter_WriteASCIIString()`**: replace `_PyUnicodeWriter_WriteASCIIString(&writer, str)` with **`PyUnicodeWriter_WriteASCII(writer, str)`**.
- **`_PyUnicodeWriter_WriteLatin1String()`**: replace `_PyUnicodeWriter_WriteLatin1String(&writer, str)` with **`PyUnicodeWriter_WriteUTF8(writer, str)`**.
- **`_PyUnicodeWriter_Prepare()`**: (no replacement).
- **`_PyUnicodeWriter_PrepareKind()`**: (no replacement).
- **`_Py_HashPointer()`**: use **`Py_HashPointer()`**.
- **`_Py_fopen_obj()`**: use **`Py_fopen()`**.

The pythoncapi-compat project [https://github.com/python/pythoncapi-compat/] can be used to get these new public functions on Python 3.13 and older. (Contributed by Victor Stinner in gh-128863 [https://github.com/python/cpython/issues/128863].)

Pending removal in future versions

The following APIs are deprecated and will be removed, although there is currently no date scheduled for their removal.

- `Py_TPFLAGS_HAVE_FINALIZE`: Unneeded since Python 3.8.
- `PyErr_Fetch()`: Use `PyErr_GetRaisedException()` instead.
- `PyErr_NormalizeException()`: Use `PyErr_GetRaisedException()` instead.
- `PyErr_Restore()`: Use `PyErr_SetRaisedException()` instead.
- `PyModule_GetFilename()`: Use `PyModule_GetFilenameObject()` instead.
- `PyOS_AfterFork()`: Use `PyOS_AfterFork_Child()` instead.
- `PySlice_GetIndicesEx()`: Use `PySlice_Unpack()` and `PySlice_AdjustIndices()` instead.
- `PyUnicode_READY()`: Unneeded since Python 3.12
- `PyErr_Display()`: Use `PyErr_DisplayException()` instead.
- `_PyErr_ChainExceptions()`: Use `_PyErr_ChainExceptions1()` instead.
- `PyBytesObject.ob_shash` member: call `PyObject_Hash()` instead.
- Thread Local Storage (TLS) API:
  - `PyThread_create_key()`: Use `PyThread_tss_alloc()` instead.
  - `PyThread_delete_key()`: Use `PyThread_tss_free()` instead.
  - `PyThread_set_key_value()`: Use `PyThread_tss_set()` instead.
  - `PyThread_get_key_value()`: Use `PyThread_tss_get()` instead.

  - `PyThread_delete_key_value()`: Use `PyThread_tss_delete()` instead.
  - `PyThread_ReInitTLS()`: Unneeded since Python 3.7.

Pending removal in Python 3.13

Modules (see **PEP 594** [https://peps.python.org/pep-0594/]):

- **`aifc`**
- **`audioop`**
- **`cgi`**
- **`cgitb`**
- **`chunk`**
- **`crypt`**
- **`imghdr`**
- **`mailcap`**
- **`msilib`**
- **`nis`**
- **`nntplib`**
- **`ossaudiodev`**
- **`pipes`**
- **`sndhdr`**
- **`spwd`**
- **`sunau`**
- **`telnetlib`**
- **`uu`**
- **`xdrlib`**

Other modules:

- **`lib2to3`**, and the **2to3** program (gh-84540 [https://github.com/python/cpython/issues/84540])

APIs:

- **`configparser.LegacyInterpolation`** (gh-90765 [https://github.com/python/cpython/issues/90765])
- `locale.resetlocale()` (gh-90817 [https://github.com/python/cpython/issues/90817])
- **`turtle.RawTurtle.settiltangle()`** (gh-50096 [https://github.com/python/cpython/issues/50096])
- **`unittest.findTestCases()`** (gh-50096 [https://github.com/python/cpython/issues/50096])
- **`unittest.getTestCaseNames()`** (gh-50096 [https://github.com/python/cpython/issues/50096])
- **`unittest.makeSuite()`** (gh-50096 [https://github.com/python/cpython/issues/50096])
- **`unittest.TestProgram.usageExit()`** (gh-67048 [https://github.com/python/cpython/issues/67048])
- **`webbrowser.MacOSX`** (gh-86421 [https://github.com/python/cpython/issues/86421])
- **`classmethod`** descriptor chaining (gh-89519 [https://github.com/python/cpython/issues/89519])

Pending removal in Python 3.14

- `argparse`: The *type*, *choices*, and *metavar* parameters of `argparse.BooleanOptionalAction` are deprecated and will be removed in 3.14. (Contributed by Nikita Sobolev in gh-92248 [https://github.com/python/cpython/issues/92248].)
- `ast`: The following features have been deprecated in documentation since Python 3.8, now cause a `DeprecationWarning` to be emitted at runtime when they are accessed or used, and will be removed in Python 3.14:
  - `ast.Num`
  - `ast.Str`
  - `ast.Bytes`
  - `ast.NameConstant`
  - `ast.Ellipsis`

  Use `ast.Constant` instead. (Contributed by Serhiy Storchaka in gh-90953 [https://github.com/python/cpython/issues/90953].)
- `asyncio`:
  - The child watcher classes `asyncio.MultiLoopChildWatcher`, `asyncio.FastChildWatcher`, `asyncio.AbstractChildWatcher` and `asyncio.SafeChildWatcher` are deprecated and will be removed in Python 3.14. (Contributed by Kumar Aditya in gh-94597 [https://github.com/python/cpython/issues/94597].)

  - **`asyncio.set_child_watcher()`**, **`asyncio.get_child_watcher()`**, **`asyncio.AbstractEventLoopPolicy.set_child_watcher()`** and **`asyncio.AbstractEventLoopPolicy.get_child_watcher()`** are deprecated and will be removed in Python 3.14. (Contributed by Kumar Aditya in gh-94597 [https://github.com/python/cpython/issues/94597].)
  - The **`get_event_loop()`** method of the default event loop policy now emits a **`DeprecationWarning`** if there is no current event loop set and it decides to create one. (Contributed by Serhiy Storchaka and Guido van Rossum in gh-100160 [https://github.com/python/cpython/issues/100160].)

- **`email`**: Deprecated the *isdst* parameter in **`email.utils.localtime()`**. (Contributed by Alan Williams in gh-72346 [https://github.com/python/cpython/issues/72346].)

- **`importlib.abc`** deprecated classes:

  - **`importlib.abc.ResourceReader`**
  - **`importlib.abc.Traversable`**
  - **`importlib.abc.TraversableResources`**

  Use **`importlib.resources.abc`** classes instead:

  - **`importlib.resources.abc.Traversable`**
  - **`importlib.resources.abc.TraversableResources`**

  (Contributed by Jason R. Coombs and Hugo van Kemenade in gh-93963 [https://github.com/python/cpython/issues/93963].)

- **`itertools`** had undocumented, inefficient, historically buggy, and inconsistent support for copy, deepcopy, and pickle operations. This will be removed in 3.14 for a significant reduction in code volume and maintenance burden. (Contributed by Raymond Hettinger in gh-101588 [https://github.com/python/cpython/issues/101588].)

- **`multiprocessing`**: The default start method will change to a safer one on Linux, BSDs, and other non-macOS POSIX platforms where `'fork'` is currently the default (gh-84559 [https://github.com/python/cpython/issues/84559]). Adding a runtime warning about this was deemed too disruptive as the majority of code is not expected to care. Use the **`get_context()`** or **`set_start_method()`** APIs to explicitly specify when your code *requires* `'fork'`. See Contexts and start methods.

- **`pathlib`**: **`is_relative_to()`** and **`relative_to()`**: passing additional arguments is deprecated.

- **`pkgutil`**: **`pkgutil.find_loader()`** and **`pkgutil.get_loader()`** now raise **`DeprecationWarning`**; use **`importlib.util.find_spec()`** instead. (Contributed by Nikita Sobolev in gh-97850 [https://github.com/python/cpython/issues/97850].)

- **`pty`**:
  - `master_open()`: use **`pty.openpty()`**.
  - `slave_open()`: use **`pty.openpty()`**.

- **`sqlite3`**:
  - **`version`** and **`version_info`**.
  - **`execute()`** and **`executemany()`** if named placeholders are used and *parameters* is a sequence instead of a **`dict`**.

- **`urllib`**: **`urllib.parse.Quoter`** is deprecated: it was not intended to be a public API. (Contributed by Gregory P.

Smith in gh-88168 [https://github.com/python/cpython/issues/88168].)

Pending removal in Python 3.15

- The import system:
  - Setting `__cached__` on a module while failing to set `__spec__.cached` is deprecated. In Python 3.15, `__cached__` will cease to be set or take into consideration by the import system or standard library. (gh-97879 [https://github.com/python/cpython/issues/97879])
  - Setting `__package__` on a module while failing to set `__spec__.parent` is deprecated. In Python 3.15, `__package__` will cease to be set or take into consideration by the import system or standard library. (gh-97879 [https://github.com/python/cpython/issues/97879])
- `ctypes`:
  - The undocumented `ctypes.SetPointerType()` function has been deprecated since Python 3.13.
- `http.server`:
  - The obsolete and rarely used `CGIHTTPRequestHandler` has been deprecated since Python 3.13. No direct replacement exists. *Anything* is better than CGI to interface a web server with a request handler.
  - The `--cgi` flag to the **python -m http.server** command-line interface has been deprecated since Python 3.13.
- `importlib`:
  - `load_module()` method: use `exec_module()` instead.
- `locale`:
  - The `getdefaultlocale()` function has been deprecated since Python 3.11. Its removal was originally

    planned for Python 3.13 (gh-90817 [https://github.com/python/cpython/issues/90817]), but has been postponed to Python 3.15. Use **`getlocale()`**, **`setlocale()`**, and **`getencoding()`** instead. (Contributed by Hugo van Kemenade in gh-111187 [https://github.com/python/cpython/issues/111187].)
- **`pathlib`**:
    - **`PurePath.is_reserved()`** has been deprecated since Python 3.13. Use **`os.path.isreserved()`** to detect reserved paths on Windows.
- **`platform`**:
    - **`java_ver()`** has been deprecated since Python 3.13. This function is only useful for Jython support, has a confusing API, and is largely untested.
- **`sysconfig`**:
    - The *check_home* argument of **`sysconfig.is_python_build()`** has been deprecated since Python 3.12.
- **`threading`**:
    - **`RLock()`** will take no arguments in Python 3.15. Passing any arguments has been deprecated since Python 3.14, as the Python version does not permit any arguments, but the C version allows any number of positional or keyword arguments, ignoring every argument.
- **`types`**:
    - **`types.CodeType`**: Accessing **`co_lnotab`** was deprecated in **PEP 626** [https://peps.python.org/pep-0626/] since 3.10 and was planned to be removed in 3.12, but it only got a proper **`DeprecationWarning`** in 3.12. May be removed in 3.15. (Contributed by Nikita Sobolev in gh-101866 [https://github.com/python/cpython/issues/101866].)
- **`typing`**:
    - The undocumented keyword argument syntax for creating **`NamedTuple`** classes (for example, `Point = NamedTuple("Point", x=int, y=int)`) has been

deprecated since Python 3.13. Use the class-based syntax or the functional syntax instead.
  - When using the functional syntax of **`TypedDict`**s, failing to pass a value to the *fields* parameter (`TD = TypedDict("TD")`) or passing `None` (`TD = TypedDict("TD", None)`) has been deprecated since Python 3.13. Use `class TD(TypedDict): pass` or `TD = TypedDict("TD", {})` to create a TypedDict with zero field.
  - The **`typing.no_type_check_decorator()`** decorator function has been deprecated since Python 3.13. After eight years in the **`typing`** module, it has yet to be supported by any major type checker.
- **`wave`**:
  - The **`getmark()`**, **`setmark()`**, and **`getmarkers()`** methods of the **`Wave_read`** and **`Wave_write`** classes have been deprecated since Python 3.13.
- **`zipimport`**:
  - **`load_module()`** has been deprecated since Python 3.10. Use **`exec_module()`** instead. (Contributed by Jiahao Li in gh-125746 [https://github.com/python/cpython/issues/125746].)

Pending removal in Python 3.16

- The import system:
  - Setting `__loader__` on a module while failing to set `__spec__.loader` is deprecated. In Python 3.16, `__loader__` will cease to be set or taken into consideration by the import system or the standard library.
- `array`:
  - The `'u'` format code (`wchar_t`) has been deprecated in documentation since Python 3.3 and at runtime since Python 3.13. Use the `'w'` format code (`Py_UCS4`) for Unicode characters instead.
- `asyncio`:
  - `asyncio.iscoroutinefunction()` is deprecated and will be removed in Python 3.16; use `inspect.iscoroutinefunction()` instead. (Contributed by Jiahao Li and Kumar Aditya in gh-122875 [https://github.com/python/cpython/issues/122875].)
  - `asyncio` policy system is deprecated and will be removed in Python 3.16. In particular, the following classes and functions are deprecated:
    - `asyncio.AbstractEventLoopPolicy`
    - `asyncio.DefaultEventLoopPolicy`
    - `asyncio.WindowsSelectorEventLoopPolicy`

        - `asyncio.WindowsProactorEventLoopPolicy`
        - `asyncio.get_event_loop_policy()`
        - `asyncio.set_event_loop_policy()`

    Users should use `asyncio.run()` or `asyncio.Runner` with *loop_factory* to use the desired event loop implementation.

    For example, to use `asyncio.SelectorEventLoop` on Windows:

    ```
    import asyncio

    async def main():
        ...

    asyncio.run(main(),
    loop_factory=asyncio.SelectorEventLoop)
    ```

    (Contributed by Kumar Aditya in gh-127949 [https://github.com/python/cpython/issues/127949].)

- `builtins`:

    - Bitwise inversion on boolean types, `~True` or `~False` has been deprecated since Python 3.12, as it produces surprising and unintuitive results (`-2` and `-1`). Use `not x` instead for the logical negation of a Boolean. In the rare case that you need the bitwise inversion of the underlying integer, convert to `int` explicitly (`~int(x)`).

- `functools`:

    - Calling the Python implementation of `functools.reduce()` with *function* or *sequence* as keyword arguments has been deprecated since Python 3.14.

- `logging`:

  Support for custom logging handlers with the *strm* argument is deprecated and scheduled for removal in Python 3.16. Define handlers with the *stream* argument instead. (Contributed by Mariusz Felisiak in gh-115032 [https://github.com/python/cpython/issues/115032].)

- `mimetypes`:

  - Valid extensions start with a ‘.’ or are empty for `mimetypes.MimeTypes.add_type()`. Undotted extensions are deprecated and will raise a `ValueError` in Python 3.16. (Contributed by Hugo van Kemenade in gh-75223 [https://github.com/python/cpython/issues/75223].)

- `shutil`:

  - The **`ExecError`** exception has been deprecated since Python 3.14. It has not been used by any function in **`shutil`** since Python 3.4, and is now an alias of `RuntimeError`.

- `symtable`:

  - The `Class.get_methods` method has been deprecated since Python 3.14.

- `sys`:

  - The `_enablelegacywindowsfsencoding()` function has been deprecated since Python 3.13. Use the `PYTHONLEGACYWINDOWSFSENCODING` environment variable instead.

- `sysconfig`:

  - The `sysconfig.expand_makefile_vars()` function has been deprecated since Python 3.14. Use the `vars` argument of `sysconfig.get_paths()` instead.

- `tarfile`:

  - The undocumented and unused `TarFile.tarfile` attribute has been deprecated since Python 3.13.

Pending removal in Python 3.17

- `collections.abc`:
    - `collections.abc.ByteString` is scheduled for removal in Python 3.17.

      Use `isinstance(obj, collections.abc.Buffer)` to test if `obj` implements the buffer protocol at runtime. For use in type annotations, either use `Buffer` or a union that explicitly specifies the types your code supports (e.g., `bytes | bytearray | memoryview`).

      `ByteString` was originally intended to be an abstract class that would serve as a supertype of both `bytes` and `bytearray`. However, since the ABC never had any methods, knowing that an object was an instance of `ByteString` never actually told you anything useful about the object. Other common buffer types such as `memoryview` were also never understood as subtypes of `ByteString` (either at runtime or by static type checkers).

      See **PEP 688** [https://peps.python.org/pep-0688/#current-options] for more details. (Contributed by Shantanu Jain in gh-91896 [https://github.com/python/cpython/issues/91896].)
- `typing`:
    - Before Python 3.14, old-style unions were implemented using the private class

`typing._UnionGenericAlias`. This class is no longer needed for the implementation, but it has been retained for backward compatibility, with removal scheduled for Python 3.17. Users should use documented introspection helpers like **`typing.get_origin()`** and **`typing.get_args()`** instead of relying on private implementation details.

- **`typing.ByteString`**, deprecated since Python 3.9, is scheduled for removal in Python 3.17.

  Use `isinstance(obj, collections.abc.Buffer)` to test if `obj` implements the buffer protocol at runtime. For use in type annotations, either use **`Buffer`** or a union that explicitly specifies the types your code supports (e.g., `bytes | bytearray | memoryview`).

  `ByteString` was originally intended to be an abstract class that would serve as a supertype of both **`bytes`** and **`bytearray`**. However, since the ABC never had any methods, knowing that an object was an instance of **`ByteString`** never actually told you anything useful about the object. Other common buffer types such as **`memoryview`** were also never understood as subtypes of **`ByteString`** (either at runtime or by static type checkers).

  See **PEP 688** [https://peps.python.org/pep-0688/#current-options] for more details. (Contributed by Shantanu Jain in gh-91896 [https://github.com/python/cpython/issues/91896].)

Pending removal in Python 3.18

- `decimal`:
  - The non-standard and undocumented `Decimal` format specifier `'N'`, which is only supported in the **`decimal`** module’s C implementation, has been deprecated since Python 3.13. (Contributed by Serhiy Storchaka in gh-89902 [https://github.com/python/cpython/issues/89902].)

Pending removal in Python 3.19

- `ctypes`:
  - Implicitly switching to the MSVC-compatible struct layout by setting `_pack_` but not `_layout_` on non-Windows platforms.

Pending removal in future versions

The following APIs will be removed in the future, although there is currently no date scheduled for their removal.

- **`argparse`**:
  - Nesting argument groups and nesting mutually exclusive groups are deprecated.
  - Passing the undocumented keyword argument *prefix_chars* to **`add_argument_group()`** is now deprecated.
  - The **`argparse.FileType`** type converter is deprecated.
- **`builtins`**:
  - Generators: `throw(type, exc, tb)` and `athrow(type, exc, tb)` signature is deprecated: use `throw(exc)` and `athrow(exc)` instead, the single argument signature.
  - Currently Python accepts numeric literals immediately followed by keywords, for example `0in x`, `1or x`, `0if 1else 2`. It allows confusing and ambiguous expressions like `[0x1for x in y]` (which can be interpreted as `[0x1 for x in y]` or `[0x1f or x in y]`). A syntax warning is raised if the numeric literal is immediately followed by one of keywords **`and`**, **`else`**, **`for`**, **`if`**, **`in`**, **`is`** and **`or`**. In a future release it will be changed to a syntax error. (gh-87999 [https://github.com/python/cpython/issues/87999])
  - Support for `__index__()` and `__int__()` method returning non-int type: these methods will be required to return an instance of a strict subclass of **`int`**.

  - Support for `__float__()` method returning a strict subclass of **`float`**: these methods will be required to return an instance of **`float`**.
  - Support for `__complex__()` method returning a strict subclass of **`complex`**: these methods will be required to return an instance of **`complex`**.
  - Delegation of `int()` to `__trunc__()` method.
  - Passing a complex number as the *real* or *imag* argument in the **`complex()`** constructor is now deprecated; it should only be passed as a single positional argument. (Contributed by Serhiy Storchaka in gh-109218 [https://github.com/python/cpython/issues/109218].)
- **`calendar`**: `calendar.January` and `calendar.February` constants are deprecated and replaced by **`calendar.JANUARY`** and **`calendar.FEBRUARY`**. (Contributed by Prince Roshan in gh-103636 [https://github.com/python/cpython/issues/103636].)
- **`codecs`**: use **`open()`** instead of **`codecs.open()`**. (gh-133038 [https://github.com/python/cpython/issues/133038])
- **`codeobject.co_lnotab`**: use the **`codeobject.co_lines()`** method instead.
- **`datetime`**:
  - **`utcnow()`**: use `datetime.datetime.now(tz=datetime.UTC)`.
  - **`utcfromtimestamp()`**: use `datetime.datetime.fromtimestamp(timestamp, tz=datetime.UTC)`.
- **`gettext`**: Plural value must be an integer.
- **`importlib`**:
  - **`cache_from_source()`** *debug_override* parameter is deprecated: use the *optimization* parameter instead.
- **`importlib.metadata`**:
  - `EntryPoints` tuple interface.
  - Implicit `None` on return values.
- **`logging`**: the `warn()` method has been deprecated since Python 3.3, use **`warning()`** instead.

- `mailbox`: Use of StringIO input and text mode is deprecated, use BytesIO and binary mode instead.
- `os`: Calling `os.register_at_fork()` in multi-threaded process.
- **`pydoc.ErrorDuringImport`**: A tuple value for *exc_info* parameter is deprecated, use an exception instance.
- `re`: More strict rules are now applied for numerical group references and group names in regular expressions. Only sequence of ASCII digits is now accepted as a numerical reference. The group name in bytes patterns and replacement strings can now only contain ASCII letters and digits and underscore. (Contributed by Serhiy Storchaka in gh-91760 [https://github.com/python/cpython/issues/91760].)
- **`sre_compile`**, **`sre_constants`** and **`sre_parse`** modules.
- `shutil`: `rmtree()`’s *onerror* parameter is deprecated in Python 3.12; use the *onexc* parameter instead.
- `ssl` options and protocols:
    - `ssl.SSLContext` without protocol argument is deprecated.
    - `ssl.SSLContext`: `set_npn_protocols()` and **`selected_npn_protocol()`** are deprecated: use ALPN instead.
    - `ssl.OP_NO_SSL*` options
    - `ssl.OP_NO_TLS*` options
    - `ssl.PROTOCOL_SSLv3`
    - `ssl.PROTOCOL_TLS`
    - `ssl.PROTOCOL_TLSv1`
    - `ssl.PROTOCOL_TLSv1_1`
    - `ssl.PROTOCOL_TLSv1_2`
    - `ssl.TLSVersion.SSLv3`
    - `ssl.TLSVersion.TLSv1`
    - `ssl.TLSVersion.TLSv1_1`
- `threading` methods:
    - **`threading.Condition.notifyAll()`**: use `notify_all()`.
    - **`threading.Event.isSet()`**: use `is_set()`.

  - **`threading.Thread.isDaemon()`**, `threading.Thread.setDaemon()`: use `threading.Thread.daemon` attribute.
  - **`threading.Thread.getName()`**, `threading.Thread.setName()`: use `threading.Thread.name` attribute.
  - **`threading.currentThread()`**: use `threading.current_thread()`.
  - **`threading.activeCount()`**: use `threading.active_count()`.
- `typing.Text` (gh-92332 [https://github.com/python/cpython/issues/92332]).
- The internal class `typing._UnionGenericAlias` is no longer used to implement `typing.Union`. To preserve compatibility with users using this private class, a compatibility shim will be provided until at least Python 3.17. (Contributed by Jelle Zijlstra in gh-105499 [https://github.com/python/cpython/issues/105499].)
- `unittest.IsolatedAsyncioTestCase`: it is deprecated to return a value that is not `None` from a test case.
- `urllib.parse` deprecated functions: `urlparse()` instead
  - `splitattr()`
  - `splithost()`
  - `splitnport()`
  - `splitpasswd()`
  - `splitport()`
  - `splitquery()`
  - `splittag()`
  - `splittype()`
  - `splituser()`
  - `splitvalue()`
  - `to_bytes()`
- `wsgiref`: `SimpleHandler.stdout.write()` should not do partial writes.
- `xml.etree.ElementTree`: Testing the truth value of an `Element` is deprecated. In a future release it will always return `True`. Prefer explicit `len(elem)` or `elem is not None` tests instead.

- `sys._clear_type_cache()` is deprecated: use `sys._clear_internal_caches()` instead.

Distributing Python Modules

Note

Information and guidance on distributing Python modules and packages has been moved to the Python Packaging User Guide [https://packaging.python.org/], and the tutorial on packaging Python projects [https://packaging.python.org/en/latest/tutorials/packaging-projects/].

Argument Clinic How-To

Note

The Argument Clinic How-TO has been moved to the Python Developer’s Guide [https://devguide.python.org/development-tools/clinic/].

How to port Python 2 Code to Python 3

author:: Brett Cannon

Python 2 reached its official end-of-life at the start of 2020. This means that no new bug reports, fixes, or changes will be made to Python 2 - it’s no longer supported: see **PEP 373** [https://peps.python.org/pep-0373/] and status of Python versions [https://devguide.python.org/versions].

If you are looking to port an extension module instead of pure Python code, please see Porting Extension Modules to Python 3.

The archived python-porting [https://mail.python.org/pipermail/python-porting/] mailing list may contain some useful guidance.

Since Python 3.11 the original porting guide was discontinued. You can find the old guide in the archive [https://docs.python.org/3.10/howto/pyporting.html].

Third-party guides

There are also multiple third-party guides that might be useful:

- Guide by Fedora [https://portingguide.readthedocs.io]
- PyCon 2020 tutorial [https://www.youtube.com/watch?v=JgIgEjASOlk]
- Guide by DigitalOcean [https://www.digitalocean.com/community/tutorials/how-to-port-python-2-code-to-python-3]

- Guide by ActiveState [https://www.activestate.com/blog/how-to-migrate-python-2-applications-to-python-3]

`aifc` — Read and write AIFF and AIFC files

Deprecated since version 3.11, removed in version 3.13.

This module is no longer part of the Python standard library. It was removed in Python 3.13 after being deprecated in Python 3.11. The removal was decided in **PEP 594** [https://peps.python.org/pep-0594/].

The last version of Python that provided the **`aifc`** module was Python 3.12 [https://docs.python.org/3.12/library/aifc.html].

`asynchat` — Asynchronous socket command/response handler

Deprecated since version 3.6, removed in version 3.12.

This module is no longer part of the Python standard library. It was removed in Python 3.12 after being deprecated in Python 3.6. The removal was decided in **PEP 594** [https://peps.python.org/pep-0594/].

Applications should use the **`asyncio`** module instead.

The last version of Python that provided the **`asynchat`** module was Python 3.11 [https://docs.python.org/3.11/library/asynchat.html].

`asyncore` — Asynchronous socket handler

Deprecated since version 3.6, removed in version 3.12.

This module is no longer part of the Python standard library. It was removed in Python 3.12 after being deprecated in Python 3.6. The removal was decided in **PEP 594** [https://peps.python.org/pep-0594/].

Applications should use the **`asyncio`** module instead.

The last version of Python that provided the **`asyncore`** module was Python 3.11 [https://docs.python.org/3.11/library/asyncore.html].

`audioop` — Manipulate raw audio data

Deprecated since version 3.11, removed in version 3.13.

This module is no longer part of the Python standard library. It was removed in Python 3.13 after being deprecated in Python 3.11. The removal was decided in **PEP 594** [https://peps.python.org/pep-0594/].

The last version of Python that provided the **`audioop`** module was Python 3.12 [https://docs.python.org/3.12/library/audioop.html].

`cgi` — Common Gateway Interface support

Deprecated since version 3.11, removed in version 3.13.

This module is no longer part of the Python standard library. It was removed in Python 3.13 after being deprecated in Python 3.11. The removal was decided in **PEP 594** [https://peps.python.org/pep-0594/].

A fork of the module on PyPI can be used instead: legacy-cgi [https://pypi.org/project/legacy-cgi/]. This is a copy of the cgi module, no longer maintained or supported by the core Python team.

The last version of Python that provided the `cgi` module was Python 3.12 [https://docs.python.org/3.12/library/cgi.html].

`cgitb` — Traceback manager for CGI scripts

Deprecated since version 3.11, removed in version 3.13.

This module is no longer part of the Python standard library. It was removed in Python 3.13 after being deprecated in Python 3.11. The removal was decided in **PEP 594** [https://peps.python.org/pep-0594/].

A fork of the module on PyPI can now be used instead: legacy-cgi [https://pypi.org/project/legacy-cgi/]. This is a copy of the cgi module, no longer maintained or supported by the core Python team.

The last version of Python that provided the **`cgitb`** module was Python 3.12 [https://docs.python.org/3.12/library/cgitb.html].

`chunk` — Read IFF chunked data

Deprecated since version 3.11, removed in version 3.13.

This module is no longer part of the Python standard library. It was removed in Python 3.13 after being deprecated in Python 3.11. The removal was decided in **PEP 594** [https://peps.python.org/pep-0594/].

The last version of Python that provided the `chunk` module was Python 3.12 [https://docs.python.org/3.12/library/chunk.html].

`crypt` — Function to check Unix passwords

Deprecated since version 3.11, removed in version 3.13.

This module is no longer part of the Python standard library. It was removed in Python 3.13 after being deprecated in Python 3.11. The removal was decided in **PEP 594** [https://peps.python.org/pep-0594/].

Applications can use the **`hashlib`** module from the standard library. Other possible replacements are third-party libraries from PyPI: legacycrypt [https://pypi.org/project/legacycrypt/], bcrypt [https://pypi.org/project/bcrypt/], or argon2-cffi [https://pypi.org/project/argon2-cffi/]. These are not supported or maintained by the Python core team.

The last version of Python that provided the **`crypt`** module was Python 3.12 [https://docs.python.org/3.12/library/crypt.html].

`distutils` — Building and installing Python modules

Deprecated since version 3.10, removed in version 3.12.

This module is no longer part of the Python standard library. It was removed in Python 3.12 after being deprecated in Python 3.10. The removal was decided in **PEP 632** [https://peps.python.org/pep-0632/], which has migration advice [https://peps.python.org/pep-0632/#migration-advice].

The last version of Python that provided the **`distutils`** module was Python 3.11 [https://docs.python.org/3.11/library/distutils.html].

Program frameworks

This chapter is no longer maintained, and the modules it contained have been moved to their respective topical documentation.

- **`cmd`** — Command Line Interface Libraries
- **`shlex`** — Unix Specific Services
- **`turtle`** — Graphical User Interfaces with Tk

`imghdr` — Determine the type of an image

Deprecated since version 3.11, removed in version 3.13.

This module is no longer part of the Python standard library. It was removed in Python 3.13 after being deprecated in Python 3.11. The removal was decided in **PEP 594** [https://peps.python.org/pep-0594/].

Possible replacements are third-party libraries from PyPI: filetype [https://pypi.org/project/filetype/], puremagic [https://pypi.org/project/puremagic/], or python-magic [https://pypi.org/project/python-magic/]. These are not supported or maintained by the Python core team.

The last version of Python that provided the **`imghdr`** module was Python 3.12 [https://docs.python.org/3.12/library/imghdr.html].

`imp` — Access the import internals

Deprecated since version 3.4, removed in version 3.12.

This module is no longer part of the Python standard library. It was removed in Python 3.12 after being deprecated in Python 3.4.

The removal notice includes guidance for migrating code from **`imp`** to **`importlib`**.

The last version of Python that provided the **`imp`** module was Python 3.11 [https://docs.python.org/3.11/library/imp.html].

`mailcap` — Mailcap file handling

Deprecated since version 3.11, removed in version 3.13.

This module is no longer part of the Python standard library. It was removed in Python 3.13 after being deprecated in Python 3.11. The removal was decided in **PEP 594** [https://peps.python.org/pep-0594/].

The last version of Python that provided the **`mailcap`** module was Python 3.12 [https://docs.python.org/3.12/library/mailcap.html].

`msilib` — Read and write Microsoft Installer files

Deprecated since version 3.11, removed in version 3.13.

This module is no longer part of the Python standard library. It was removed in Python 3.13 after being deprecated in Python 3.11. The removal was decided in **PEP 594** [https://peps.python.org/pep-0594/].

The last version of Python that provided the **`msilib`** module was Python 3.12 [https://docs.python.org/3.12/library/msilib.html].

`nis` — Interface to Sun’s NIS (Yellow Pages)

Deprecated since version 3.11, removed in version 3.13.

This module is no longer part of the Python standard library. It was removed in Python 3.13 after being deprecated in Python 3.11. The removal was decided in **PEP 594** [https://peps.python.org/pep-0594/].

The last version of Python that provided the **`nis`** module was Python 3.12 [https://docs.python.org/3.12/library/nis.html].

`nntplib` — NNTP protocol client

Deprecated since version 3.11, removed in version 3.13.

This module is no longer part of the Python standard library. It was removed in Python 3.13 after being deprecated in Python 3.11. The removal was decided in **PEP 594** [https://peps.python.org/pep-0594/].

The last version of Python that provided the **`nntplib`** module was Python 3.12 [https://docs.python.org/3.12/library/nntplib.html].

`ossaudiodev` — Access to OSS-compatible audio devices

Deprecated since version 3.11, removed in version 3.13.

This module is no longer part of the Python standard library. It was removed in Python 3.13 after being deprecated in Python 3.11. The removal was decided in **PEP 594** [https://peps.python.org/pep-0594/].

The last version of Python that provided the **`ossaudiodev`** module was Python 3.12 [https://docs.python.org/3.12/library/ossaudiodev.html].

`pipes` — Interface to shell pipelines

Deprecated since version 3.11, removed in version 3.13.

This module is no longer part of the Python standard library. It was removed in Python 3.13 after being deprecated in Python 3.11. The removal was decided in **PEP 594** [https://peps.python.org/pep-0594/].

Applications should use the **`subprocess`** module instead.

The last version of Python that provided the **`pipes`** module was Python 3.12 [https://docs.python.org/3.12/library/pipes.html].

`smtpd` — SMTP Server

Deprecated since version 3.6, removed in version 3.12.

This module is no longer part of the Python standard library. It was removed in Python 3.12 after being deprecated in Python 3.6. The removal was decided in **PEP 594** [https://peps.python.org/pep-0594/].

A possible replacement is the third-party aiosmtpd [https://pypi.org/project/aiosmtpd/] library. This library is not maintained or supported by the Python core team.

The last version of Python that provided the **`smtpd`** module was Python 3.11 [https://docs.python.org/3.11/library/smtpd.html].

`sndhdr` — Determine type of sound file

Deprecated since version 3.11, removed in version 3.13.

This module is no longer part of the Python standard library. It was removed in Python 3.13 after being deprecated in Python 3.11. The removal was decided in **PEP 594** [https://peps.python.org/pep-0594/].

Possible replacements are third-party modules from PyPI: filetype [https://pypi.org/project/filetype/], puremagic [https://pypi.org/project/puremagic/], or python-magic [https://pypi.org/project/python-magic/]. These are not supported or maintained by the Python core team.

The last version of Python that provided the **`sndhdr`** module was Python 3.12 [https://docs.python.org/3.12/library/sndhdr.html].

`spwd` — The shadow password database

Deprecated since version 3.11, removed in version 3.13.

This module is no longer part of the Python standard library. It was removed in Python 3.13 after being deprecated in Python 3.11. The removal was decided in **PEP 594** [https://peps.python.org/pep-0594/].

A possible replacement is the third-party library python-pam [https://pypi.org/project/python-pam/]. This library is not supported or maintained by the Python core team.

The last version of Python that provided the **`spwd`** module was Python 3.12 [https://docs.python.org/3.12/library/spwd.html].

`sunau` — Read and write Sun AU files

Deprecated since version 3.11, removed in version 3.13.

This module is no longer part of the Python standard library. It was removed in Python 3.13 after being deprecated in Python 3.11. The removal was decided in **PEP 594** [https://peps.python.org/pep-0594/].

The last version of Python that provided the **`sunau`** module was Python 3.12 [https://docs.python.org/3.12/library/sunau.html].

`telnetlib` — Telnet client

Deprecated since version 3.11, removed in version 3.13.

This module is no longer part of the Python standard library. It was removed in Python 3.13 after being deprecated in Python 3.11. The removal was decided in **PEP 594** [https://peps.python.org/pep-0594/].

Possible replacements are third-party libraries from PyPI: telnetlib3 [https://pypi.org/project/telnetlib3/] or Exscript [https://pypi.org/project/Exscript/]. These are not supported or maintained by the Python core team.

The last version of Python that provided the `telnetlib` module was Python 3.12 [https://docs.python.org/3.12/library/telnetlib.html].

`uu` — Encode and decode uuencode files

Deprecated since version 3.11, removed in version 3.13.

This module is no longer part of the Python standard library. It was removed in Python 3.13 after being deprecated in Python 3.11. The removal was decided in **PEP 594** [https://peps.python.org/pep-0594/].

The last version of Python that provided the `uu` module was Python 3.12 [https://docs.python.org/3.12/library/uu.html].

`xdrlib` — Encode and decode XDR data

Deprecated since version 3.11, removed in version 3.13.

This module is no longer part of the Python standard library. It was removed in Python 3.13 after being deprecated in Python 3.11. The removal was decided in **PEP 594** [https://peps.python.org/pep-0594/].

The last version of Python that provided the **`xdrlib`** module was Python 3.12 [https://docs.python.org/3.12/library/xdrlib.html].
